Conference Chairs

General Chairs
Audrey Laplante *(Université de Montréal, Montréal, Canada)*
Ichiro Fujinaga *(McGill University, Montréal, Canada)*

Scientific Program Chairs
Julie Cumming *(McGill University, Montréal, Canada)*
Jin Ha Lee *(University of Washington, Seattle, USA)*
Brian McFee *(New York University, New York, USA)*
Markus Schedl *(Johannes Kepler University, Linz, Austria)*

Publication Chairs
Johanna Devaney *(Brooklyn College and the CUNY Graduate Center, New York, USA)*
Cory McKay *(Marianopolis College, Montréal, Canada)*
Eva Zangerle *(University of Innsbruck, Innsbruck, Austria)*

Tutorial Chairs
Blair Kaneshiro *(Stanford University, Stanford, USA)*
Mohamed Sordo *(Pandora, Oakland, USA)*

Late-Breaking / Demo Chairs
Christian Frisson *(McGill University, Montréal, Canada)*
Xiao Hu *(University of Hong Kong, Hong Kong, China)*

Satellite Events Chairs
Jordan B. L. Smith *(ByteDance / TikTok, London, UK)*
Finn Upham *(McGill University, Montréal, Canada)*

Women in MIR Chairs
Claire Arthur *(Georgia Institute of Technology, Atlanta, USA)*
Katherine M. Kinnaird *(Smith College, Northampton, USA)*

Sponsorship Chairs
Elena Georgieva *(New York University, New York, USA and Stanford University, Stanford, USA)*
Zhengshan Shi *(Stanford University, Stanford, USA)*

Industry Chairs
Rachel Bittner *(Spotify, New York, USA)*
Thor Kell *(Spotify, New York, USA)*

Music Chairs
Guillaume Boutard *(Université de Montréal, Montréal, Canada)*
Gabriel Vigliensoni *(McGill University, Montréal, Canada and Goldsmiths, University of London, London, UK)*

Virtual Technology Chair
Finn Upham *(McGill University, Montréal, Canada)*

Website and Conference Management Software Chairs
Néstor Nápoles López *(McGill University, Montréal, Canada)*
Evan Savage *(McGill University, Montréal, Canada)*

Local Arrangements Chairs
Emily Hopkins *(McGill University, Montréal, Canada)*
Gabriel Vigliensoni *(McGill University, Montréal, Canada and Goldsmiths, University of London, London, UK)*

Volunteers Chair
Caroline Traube *(Université de Montréal, Montréal, Canada)*

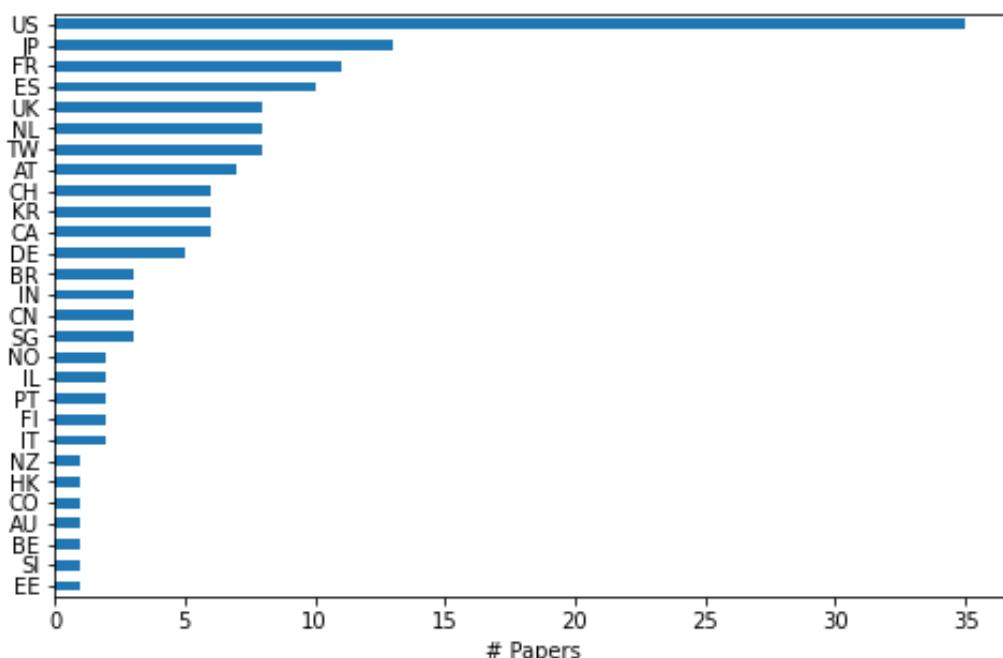
Preface

Welcome to ISMIR 2020, the 21st International Society for Music Information Retrieval Conference. ISMIR is the world's leading research forum on processing, searching, organizing, and accessing music-related data. Our community reflects a diversity of scientific disciplines, seniority levels, professional affiliations, and cultural backgrounds. It always has been explicitly interested in fostering and stimulating this diversity, leading to better science and better music services. Due to Covid-19, our 21st ISMIR conference has become our first fully online conference. We hope that this new form of interaction will allow more people, from more different places and communities, to participate. The organizing team in Montreal, and the international team of organizers, reviewers, and meta-reviewers, welcome you to our virtual meeting place.

Scientific Program

A total of 326 abstracts were registered, of which 300 were submitted as full papers eligible for review. The reviewing model was similar to that of previous years, consisting of a two-tier, double-blind process performed by 313 (anonymous) reviewers and 71 meta-reviewers. The scientific program chairs (SPC) anticipated limited availability of reviewers due to the COVID-19 crisis. This, combined with a 20% increase in the number of papers relative to the previous year, led the SPC to actively recruit a 50% larger reviewing pool to reduce the number of papers for which each individual reviewer is responsible. The SPC was happy to welcome a large number of first-time reviewers to the pool, but to ensure that each paper is adequately reviewed, we increased the number of reviewers assigned to each paper. The SPC would also like to thank all community members for their overwhelming response to our requests for additional reviewers and meta-reviewers.

Each paper was assigned to a single meta-reviewer and 4 reviewers, to ensure that each would eventually receive at least 3 completed reviews, accounting for the foreseen limited availability of some reviewers. Meta-reviewers were also instructed to complete a full review of each of their assigned papers, in addition to the final meta-review summarizing the individual reviews. Each meta-reviewer was responsible for between 2 and 5 papers, and each reviewer was responsible for no more than 4 papers. The initial reviewing phase was followed by a discussion period, in which reviewers and meta-reviewers could discuss and revise their assessments of each paper. Meta-reviewers were then instructed to summarize the discussion and reviews in the final report. The SPC finally rendered decisions on each paper.


Although the ISMIR 2020 conference is virtual and physical space no longer provided, a constraint on the number of papers we could accept and the allocated time for the conference program resulted in a program of comparable size to previous years. Of the 300 papers reviewed, 115 were accepted for publication, resulting in an acceptance rate of 38.3%. At submission time, authors selected primary and secondary subject areas for their paper. The following table summarizes the number of eligible submissions and accepted papers for each primary category.

Subject Area	Submitted	Accepted	Accept %
Applications	42	15	36
Domain knowledge	61	22	36
Evaluation, datasets, reproducibility	33	10	30
Human-centered MIR	18	8	44
MIR fundamentals	16	7	44
MIR tasks	83	29	35
Musical features and properties	43	22	51
Philosophical and ethical discussions	4	2	50
TOTAL	300	115	38

The table below summarizes the publication statistics over the 21-year-history of the conference.

Year	Location	Oral	Poster	Total	Authors	Unique Authors	Authors / Paper	Unique Authors / Paper
2000	Plymouth	19	16	35	68	63	1.9	1.8
2001	Indiana	25	16	41	100	86	2.4	2.1
2002	Paris	35	22	57	129	117	2.3	2.1
2003	Baltimore	26	24	50	132	111	2.6	2.2
2004	Barcelona	61	44	105	252	214	2.4	2.0
2005	London	57	57	114	316	233	2.8	2.0
2006	Victoria	59	36	95	246	198	2.6	2.1
2007	Vienna	62	65	127	361	267	2.8	2.1
2008	Philadelphia	24	105	105	296	253	2.8	2.4
2009	Kobe	38	85	123	375	292	3.0	2.4
2010	Utrecht	24	86	110	314	263	2.0	2.4
2011	Miami	36	97	133	395	322	3.0	2.4
2012	Porto	36	65	101	324	264	3.2	2.6
2013	Curitiba	31	67	98	395	236	3.0	2.4
2014	Taipei	33	73	106	343	271	3.2	2.6
2015	Málaga	24	90	114	370	296	3.2	2.6
2016	New York	25	88	113	341	270	3.0	2.4
2017	Suzhou	24	73	97	324	248	3.3	2.6
2018	Paris			104	337	265	3.2	2.5
2019	Delft			114	390	315	3.4	2.8
2020	**Montréal / Virtual**			**115**	**426**	**343**	**3.7**	**3.0**

The figure below illustrates the number of papers accepted with at least one contributing author from each country. Geographic affiliations were inferred from self-reported author affiliations and email addresses.

Best Paper Awards

The SPC established 6 paper award categories: Best Research, Best Application, Best New Direction, Best Multi/Interdisciplinary Research, Best Evaluation, and Best Reproducibility. The papers considered for an award were those with the highest review scores, as well as papers nominated for an award by meta-reviewers. We formed a best-paper-award committee comprising 4 highly renowned members of the MIR community and the SPC. Each member of the committee identified their conflicts of interest and judged only the remaining other papers, as well as reviews and meta-reviews of those papers. They then proposed papers from that group for each award category and provided justifications for their decisions. Once all members of the committee had completed their nominations, the whole committee met to make the final decisions.

Best Reviewer Awards

Based on the scores provided by meta-reviewers on the quality of individual reviews, in relation to the number of papers reviewed by each reviewer, the SPC selected a total of 13 awardees.

Organizing a Conference During a Pandemic

The organizing team had to face several challenges while planning this conference. After having planned for a regular, face-to-face meeting in Montreal, we had to come to the conclusion that this year's ISMIR Conference would have to be entirely virtual when it became clear that the COVID-19 pandemic would not be over in time for allowing people to travel and safely attend the conference. After the initial disappointment, however, the team was very enthusiastic to plan for the first virtual ISMIR Conference, and saw this as an opportunity to innovate and create a positive experience for all participants, while ensuring that the conference would be more affordable, accessible, inclusive, and sustainable thanks to this new format.

WiMIR

WiMIR is a group of people dedicated to promoting the role of, and increasing opportunities for, women in the MIR field. WiMIR's initiatives started as informal gatherings around breakfast or lunch during ISMIR conferences (2011–2013), and moved to formal WiMIR events included in the conference program (2015–today) garnering a high turnout of both women and allies. These events provide occasions for people to network and to discuss several important issues ranging from mentorship and conference support, to improving the representation of women and, more broadly, diversity, in the community. In 2018, WiMIR started hosting its own workshop as a satellite event, in which attendees of all genders

participated in high numbers. These workshops aim to offer participants an opportunity for networking, put the spotlight on the work done by women in the field, and foster collaboration between women and allies by proposing group work led by project guides to try to solve small research problems or to undertake new research projects that could lead to longer-term collaborations.

WiMIR and the ISMIR 2020 organizing team worked together to increase women participation and ensure a good representation of women in the conference program. Both conference keynote speakers are esteemed female researchers with an impressive career path. The program also includes 9 meetup sessions with notable women in MIR that were organized by the ISMIR 2020 WiMIR chairs. Additionally, 3 types of grants were offered to female participants: registration grants, publishing fee grants, and, for the first time for an ISMIR conference, childcare grants.

Like for the main conference, the WiMIR workshop organizers had to rethink the event in the context of the pandemics. The workshop consisted this year in 4 sessions that took place over 8 weeks, featured speakers from India, Australia, California, and Europe, and attracted over 450 participants. WiMIR also ran this year the fifth round of its mentoring program, which aims at connecting "women students, postdocs, early-stage researchers, industry employees, and faculty to more senior women and men in MIR who are dedicated to increasing opportunities for women in the field" (https://wimir.wordpress.com/mentoring-program/).

Diversity & Inclusion

Diversity and inclusion are values that are dear to the ISMIR 2020 organizing team. The Black Live Matters movement and research on algorithmic racism have only increased our awareness of the need for more diversity in our field. Knowing that people from the Black community were severely underrepresented among attendees at previous ISMIR conferences, efforts were made to reach out to Black people who could be interested in MIR. Therefore, in addition to the WiMIR grants mentioned above, fee registration waivers were offered to people who self-identified as Black. ISMIR 2020 also featured the first African American keynote speaker in an ISMIR conference, Dr. Safiya U. Noble.

The virtual format of the conference also allowed us to significantly lower the registration fees for the conference. Additionally, it was decided that not only would students be able to benefit from a reduced fee, but also people from low GDP countries, or with low income.

Keynote Speakers

For ISMIR 2020, we are honored to host 2 distinguished keynote speakers:

Safiya U. Noble, Associate Professor, Department of Information Studies, University of California, Los Angeles, presenting "Taking on big tech: New paradigms for new possibilities."

Johanna Devaney, Assistant Professor of Music, Brooklyn College, and Graduate Center, CUNY, presenting "Beyond the current conception of musical performance in MIR" (WiMIR keynote).

Tutorials

ISMIR 2020 tutorial chairs have selected 5 tutorials that will be presented on Sunday, October 11:

Tutorial 1: Prototyping and scaling audio research with Klio by Fallon Chen and Lynn Root;

Tutorial 2: Analysis of expressive timing in recorded music performances by Nico Schüler;

Tutorial 3: Metric learning for music information retrieval by Brian McFee, Jongpil Lee, and Juhan Nam;

Tutorial 4: Open-source tools & data for music source separation: A practical guide for the MIR practitioner by Ethan Manilow, Prem Seetharaman, and Justin Salamont;

Tutorial 5: Version identification in the 20s by Furkan Yesiler, Christopher Tralie, and Joan Serrà.

Late Breaking/Demo and Industry Session

The Late Breaking/Demo (LBD) and Industry session will take place on Friday, October 15. LBD posters feature prototype systems, initial concepts, and early results that have not yet fully matured but are of interest to the MIR community. Proposals went through a light review by the LBD chairs, at the end of which 27 were admitted for presentation. Extended abstracts are available online on the conference website.

Meetup with Industry

As part of ISMIR 2020, a virtual Meetup with Industry series will be hosted. This series includes Interview masterclasses, where industry interviewers will perform mock interviews with volunteers and provide real time feedback, and code review masterclasses on good coding practices from an industry standpoint during which experienced developers will live-review volunteer submitted repositories.

Music

ISMIR music chairs invited composers, technologists, and performers to submit pieces from any musical genre and in any style of electronic, acoustic, or mixed electroacoustic music that explored the notion of music information in the widest sense of the term. The musical works that were submitted were subjected to blind review by the ISMIR 2020 music chairs and an international panel of musicians. The following compositions were selected and will be presented in the 3 music sessions scheduled throughout the conference:

#otherbeats, by Marcel Zaes;

A Room with Chaconne (Bach), by Seth Thorn;

Attempts at Stillness, by Pierre Alexandre Tremblay;

bell / boom, by Jeremy Hyrkas;

Blue Sky Catastrophe, by Seth Shafer;

cecia, by the CECIA team;

DigiTral, by Matheos Zaharopoulos and Georgios Varoutsos;

Generative Sibelius, by Juan Carlos Vasquez;

I'll Marry You, Punk Come, by CJ Carr;

Moon via Spirit, by Lauren Hayes;

Mosaicing, by Panayiotis Kokoras;

Sound | Figuration, by Hongshuo Fan;

Spectre (for processed solo voice), by Max Addae;

Super Colliders, by Takuto Fukuda;

The Pulse of The Sunrise, by Peyman Heydarian;

Transcognition, by Fernando Egido;

Trees, by Alexandra Uitdenbogerd.

Satellite Events

In addition to the main conference, 4 satellite events are offered to participants:

WiMIR 3rd Annual Workshop, held before the conference in 4 sessions across 8 weeks, from August 22 to October 3;

7th International Conference on Digital Libraries for Musicology (DLfM), held on October 16 as a full-day virtual conference;

NLP4MusA: First Workshop on NLP for Music and Audio, held on October 16 and 17 as a virtual conference with live presentations on the 16th that will be streamed on the 17th, and live Q&A sessions on both days;

HAMR Hackathon, held asynchronously over October 16 and 17.

Keynote Talks

Keynote Talk

Taking on Big Tech: New Paradigms for New Possibilities

Dr. Safiya U. Noble
Associate Professor in the Departments of Information Studies and African American Studies
Co-Director of the Center for Critical Internet Inquiry (C2i2)
University of California, Los Angeles (UCLA)

Abstract

In her recent best-selling book *Algorithms of Oppression,* Dr. Safiya Noble challenges the idea that "Big Tech" offers an equal playing field for all forms of ideas, identities, and activities. Her work argues that the combination of private interests, along with the monopoly status of a relatively small number of internet companies, leads to a limited understanding of how racism is created, maintained, and disseminated in everyday digital engagements.

Data discrimination is a real social problem, and in this talk, Noble offers a powerful set of data points, examples, and provocations. She asserts we are just at the beginning of creating new paradigms of justice with the tech sector.

Biography

Dr. Safiya Umoja Noble is an Associate Professor at the University of California, Los Angeles (UCLA) in the Department of Information Studies where she serves as the Co-Founder and Co-Director of the UCLA Center for Critical Internet Inquiry (C2i2). She also holds appointments in African American Studies and Gender Studies. She is a Research Associate at the Oxford Internet Institute at the University of Oxford and has been appointed as a Commissioner on the Oxford Commission on AI & Good Governance (OxCAIGG). She is a board member of the Cyber Civil Rights Initiative, serving those vulnerable to online harassment.

Previously, she was a visiting faculty member to the USC Annenberg School for Communication and Journalism, and began her academic career as an Assistant Professor in the College of Media and the Institute of Communications Research at the University of Illinois at Urbana-Champaign.

Dr. Noble is the recipient of a Hellman Fellowship and the UCLA Early Career Award. Her academic research focuses on the design of digital media platforms on the internet and their impact on society. Her work is both sociological and interdisciplinary, marking the ways that digital media impacts and intersects with issues of race, gender, culture, and technology. She is regularly quoted for her expertise on issues of algorithmic discrimination and technology bias by national and international press including *The Guardian,* the BBC, CNN International, *USA Today, Wired, Time, Full Frontal with Samantha Bee, The New York Times,* and Virginia Public Radio, and a host of local news and podcasts, including *Science Friction,* and *Science Friday* to name a few. Recently, she was named in the "Top 25 Doers, Dreamers, and Drivers of 2019" by *Government Technology* magazine.

Dr. Noble is the co-editor of two edited volumes: *The Intersectional Internet: Race, Sex, Culture and Class Online* and *Emotions, Technology & Design*. She currently serves as an Associate Editor for the *Journal of Critical Library and Information Studies,* and is the co-editor of the Commentary & Criticism section of the *Journal of Feminist Media Studies*. She is a member of several academic journal and advisory boards, and holds a Ph.D. and M.S. in Library & Information Science from the University of Illinois at Urbana-Champaign, and a B.A. in Sociology from California State University, Fresno where she was recently awarded the Distinguished Alumni Award for 2018.

WiMIR Keynote Talk

Performance Matters

Beyond the Current Conception of Musical Performance in MIR

Dr. Johanna Devaney
Assistant Professor, Conservatory of Music, Brooklyn College
Faculty in the Data Analysis and Visualization MA program, Graduate Center
Faculty in the Music PhD program, Graduate Center
City University of New York (CUNY)

Abstract

This talk will reflect on what we can observe about musical performance in the audio signal and where MIR techniques have succeeded and failed in enhancing our understanding of musical performance. Since its foundation, ISMIR has showcased a range of approaches for studying musical performance. Some of these have been explicit approaches for studying expressive performance while others implicitly analyze performance with other aspects of the musical audio. Building on my own work developing tools for analyzing musical performance, I will consider not only the assumptions that underlie the questions we ask about performance but what we learn and what we miss in our current approaches to summarizing performance-related information from audio signals. I will also reflect on a number of related questions, including what do we gain by summarizing over large corpora versus close reading of a select number of recordings. What do we lose? What can we learn from generative techniques, such as those applied in style transfer? And finally, how can we integrate these disparate approaches in order to better understand the role of performance in our conception of musical style?

Biography

Johanna Devaney is an Assistant Professor at Brooklyn College and the CUNY Graduate Center. At Brooklyn College she teaches primarily in the Music Technology and Sonic Arts areas and at the Graduate Center she is appointed to the Music and the Data Analysis and Visualization programs. Previously, she was an Assistant Professor of Music Theory and Cognition at Ohio State University and a postdoctoral scholar at the Center for New Music and Audio Technologies (CNMAT) at the University of California at Berkeley. Johanna completed her PhD in music technology at the Schulich School of Music of McGill University. She also holds an MPhil degree in music theory from Columbia University and an MA in composition from York University in Toronto.

Johanna's research focuses on interdisciplinary approaches to the study of musical performance. Primarily, she examines the ways in which recorded performances can be used to study performance practice and develops computational tools to facilitate this. Her work draws on the disciplines of music, computer science, and psychology, and has been funded by the Social Sciences and Humanities Research Council of Canada (SSHRC), the Google Faculty Research Awards program and the National Endowment for the Humanities (NEH) Digital Humanities program.

Tutorials

Tutorial 1

Prototyping and Scaling Audio Research with Klio

Fallon Chen, Lynn Root, Dan Simon and Shireen Kheradpey

Abstract

This tutorial will walk attendees through the use of a Python framework called klio that makes use of the Apache Beam Python SDK to parallelize the execution of audio processing algorithms over a large dataset. Apache Beam is a portable and extensible programming model that unifies distributed batch and streaming processing. It manages the I/O and parallelized execution needed for large-scale data processing. Any audio processing algorithm that can be executed by a Python process and has dependencies that can be installed on machines supported by Apache Beam runners can be run with klio. Audio processing algorithms that have been added to a klio data processing job can be run locally on the practitioner's machine, before being run on large-scale data processing systems like Google Cloud Dataflow. This enables the practitioner to make quick local changes to their algorithm and test it on a few files before deploying a longer running job on more files.

The intended audience of this tutorial are audio processing practitioners who have wrestled with the complexity of iterating upon and coordinating the execution of algorithms that both consume and produce large audio datasets. klio provides best-practice standards and abstractions, encoded in its Python-based command line interface and API, that help audio practitioners prototype, organize and scale their work.

During the tutorial, attendees will receive:

- An overview of klio that establishes core concepts and features
- Guidance through building a klio audio processing graph and running it on an audio dataset

Biographies

Fallon Chen is a Senior Engineer at Spotify, where she builds libraries and tools for audio processing. She holds a M.S. in Computer Science from the University of California, San Diego, and a B.S. in Computer Science from the University of California, Davis. Her favorite genre is industrial techno.

Lynn Root is a Staff Engineer at Spotify and resident FOSS evangelist. She is a seasoned speaker on building and maintaining distributed systems, and maintains Spotify's audio processing framework. Lynn is a global leader of diversity in the Python community, and the former Vice Chair of the Python Software Foundation Board of Directors. When her hands are not on a keyboard, they are usually holding a bass guitar.

Tutorial 2

Analysis of Expressive Timing in Recorded Music Performances
Nico Schüler

Abstract

This tutorial will briefly summarize research on expressive timing in music, present an original research project (as an example) on rubato in four performances of Bach's Invention No. 9, explain and demonstrate how to use the freeware Sonic Visualiser as well as Excel for the analysis of expressive timing in music, and participants will, with the help of the tutorial leader, pursue their own analysis of other performances of Bach's Invention No. 9. (Recordings will be provided.) We will combine the data collected (in Excel files) to look for similarities and differences in the various performances and how expressive timing correlates to certain musical features. (An analytical score of the piece will be provided.) We will collectively formulate research findings.

This tutorial is suitable for anyone who is curious about the topic. Beyond curiosity, participants do not need to have a music or computer science background. Those interested in participating in the analyses should bring a laptop (Windows computer or Mac) to the tutorial, with Sonic Visualiser (http://sonicvisualiser.org) and the VAMP plugin "Note Onset Detector" (http://www.vamp-plugins.org) installed.

Biography

Professor Dr. **Nico Schüler** is University Distinguished Professor of Music Theory & Musicology at Texas State University. His main research interests are computer applications in music research, methods and methodology of music research, interdisciplinary aspects of 19th/20th century music, music theory pedagogy, and music historiography. He has given numerous international workshops on computer-applications in music. He is the editor of the research book series Methodology of Music Research, the author and / or editor of 21 books, and the author of more than 120 articles. Among his most recent books are Musical Listening Habits of College Students (2010) and Computer-Assisted Music Analysis (2014). http://www.nicoschuler.com, mnico.schuler@txstate.edu.

Tutorial 3

Metric Learning for Music Information Retrieval

Brian McFee, Jongpil Lee and Juhan Nam

Abstract

Metric learning is a paradigm of representation learning, in which proximity between the representations of items is optimized to correspond to a notion of similarity. Compared to the classification, metric learning can leverage more flexible forms of supervision, for example, two audio clips belong to the same artist or not, or have the same tempo or not. This enables the learning model to take a large or indefinite number of classes. Moreover, metric learning handles the embedding space directly by measuring the distance between the transformations of different examples. This facilitates usage of different domains or modalities of inputs in the same framework (e.g., audio embedding in one input and word embedding in another input). Such flexible and adaptable characteristics of metric learning have been enjoyed in many of machine learning tasks, particularly, similarity-based content retrieval. In recent years, interest in metric learning from the MIR community has also increased. Considering the multi-faceted and hierarchical-level of notions in similarity (e.g., semantic-level, score-level or audio-level) and diverse forms of data (e.g., audio, MIDI, text labels, lyrics, album covers, and user data), we see a great potential of metric learning in music. Therefore, introducing the method in an educational manner and surveying recent progress will be timely and helpful to relevant researchers. In this tutorial, we plan to present three lectures as follows:

1. **Metric learning foundations:** This lecture introduces mathematical foundations of metric learning.
2. **Deep metric learning and applications to MIR (1): core tasks -** This lecture introduces recent deep metric learning methods and their applications to music classification and similarity-based retrieval tasks.
3. **Deep metric learning and applications to MIR (2): variations -** This lecture introduces various applications of deep metric learning in MIR, showing how researchers have bridged diverse domains and modalities of input in metric learning.

Brian McFee is Assistant Professor of Music Technology and Data Science New York University. He received the B.S. degree (2003) in Computer Science from the University of California, Santa Cruz, and M.S. (2008) and Ph.D. (2012) degrees in Computer Science and Engineering from the University of California, San Diego. His work lies at the intersection of machine learning and audio analysis. He is an active open source software developer, and the principal maintainer of the librosa package for audio analysis.

Jongpil Lee received the B.S. degree in electrical engineering from Hanyang University, Seoul, South Korea, in 2015, the M.S. degree, in 2017, from the Graduate School of Culture Technology, Korea Advanced Institute of Science and Technology, Daejeon, South Korea, where he is currently working toward the Ph.D. degree. He interned at Naver Clova Artificial Intelligence Research in the summer of 2017 and at Adobe Audio Research Group in the summer of 2019. His current research interests include machine learning and signal processing applied to audio and music applications.

Juhan Nam is an Associate Professor of the Graduate School of Culture Technology at the Korea Advanced Institute of Science and Technology (KAIST), South Korea. Before joining KAIST, he was a staff research engineer at Qualcomm. Before his research career, he was a software/DSP engineer at Young Chang (Kurzweil). He received the Ph.D. degree (2013) in Music from Stanford University, studying at the Center for Computer Research in Music and Acoustics (CCRMA). He is interested in various research topics at the intersection of music, signal processing, and machine learning.

Tutorial 4

Open-Source Tools & Data for Music Source Separation: A Practical Guide for the MIR Practitioner

Ethan Manilow, Prem Seetharaman and Justin Salamon

Abstract

Musical source separation has become increasingly effective in recent years. As such, applications of music source separation have the potential to touch many aspects of MIR research. However, from a user's perspective, either in doing source separation research from scratch or in applying source separation to other tasks (e.g. polyphonic music transcription), there are still significant roadblocks. Code and data are released on a paper-by-paper basis, making it difficult to compare, use and extend existing techniques. This limits the usefulness of source separation for researchers not actively steeped in its many nuances, and hinders its applicability to broader MIR research.

In this tutorial, we present a set of complementary, easy-to-use, open-source tools and datasets for source separation research, evaluation, and deployment. We show how they interlock with one another, and how they can be used in concert to structure source separation within a project for research or deployment. Finally, we propose a generic and well-tested project structure for efficiently doing modern source separation research, from sweeping over hyperparameters, to setting up competitive baselines, to augmenting your datasets.

Participants of this tutorial will leave with:

1. A practical overview of source separation including history and current research trends.
2. The ability to make educated decisions about how to best include source separation in their workflow.
3. The ability to select the proper separation algorithm or a pre-trained model for their research.
4. The ability to effectively train a custom model for their research using open-source tools.

Our tutorial is aimed at researchers and practitioners that are familiar with audio and machine learning but have little or no experience with source separation. Our primary resources will be the following open-source/data projects: [nussl], [scaper], [Slakh2100], and [MUSDB18]. References to additional tools and datasets (including for non-music audio) will be provided.

Biographies

Ethan Manilow is a PhD candidate in Computer Science at Northwestern University under advisor Prof. Bryan Pardo. His research lies in the intersection of signal processing and machine learning, with a focus on source separation, automatic music transcription, and open source datasets and applications. Previously he was an intern at Mitsubishi Electric Research Labs (MERL) and at Google Magenta. He is one of the lead developers of nussl, an open source audio separation library.

Prem Seetharaman is a research scientist at Descript in San Francisco. Previously, he was a teaching fellow at Northwestern University, where he received his PhD in 2019 advised by Bryan Pardo. The objective of his research is to create machines that can understand the auditory world. He works in computer audition, machine learning, and human computer interaction. He is one of the lead developers of nussl, an open source audio separation library, and Scaper, a library for soundscape generation & augmentation.

Justin Salamon is a research scientist and member of the Audio Research Group at Adobe Research in San Francisco. Previously he was a senior research scientist at the Music and Audio Research Laboratory and Center for Urban Science and Progress of New York University. His research focuses on the application of machine learning and signal processing to audio & video, with applications in machine listening, representation learning & self-supervision, music information retrieval, bioacoustics, environmental sound analysis and open-source software & data. He is the lead developer of Scaper, a library for soundscape generation & augmentation.

Tutorial 5

Version Identification in the 20s

Furkan Yesiler, Christopher Tralie and Joan Serrà

Abstract

The version identification (VI) task concerns detecting and retrieving a set of songs that originate from the same underlying musical composition. Versions (or cover songs) convey the same musical entity while incorporating differences in several musical characteristics, including the differences in timbre, tempo, key, lyrics, and even added/deleted sections. The main applications include digital rights management and music catalog organization.

For more than a decade, VI systems suffered from the accuracy-scalability trade-off, with attempts to increase accuracy resulting in cumbersome, non-scalable systems. Recent years however have witnessed an increase in deep learning-based VI approaches that take a step toward bridging the accuracy-scalability gap, and we start seeing the possibility to deploy such systems in real-world applications. Although this trend positively influences the number of researchers and institutions working on VI, it may also result in obscuring the literature before the deep learning era. To appreciate the 20 years of novel ideas in VI and to facilitate building better systems in the next decade, we believe that now may be the right time to review some of the successful ideas and applications proposed in VI literature and connect them to current systems and ideas.

We will start the tutorial by explaining common input representations and feature post-processing steps. We will continue with comparing the pros and cons of alignment-based and embedding-based approaches, which constitute the two main perspectives for similarity estimation in VI. Lastly, after discussing a number of ideas that can be incorporated into any VI system, we will conclude by presenting the current challenges and future directions in VI research. Our goal is for the audience to leave with a thorough appreciation of both the history of the task and current directions, and that this context will allow them to jump into conducting novel research in the area.

Biographies

Furkan Yesiler is a PhD candidate at the Music Technology Group (MTG) of Universitat Pompeu Fabra (Barcelona). His research is focused on leveraging deep learning techniques to build accurate and scalable music version identification (VI) systems for industrial use cases. His recent contributions include MOVE, a state-of-the-art VI system based on musically-motivated principles; Da-TACOS, a large-scale VI benchmark set; and acoss, an open-source framework for feature extraction and benchmarking designed for VI. He received his MSc in Sound and Music Computing also from the MTG, with a focus on singing voice research. He graduated summa cum laude with two BSc degrees in computer engineering and industrial engineering from Koc University (Istanbul), where he was accepted with a full scholarship. During his bachelor's studies, he did internships in management consulting and M&A advisory companies in Istanbul, managed a student club with 200+ members, participated in a number of rowing competitions and musical theater shows, and spent a trimester at the University of California, Santa Barbara.

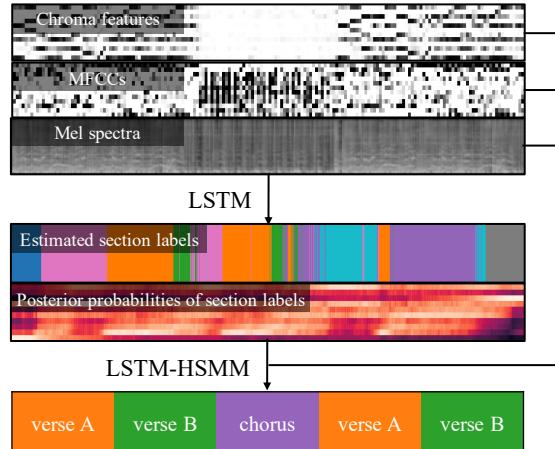
Christopher Tralie is an assistant professor in Math and Computer Science at Ursinus College in Collegeville, Pennsylvania, USA. He works in applied geometry/topology and geometric signal processing, and his work spans shape-based music structure analysis and version identification, video analysis, multimodal time series analysis, and geometry-aided data visualization. He received a B.S.E. from Princeton University 2011, a master's at Duke University in 2013, and a Ph.D. at Duke University in 2017, all in Electrical Engineering. His Ph.D. was primarily supported by an NSF Graduate Fellowship, and his dissertation is entitled "Geometric Multimedia Time Series." He did a postdoc at Duke University in Mathematics and a postdoc at Johns Hopkins University in Complex Systems. He was awarded a Bass Instructional Teaching fellowship at Duke University, and he maintains an active interest in pedagogy and outreach, including longitudinal mentoring of underprivileged youths in STEAM (STEM + arts) education.

Joan Serrà is a staff researcher with Dolby Labs in Barcelona since 2019, where he works on deep learning and audio processing. He did his MSc (2007) and PhD (2011) in automatic version identification at the Music Technology Group of Universitat Pompeu Fabra. He also did a postdoc in artificial intelligence at IIIA-CSIC (2011-2015). After that, he was a machine learning researcher at Telefónica R&D (2015-2019). He has had research stays at the Max Planck Institute for the Physics of Complex Systems (2010) and the Max Planck Institute for Computer Science (2011). He has been involved in more than 10 research projects, funded by National and European institutions, and co-authored over 100 publications, many of them highly-cited and in top-tier venues, including NeurIPS, ICLR, ICML, InterSpeech, ICASSP, and ISMIR.

Paper Session 1

MUSIC STRUCTURE ANALYSIS BASED ON AN LSTM-HSMM HYBRID MODEL

Go Shibata   Ryo Nishikimi   Kazuyoshi Yoshii

Graduate School of Informatics, Kyoto University, Japan


`{gshibata, nishikimi, yoshii}@sap.ist.i.kyoto-u.ac.jp`

ABSTRACT

This paper describes a statistical music structure analysis method that splits an audio signal of popular music into musically meaningful sections at the beat level and classifies them into predefined categories such as *intro*, *verse*, and *chorus*, where beat times are assumed to be estimated in advance. A basic approach to this task is to train a recurrent neural network (*e.g.*, long short-term memory (LSTM) network) that directly predicts section labels from acoustic features. This approach, however, suffers from frequent musically unnatural label switching because the homogeneity, repetitiveness, and duration regularity of musical sections are hard to represent explicitly in the network architecture. To solve this problem, we formulate a unified hidden semi-Markov model (HSMM) that represents the generative process of homogeneous mel-frequency cepstrum coefficients, repetitive chroma features, and mel spectra from section labels, where the emission probabilities of mel spectra are computed from the posterior probabilities of section labels predicted by an LSTM. Given these acoustic features, the most likely label sequence can be estimated with Viterbi decoding. The experimental results show that the proposed LSTM-HSMM hybrid model outperformed a conventional HSMM.

1. INTRODUCTION

Music structure analysis is the fundamental task in the field of music information retrieval (MIR) [1] because the musical structure, which consists of several sections including intro, verse, bridge, and chorus, is one of the most important elements of popular music. Most studies have tackled the segmentation task, which splits audio signals into several sections [2–12], the clustering task, which categorizes such sections into several classes [13–23], or both. Beyond the clustering task that gives arbitrary labels such as "A" and "B" to detected sections, we tackle the labeling task that gives concrete labels such as "verse A", "verse B", and "chorus" [4, 24] because such musically meaningful labels are useful for playback navigation [25]. Because section

Figure 1. Proposed music structure analysis method.

labels are subjective features of music, the labeling task is still challenging. Although deep neural networks (DNNs) have widely been used for frame-level classification tasks in MIR, they often suffer from frequent musically unnatural label switching.

In music structure analysis, the *homogeneity* and *repetitiveness* of acoustic features, the *regularity* of section durations, and the *novelty* of section boundaries, have considered as the four main noticeable aspects of musical sections [1, 11]. Using a sufficient amount of music signals with section label annotations, one could train a labeling DNN in a supervised manner such that the four aspects are learned implicitly. Another approach is to formulate a probabilistic generative model of acoustic features that can explicitly represent the four aspects and infer latent sections from observed features. A hierarchical hidden semi-Markov model (HSMM) based on the homogeneity, repetitiveness, and regularity, for example, has recently been proposed for joint segmentation and clustering [26]. The complementary properties of these approaches call for a hybrid approach for joint segmentation and labeling.

In this paper, we propose a deep generative approach to music structure analysis that integrates the labeling capability of a bidirectional long short-term memory (BLSTM) network into the classical shallow generative framework of the HSMM (Fig. 1). The unified model represents the generative processes of mel-frequency cepstrum coefficients (MFCCs) that are *homogeneous* in each section, chroma features that are *repeated* in sections of the same label, and mel spectra, from sections having *regular* durations. The

BLSTM network that estimates section labels from mel spectra at the frame level is trained in a supervised manner. The emission probabilities of mel spectra from sections are computed at run-time by referring to the posterior probabilities of section labels estimated by the network and the empirical prior distributions of section labels. Given acoustic features, the latent section sequence as well as the initial, transition, duration, and terminal probabilities of sections are estimated in a Bayesian manner with Gibbs sampling followed by Viterbi decoding, where the latent section sequence is initialized by the network to avoid bad local optima.

The main contribution of this paper is to propose a statistical joint segmentation and labeling method based on a Bayesian LSTM-HSMM hybrid model that can be adapted to each musical piece. Because the statistical characteristics of sections are specific to each musical piece, Bayesian inference based on the empirical prior distributions of those characteristics plays an essential role for improving the performance of music structure analysis. We experimentally show that the proposed method significantly outperformed a cascade model using the labeling results of the BLSTM in the post-processing and an LSTM-HSMM model using only Viterbi decoding.

2. RELATED WORK

This section reviews music structure analysis methods in terms of segmentation, clustering, and labeling.

2.1 Segmentation

In the segmentation task, the novelty plays a central role. Foote [2] detected peaks from a novelty curve obtained by convoluting a checkerboard kernel with the diagonal elements of a self-similarity matrix (SSM). Jensen [3] detected section boundaries such that a homogeneity- and novelty-aware cost function is minimized. Goto [4] and Serrà *et al.* [5] proposed novelty curves computed from lag SSMs showing repetitions as vertical lines. These methods were integrated for better segmentation [6] and the method [5] was extended for clustering [7]. Recently, Ullrich *et al.* [8] proposed a supervised method based on a convolutional neural network, which was extended to deal with coarse and fine boundary annotations [9]. Smith *et al.* [10] emphasized the importance of considering the regularity in the main analysis step, not in the post-processing step. Sargent *et al.* [11] focused on the regularity to favor comparable-size sections. Maezawa [12] used an LSTM network based on a cost function considering the homogeneity, repetitiveness, novelty, and regularity.

2.2 Clustering and Labeling

Cooper *et al.* [13] sequentially performed segmentation [2] and clustering based on intra- and inter-section characteristics. Goodwin *et al.* [14] efficiently detected off-diagonal stripes as repetitions from an SSM using dynamic programming. To deal with the repetitiveness and homogeneity, Grohganz *et al.* [15] converted a repetitiveness-aware SSM with off-diagonal stripes into a homogeneity-aware SSM with a block-diagonal structure. Nieto *et al.* [16] used a convex variant of nonnegative matrix factorization for segmentation and clustering. McFee *et al.* [17] encoded repetitive structures into a graph and performed spectral clustering for graph partitioning. Cheng *et al.* [18] converted a path-enhanced SSM into a block-enhanced SSM using nonnegative matrix factor deconvolution as in [15].

Several studies have taken a statistical approach based on generative models for joint segmentation and clustering. Aucouturier *et al.* [19] used a standard HMM. Levy *et al.* [20] proposed an HSMM based on the regularity of section durations. Ren *et al.* [21] proposed a nonparametric Bayesian HMM that can estimate an appropriate number of sections. Barrington *et al.* [22] proposed a nonparametric Bayesian switching linear dynamical system (LDS) that has the ability of automatic model complexity control.

Only a few studies have attempted to estimate musically meaningful labels. Maddage *et al.* [27] proposed a labeling method based on a typical music structure and the role of each section. Paulus *et al.* [24] performed segmentation, clustering, and labeling using a probabilistic fitness measure for the N-grams of sections.

3. PROPOSED METHOD

This section describes the proposed method for music structure analysis.

3.1 Problem Specification

The task we tackle in this paper is specified as follows:

Assumption: The beat times of a target music audio are estimated in advance by a beat tracking method [28].
Input: Beat-level chroma features $\mathbf{X}^c \triangleq \mathbf{x}_{1:T}^c$ ($\mathbf{x}_t^c \in \mathbb{R}^{12}$), MFCCs $\mathbf{X}^m \triangleq \mathbf{x}_{1:T}^m$ ($\mathbf{x}_t^m \in \mathbb{R}^{12}$), and mel spectra $\mathbf{X}^s \triangleq \mathbf{x}_{1:T}^s$ ($\mathbf{x}_t^s \in \mathbb{R}^{128}$) obtained from the target music signal, where T is the number of beats (quarter notes).
Output: Section labels $\mathbf{Z} \triangleq z_{1:N}$ ($z_n \in \{1, \ldots, K\}$) with durations $\mathbf{D} \triangleq d_{1:N}$ ($d_n \in \{1, \ldots, L\}$), where N is the number of sections, K is the number of distinct section labels, and L is the maximum number of beats in a section.

The notation $i{:}j$ represents a set of indices from i to j. Let $\mathbf{X}$ be $\{\mathbf{X}^c, \mathbf{X}^m, \mathbf{X}^s\}$, and $\mathbf{x}$ be $\{\mathbf{x}^c, \mathbf{x}^m, \mathbf{x}^s\}$.

3.2 Model Formulation

As shown in Fig. 2, we formulate a hierarchical HSMM of observed features $\mathbf{X}$ with latent sequences of section labels and abstract chord labels. Let $\mathbf{S} \triangleq \mathbf{S}_{1:N}$ be a sequence of chord sequences, where $\mathbf{S}_n \triangleq s_{n,1:d_n}$ ($s_{n,\tau} \in \{1, \ldots, M\}$) is a chord sequence in section n and M is the maximum number of chords in a section. The full probabilistic model $p(\mathbf{X}, \mathbf{Z}, \mathbf{D}, \mathbf{S})$ is defined as

$$p(\mathbf{X}, \mathbf{Z}, \mathbf{D}, \mathbf{S}) = p(\mathbf{X}|\mathbf{Z}, \mathbf{D}, \mathbf{S})p(\mathbf{S}|\mathbf{Z}, \mathbf{D})p(\mathbf{Z}, \mathbf{D}), \quad (1)$$

where $p(\mathbf{X}|\mathbf{Z}, \mathbf{D}, \mathbf{S})$ is an acoustic model of observed features $\mathbf{X}$, $p(\mathbf{S}|\mathbf{Z}, \mathbf{D})$ is a left-to-right Markov model of chord

labels $\mathbf{S}$ and $p(\mathbf{Z}, \mathbf{D})$ is an ergodic semi-Markov model of section labels $\mathbf{Z}$ with durations $\mathbf{D}$.

3.2.1 Semi-Markov Chain of Section Labels

The ergodic semi-Markov model $p(\mathbf{Z}, \mathbf{D})$ in Eq. (1) represents the generative process of section labels $\mathbf{Z}$ and their durations $\mathbf{D}$ as follows:

$$p(\mathbf{Z}, \mathbf{D}) = p(z_1, d_1) \prod_{n=2}^{N} p(z_n, d_n | z_{n-1}, d_{n-1}), \quad (2)$$

where the individual terms are given by

$$p(z_1, d_1) = \rho_{z_1} \psi_{d_1}, \quad (3)$$

$$p(z_n, d_n | z_{n-1}, d_{n-1}) = \pi_{z_{n-1} z_n} \psi_{d_n}, \quad (4)$$

$$p(z_N, d_N | z_{N-1}, d_{N-1}) = \pi_{z_{N-1} z_N} \psi_{d_N} \upsilon_{z_N}, \quad (5)$$

where ρ_z, $\pi_{zz'}$, and υ_z are the initial, transition, and terminal probabilities of section labels and ψ_d is the duration probability.

3.2.2 Left-to-Right Markov Chain of Chord Labels

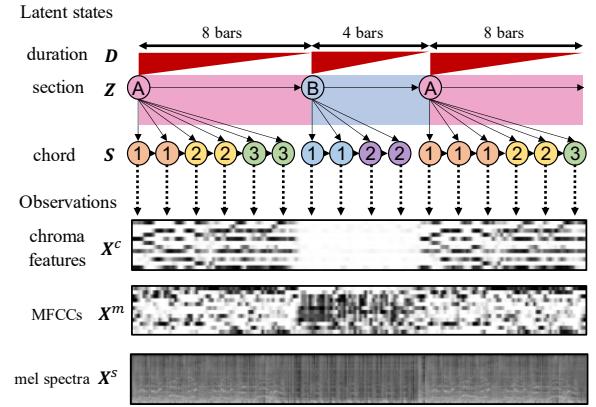
The left-to-right Markov model $p(\mathbf{S}|\mathbf{Z}, \mathbf{D})$ in Eq. (1) represents the generative process of chord labels $\mathbf{S}$ as follows:

$$p(\mathbf{S}|\mathbf{Z}, \mathbf{D}) = \prod_{n=1}^{N} p(s_{n,1}) \prod_{\tau=2}^{d_n} p(s_{n,\tau} | s_{n,\tau-1}, z_n), \quad (6)$$

where the individual terms are given by

$$p(s_{n,1} = 1) = 1, \quad (7)$$

$$p(s_{n,\tau} | s_{n,\tau-1}, z_n) = \phi_{s_{n,\tau-1} s_{n,\tau}}^{(z_n)}, \quad (8)$$

where z_n is the corresponding section label and $\phi_{ss'}^{(z)}$ is the transition probability from state s to state s'. The left-to-right Markov model meets a condition that the initial state has $s_{n,1} = 1$ and $s_{n,\tau_1} \leq s_{n,\tau_2}$ for $\tau_1 < \tau_2$. We introduce a hyperparameter σ that describes the maximum number of states that may be skipped in a transition; a transition from state s to state $s + \sigma$ is allowed. In this way, the model allows chord labels to be repeated with some variations in sections of the same label.


3.2.3 Emission of Acoustic Features

Given that the chroma features $\mathbf{X}^c$, the MFCCs $\mathbf{X}^m$, and the mel spectra $\mathbf{X}^s$ are conditionally and temporally independent, the acoustic model $p(\mathbf{X}|\mathbf{Z}, \mathbf{D}, \mathbf{S})$ in Eq. (1) is factorized as follows:

$$p(\mathbf{X}|\mathbf{Z}, \mathbf{D}, \mathbf{S}) = \prod_{t=1}^{T} \chi_{z_t, s_t}^{c}(\mathbf{x}_t^c) \chi_{z_t}^{m}(\mathbf{x}_t^m) \chi_{z_t}^{s}(\mathbf{x}_t^s), \quad (9)$$

where z_t and s_t are the section and chord labels at beat t, respectively, determined by the section-level latent variables $\mathbf{Z}$, $\mathbf{D}$, and $\mathbf{S}$, and $\chi_{z,s}^c$, χ_z^m, and χ_z^s are the emission probabilities of chroma features $\mathbf{x}^c$, MFCCs $\mathbf{x}^m$, and mel spectra $\mathbf{x}^s$, respectively.

The chroma features $\mathbf{x}^c \in \mathbb{R}^{12}$ are generated depending on both the section label z and the chord label s having the left-to-right property. The chord/chroma repetitiveness is thus represented by applying the same set of emission probabilities to all sections of the same label. The emission

Figure 2. Proposed LSTM-HSMM hybrid model.

probability $\chi_{z,s}^c(\mathbf{x}^c)$ in Eq. (9) is given by a multivariate Gaussian distribution as follows:

$$\chi_{z,s}^c(\mathbf{x}^c) = \mathcal{N}(\mathbf{x}^c | \boldsymbol{\mu}_{z,s}^c, (\mathbf{\Lambda}_{z,s}^c)^{-1}), \quad (10)$$

where $\boldsymbol{\mu}_{z,s}^c$ and $\mathbf{\Lambda}_{z,s}^c$ are a mean vector and a precision matrix, respectively.

The MFCCs $\mathbf{x}^m \in \mathbb{R}^{12}$ are generated depending on the section label z. This allows the model to capture the homogeneity of the timbral characteristics of each section. The emission probability $\chi_z^m(\mathbf{x}^m)$ in Eq. (9) is also given by a multivariate Gaussian distribution as follows:

$$\chi_z^m(\mathbf{x}^m) = \mathcal{N}(\mathbf{x}^m | \boldsymbol{\mu}_z^m, (\mathbf{\Lambda}_z^m)^{-1}), \quad (11)$$

where $\boldsymbol{\mu}_z^m$ and $\mathbf{\Lambda}_z^m$ are a mean vector and a precision matrix, respectively.

The mel spectra $\mathbf{x}^s \in \mathbb{R}^{128}$ are generated depending on the section label z. The emission probability $\chi_z^s(\mathbf{x}^s)$ in Eq. (9) is computed as follows:

$$\chi_z^s(\mathbf{x}^s) = p(\mathbf{x}^s | z) \propto \frac{p(z|\mathbf{x}^s)}{p(z)}, \quad (12)$$

where $p(z)$ is a unigram probability of section labels, and the probability $p(z|\mathbf{x}^s)$ is estimated by a labeling network (BLSTM) that infers section labels from mel spectra at the frame level. Let $p(z|\mathbf{x}^s)$ be the average of the frame-level outputs of the network in beat units.

3.2.4 Prior Distributions Based on Musical Knowledge

To use prior knowledge about musical sections, we formulate a Bayesian HSMM by putting conjugate prior distributions on the model parameters $\mathbf{\Theta} \triangleq \{\boldsymbol{\rho}, \boldsymbol{\psi}, \boldsymbol{\pi}, \boldsymbol{\upsilon}, \boldsymbol{\phi}, \boldsymbol{\mu}, \mathbf{\Lambda}\}$ [26]. We put Gaussian-Wishart prior distributions on the multivariate Gaussian parameters as follows:

$$\boldsymbol{\mu}_{z,s}^c, \mathbf{\Lambda}_{z,s}^c \sim \mathcal{N}(\boldsymbol{\mu}_{z,s}^c | \mathbf{m}_0^c, (\beta_0^c \mathbf{\Lambda}_{z,s}^c)^{-1}) \, \mathcal{W}(\mathbf{\Lambda}_{z,s}^c | \mathbf{W}_0^c, \nu_0^c),$$

$$\boldsymbol{\mu}_z^m, \mathbf{\Lambda}_z^m \sim \mathcal{N}(\boldsymbol{\mu}_z^m | \mathbf{m}_0^m, (\beta_0^m \mathbf{\Lambda}_z^m)^{-1}) \, \mathcal{W}(\mathbf{\Lambda}_z^m | \mathbf{W}_0^m, \nu_0^m),$$

where $\mathbf{m}_0^c$, β_0^c, $\mathbf{W}_0^c$, ν_0^c, $\mathbf{m}_0^m$, β_0^m, $\mathbf{W}_0^m$, and ν_0^m are hyperparameters. We then put Dirichlet prior distributions on the categorical parameters as follows:

$$\boldsymbol{\rho} \triangleq \rho_{1:K} \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\rho}}), \quad (13)$$

$$\boldsymbol{\psi} \triangleq \psi_{1:L} \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\psi}}), \quad (14)$$

$$\boldsymbol{\pi}_z \triangleq \pi_{z(1:K)} \sim \text{Dirichlet}(\mathbf{a}^{\boldsymbol{\pi}_z}), \quad (15)$$

$$\boldsymbol{v} \triangleq v_{1:K} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{v}}), \tag{16}$$

$$\boldsymbol{\phi}_s^{(z)} \triangleq \phi_{s(1:M)}^{(z)} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\phi}}), \tag{17}$$

where $\mathbf{a}^{\boldsymbol{\rho}}$, $\mathbf{a}^{\boldsymbol{\psi}}$, $\mathbf{a}^{\boldsymbol{\pi}_z}$, $\mathbf{a}^{\boldsymbol{v}}$, and $\mathbf{a}^{\boldsymbol{\phi}}$ are hyperparameters. The key advantage of Bayesian inference is that unnecessary sections can be automatically removed by controlling these sparseness-related hyperparameters.

Because "verse B" tends to come after "verse A", and section durations tend to be the integer multiples of the four measures in popular music, such a statistical tendency can be incorporated in the prior distribution. Specifically, we set $\mathbf{a}^{\boldsymbol{\rho}}$ to the empirical initial section probabilities $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{\rho}}$, $\mathbf{a}^{\boldsymbol{\pi}_z}$ to the empirical section transition probabilities $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{\pi}_z}$, $\mathbf{a}^{\boldsymbol{v}}$ to the empirical terminal section probabilities $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{v}}$, and $\mathbf{a}^{\boldsymbol{\psi}}$ to the empirical section duration probabilities $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{\psi}}$. These probabilities are multiplied by a constant factor.

3.3 Bayesian Inference

Because the posterior distribution $p(\mathbf{Z}, \mathbf{D}, \mathbf{S}, \boldsymbol{\Theta}|\mathbf{X})$ is analytically intractable, we use the Gibbs sampling method. We first sample the latent variables $\mathbf{Z}$, $\mathbf{D}$, and $\mathbf{S}$ from the distribution $p(\mathbf{Z}, \mathbf{D}, \mathbf{S}|\boldsymbol{\Theta}, \mathbf{X})$ and then sample the model parameters $\boldsymbol{\Theta}$ from the distribution $p(\boldsymbol{\Theta}|\mathbf{Z}, \mathbf{D}, \mathbf{S}, \mathbf{X})$.

3.3.1 Pretraining

We compute the empirical distributions $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{\rho}}$, $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{\psi}}$, $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{\pi}_z}$, and $\mathbf{a}_{\mathrm{emp}}^{\boldsymbol{v}}$ from training data. $\left(a_{\mathrm{emp}}^{\boldsymbol{\rho}}\right)_z$ is the number of times that the sequence of section labels starts from a section z. $\left(a_{\mathrm{emp}}^{\boldsymbol{\psi}}\right)_d$ is the number of times that section labels have a duration d. $\left(a_{\mathrm{emp}}^{\boldsymbol{\pi}_z}\right)_{z'}$ is the number of transitions from a state z to a state z'. $\left(a_{\mathrm{emp}}^{\boldsymbol{v}}\right)_z$ is the number of times that the sequence of section labels ends with a section z.

3.3.2 Initialization of Latent Variables

To avoid bad local optima, we initialize the section labels $\mathbf{Z}$ and durations $\mathbf{D}$ with the labeling network. The frame-level posterior probabilities of section labels estimated by the network are averaged in each beat t. A section label of each beat is estimated to be one that achieves the maximum value of the posterior probability at the beat. Consecutive section labels are considered as a single section; however, when the duration length of an integrated section is shorter than four beats (one bar), the section is further merged into a left or right section depending on the posterior probabilities. Because it is inefficient to deal with sections that are too long, we divide sections with a duration length longer than 32 beats into 32-beat units. After that, we perform the sampling of chord sequences $\mathbf{S}$ and model parameters $\boldsymbol{\Theta}$.

3.3.3 Sampling Latent Variables

We use the forward filtering-backward sampling algorithm for sampling $\mathbf{Z}$, $\mathbf{D}$, and $\mathbf{S}$. We introduce variables z_t and d_t that denote the section label and duration starting at beat $t - d_t + 1$ and ending at beat t. We also define the marginalized emission probability for this section $\omega_{z_t}(\mathbf{x}_{t-d_t+1:t})$, which can be calculated by the forward algorithm for the Markov model of chord labels.

In the forward filtering step for the Markov model of section labels, we initialize and update the forward variables $\alpha_t(z_t, d_t) = p(z_t, d_t, \mathbf{x}_{1:t})$ as follows:

$$\alpha_t(z_t, d_t = t) = \rho_{z_t} \psi_{d_t} \omega_{z_t}(\mathbf{x}_{1:t}), \tag{18}$$

$$\alpha_t(z_t, d_t) \\ = \sum_{z', d'} \alpha_{t-d_t}(z', d') \pi_{z' z_t} \psi_{d_t} \omega_{z_t}(\mathbf{x}_{t-d_t+1:t}). \tag{19}$$

In the backward sampling step, the section labels $\mathbf{Z}$ and durations $\mathbf{D}$ are sequentially sampled in the reverse order:

$$p(z_T, d_T|\mathbf{X}) \propto \alpha_T(z_T, d_T). \tag{20}$$

When variables z_t and d_t are already sampled, the variables $z_{t'}$ and $d_{t'}$ at beat $t' = t - d_t$ are sampled according to the probability

$$p(z_{t'}, d_{t'}|z_{t:T}, d_{t:T}, \mathbf{X}) \propto \alpha_{t'}(z_{t'}, d_{t'}) \pi_{z_{t'} z_t}. \tag{21}$$

Next, the chord labels $\mathbf{S}$ are sampled using the sampled $\mathbf{Z}$ and $\mathbf{D}$. Each chord sequence $\mathbf{S}_n$ is sampled by forward filtering-backward sampling for the Markov model of chord labels in section n. In the forward filtering step, we calculate the probabilities $\zeta_{n, s_{n,\tau}}$ recursively as follows:

$$\zeta_{n, s_{n,1}} = p(s_{n,1}, \mathbf{x}_1|z_n, d_n) \\ = \delta_{s_{n,1}1} \chi_{z_n, 1}(\mathbf{x}_1), \tag{22}$$

$$\zeta_{n, s_{n,\tau}} = p(s_{n,\tau}, \mathbf{x}_{1:\tau}|z_n, d_n) \tag{23}$$

$$= \left(\sum_{s_{n,\tau-1}} \zeta_{n, s_{n,\tau-1}} \phi_{s_{n,\tau-1} s_{n,\tau}}^{(z_n)} \right) \chi_{z_n, s_{n,\tau}}(\mathbf{x}_\tau),$$

where $\mathbf{x}_\tau$ is a vector of observed features at the beat $\tau \in \{1, \ldots, d_n\}$ considered in relation to the section boundary, and $\chi_{z,s}(\mathbf{x})$ is a merged emission probability $p(\mathbf{x}|z, s)$. In the backward sampling step, the chord sequence $\mathbf{S}_n$ is sampled in the reverse order as follows:

$$p(s_{n,d_n}|z_n, d_n, \mathbf{x}_{1:d_n}) \propto \zeta_{n, s_{n,d_n}}, \tag{24}$$

$$p(s_{n,\tau}|z_n, d_n, s_{n,\tau+1:d_n}, \mathbf{x}_{1:d_n}) \propto \zeta_{n, s_{n,\tau}} \phi_{s_{n,\tau} s_{n,\tau+1}}^{(z_n)}. \tag{25}$$

3.3.4 Sampling Model Parameters

We use the Gibbs sampling method for updating the model parameters as follows:

$$\boldsymbol{\rho} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\rho}} + \mathbf{b}^{\boldsymbol{\rho}}), \tag{26}$$

$$\boldsymbol{\pi}_z \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\pi}_z} + \mathbf{b}^{\boldsymbol{\pi}_z}), \tag{27}$$

$$\boldsymbol{\psi} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\psi}} + \mathbf{b}^{\boldsymbol{\psi}}), \tag{28}$$

$$\boldsymbol{v} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{v}} + \mathbf{b}^{\boldsymbol{v}}), \tag{29}$$

$$\boldsymbol{\phi}_s^{(z)} \sim \mathrm{Dirichlet}(\mathbf{a}^{\boldsymbol{\phi}} + \mathbf{b}^{\phi_s^{(z)}}), \tag{30}$$

$$\boldsymbol{\Lambda}_{z,s}^c \sim \mathcal{W}(\mathbf{W}_{z,s}^c, \nu_{z,s}^c), \tag{31}$$

$$\boldsymbol{\mu}_{z,s}^c|\boldsymbol{\Lambda}_{z,s}^c \sim \mathcal{N}(\mathbf{m}_{z,s}^c, (\beta_{z,s}^c \boldsymbol{\Lambda}_{z,s}^c)^{-1}), \tag{32}$$

$$\boldsymbol{\Lambda}_z^m \sim \mathcal{W}(\mathbf{W}_z^m, \nu_z^m), \tag{33}$$

$$\boldsymbol{\mu}_z^m|\boldsymbol{\Lambda}_z^m \sim \mathcal{N}(\mathbf{m}_z^m, (\beta_z^m \boldsymbol{\Lambda}_z^m)^{-1}), \tag{34}$$

where $\mathbf{b}^{\boldsymbol{\rho}} \in \mathbb{R}^K$, $\mathbf{b}^{\boldsymbol{\pi}_z} \in \mathbb{R}^K$, $\mathbf{b}^{\boldsymbol{\psi}} \in \mathbb{R}^L$, $\mathbf{b}^{\boldsymbol{v}} \in \mathbb{R}^K$, and $\mathbf{b}^{\phi_s^{(z)}} \in \mathbb{R}^M$ are vectors that count the sampled data. $b_z^{\boldsymbol{\rho}}$ is 1 if $z = z_1$ and 0 otherwise, $b_{z'}^{\boldsymbol{\pi}_z}$ is the number of transitions from state z to state z', $b_d^{\boldsymbol{\psi}}$ is the number of times that sampled sections have a duration of d, $b_z^{\boldsymbol{v}}$ is 1

if $z = z_N$ and 0 otherwise, and $b_{s'}^{\phi_s^{(z)}}$ is the number of transitions from state s to state s' in the Markov model of chord labels in section z. The parameters $\mathbf{m}_{z,s}^c$, $\beta_{z,s}^c$, $\mathbf{W}_{z,s}^c$, and $\nu_{z,s}^c$ are calculated as follows:

$$\beta_{z,s}^c = \beta_0^c + N_{z,s}, \quad \nu_{z,s}^c = \nu_0^c + N_{z,s}, \tag{35}$$

$$\mathbf{m}_{z,s}^c = \frac{1}{\beta_{z,s}^c}(\beta_0^c \mathbf{m}_0^c + N_{z,s}\overline{\mathbf{x}}_{z,s}^c), \tag{36}$$

$$(\mathbf{W}_{z,s}^c)^{-1} = (\mathbf{W}_0^c)^{-1} + N_{z,s}\mathbf{U}_{z,s}^c$$
$$+ \frac{\beta_0^c N_{z,s}}{\beta_0^c + N_{z,s}}(\overline{\mathbf{x}}_{z,s}^c - \mathbf{m}_0^c)(\overline{\mathbf{x}}_{z,s}^c - \mathbf{m}_0^c)^{\mathrm{T}}, \tag{37}$$

where we have defined

$$N_{z,s} = \sum_{t=1}^{T} \delta_{z_t z}\delta_{s_t s}, \tag{38}$$

$$\overline{\mathbf{x}}_{z,s}^c = \frac{1}{N_{z,s}}\sum_{t=1}^{T} \delta_{z_t z}\delta_{s_t s}\mathbf{x}_t^c, \tag{39}$$

$$\mathbf{U}_{z,s}^c = \frac{1}{N_{z,s}}\sum_{t=1}^{T} \delta_{z_t z}\delta_{s_t s}(\mathbf{x}_t^c - \overline{\mathbf{x}}_{z,s}^c)(\mathbf{x}_t^c - \overline{\mathbf{x}}_{z,s}^c)^{\mathrm{T}}. \tag{40}$$

The parameters $\mathbf{m}_z^m$, β_z^m, $\mathbf{W}_z^m$, and ν_z^m can be calculated similarly.

3.3.5 Viterbi Training

Since the samples from the Gibbs sampler are not necessarily local optima of the posterior distribution, we apply Viterbi training in the last step of the parameter estimation. Specifically, we apply the Viterbi algorithm (instead of the forward filtering-backward sampling algorithm) to estimate the latent variables and update the model parameters to the expectation values of the posterior probabilities (instead of samples from those probabilities). It is known that Viterbi training is generally efficient for finding an approximate local minimum [29].

3.3.6 Refinements

We introduce a weighting factor $w_{\mathrm{dur}}(\geq 1)$ for the duration probability to enhance its effect. Specifically, we replace the probability factor ψ_d in the forward algorithm (18) and (19) with $(\psi_d)^{w_{\mathrm{dur}}}$. Similar replacements are applied to the Viterbi training step and the final estimation step of the latent states explained in Section 3.4. We also introduce a weighting factor w_{label} that balances the emission probabilities for mel spectra with the other emission probabilities. We replace the emission probability $\chi_z^s(\mathbf{x}^s)$ in (9) with $(\chi_z^s(\mathbf{x}^s))^{w_{\mathrm{label}}}$.

3.4 Estimation of Musical Sections

After training the model parameters $\mathbf{\Theta}$, we compute the maximum a posteriori (MAP) estimate of the musical sections. Specifically, we maximize the posterior probability $p(\mathbf{Z}, \mathbf{D}|\mathbf{\Theta}, \mathbf{X})$ with respect to the section labels $\mathbf{Z}$ and durations $\mathbf{D}$. This can be solved by integrating out the chord labels $\mathbf{S}$ and applying the Viterbi algorithm for HSMMs [30] to the Markov model of section labels.

4. EVALUATION

Experiments were conducted to investigate the performance of the proposed method.

4.1 Experimental Conditions

To evaluate our model, we used the 100 pieces from the RWC Popular Music Database [31] with structure annotations [32] for evaluation. We extracted chroma features using the deep feature extractor [33] and MFCCs and mel spectrograms using the librosa library [34]. Beat information was obtained using the madmom library [28]. The labeling network consisted of a single-layer BLSTM with 2048×2 cells and a fully-connected layer with output dimension K. The network was trained with 10-fold cross validation, and the empirical distributions $\mathbf{a}_{\mathrm{emp}}^{\rho}$, $\mathbf{a}_{\mathrm{emp}}^{\psi}$, $\mathbf{a}_{\mathrm{emp}}^{\pi_z}$, and $\mathbf{a}_{\mathrm{emp}}^{v}$ were trained with piece-wise cross validation for the 100 pieces. For parameter estimation, we iterated the Gibbs sampling 15 times and the Viterbi training 3 times, which took around five times longer than the duration of an input signal with a standard CPU.

The hyperparameters of the proposed model were set as follows: $K = 10$, $L = 40$, $M = 16$, $\sigma = 1$, $w_{\mathrm{dur}} = 4$, $w_{\mathrm{label}} = 0.5$, $\mathbf{a}^{\rho} = 1 \cdot \mathbf{a}_{\mathrm{emp}}^{\rho}$, $\mathbf{a}^{\pi} = 1 \cdot \mathbf{a}_{\mathrm{emp}}^{\pi}$, $\mathbf{a}^{\psi} = 64 \cdot \mathbf{a}_{\mathrm{emp}}^{\psi}$, $\mathbf{a}^{v} = 1 \cdot \mathbf{a}_{\mathrm{emp}}^{v}$, $\mathbf{a}^{\phi} = \mathbb{I}$, $\mathbf{m}_0^c = \mathbb{E}[\mathbf{X}^c]$, $\beta_0^c = 64$, $\mathbf{W}_0^c = (\nu_0^c \mathrm{cov}[\mathbf{X}^c])^{-1}$ with $\nu_0^c = 512$, $\mathbf{m}_0^m = \mathbb{E}[\mathbf{X}^m]$, $\beta_0^m = 2$, and $\mathbf{W}_0^m = (\nu_0^m \mathrm{cov}[\mathbf{X}^m])^{-1}$ with $\nu_0^m = 16$, where $\mathbb{I}$ denotes a vector with all entries equal to 1. The first parameter K was determined according to the number of labels used in [24], as shown in the legend in Fig. 3. The next two parameters L and M were determined by consulting the statistics of the annotated data. In the data, most sections have a length of 40 beats or less. If we assume a section length of 32 beats (8 measures) and a chord duration of 2 beats, the expected number of chords in each section is 16. The value of σ was set to 1 for simplicity. The other parameters were determined by a coarse optimization w.r.t. the evaluation measures explained below. Each parameter was optimized by a grid search, fixing the other parameters. Further optimization of the parameters is left for future work.

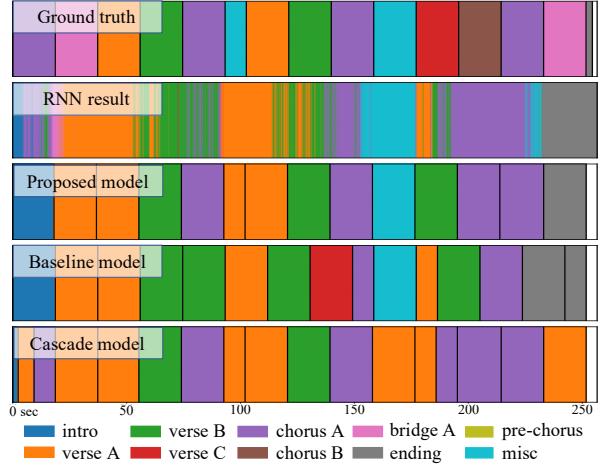
We evaluated the estimation results in terms of segmentation, clustering, and labeling. The qualities of segmentation and clustering were evaluated in the same way as MIREX [35]. The quality of segmentation was evaluated by the F-measures of section boundaries denoted by $F_{0.5}$ and $F_{3.0}$ [36]. Specifically, an estimated boundary is accepted as correct if it is within $\pm 0.5/3.0$ seconds from the ground-truth boundary. The precision rate is the percentage of correct boundaries in estimated boundaries, the recall rate is the percentage of true boundaries that are correctly estimated, and the F-measures $F_{0.5}$ and $F_{3.0}$ are defined as the harmonic means of the precision and recall rates.

The quality of clustering was evaluated by the pairwise F-measure denoted by F_{pair} [37] defined as follows. We compared pairs of frames (with a length of 100 ms) that are labeled with the same class in an estimation result with those in the ground truth. The precision rate, recall rate,

Method	Segmentation		Clustering	Labeling
	$F_{0.5}$ (%)	$F_{3.0}$ (%)	F_{pair} (%)	(%)
GS3 [39]	**52.3**	73.5	54.2	n/a
SUG2 [40]	25.8	**73.7**	37.3	n/a
FK2 [41]	30.0	65.7	63.4	n/a
Paulus'09 [24]	n/a	63.0	**63.7**	34.4
Cascade model	38.3	63.9	54.9	38.8
Baseline model	30.6	53.5	43.3	39.5
Proposed model	43.3	66.5	54.6	**45.3**

Table 1. Evaluation results of a comparative experiment.

and F-measure are defined as follows:

$$P_{\text{pair}} = \frac{|P_E \cap P_A|}{|P_E|}, \quad R_{\text{pair}} = \frac{|P_E \cap P_A|}{|P_A|}, \quad (41)$$


$$F_{\text{pair}} = \frac{2 P_{\text{pair}} R_{\text{pair}}}{P_{\text{pair}} + R_{\text{pair}}}, \quad (42)$$

where P_E denotes the set of similarly labeled frame pairs in the estimation and P_A denotes that in the ground truth. These values are calculated using the `mir_eval` library [38]. The quality of labeling was evaluated by the accuracy in frame units, as in [24]. This is calculated by comparing a label assigned to each frame in the result and the ground truth.

For comparison in the segmentation and the clustering, we refer to GS3 [39], SUG2 [40], and FK2 [41], published in MIREX. In addition, for comparison in all three viewpoints, we quoted the result of [24] and ran two models, a cascade model and a baseline model. In the cascade model, the frame-level labels obtained by the BLSTM were counted for each cluster obtained by the HSMM [26]. The most frequently occurring label in a cluster was estimated to be the label in that cluster. Although the baseline model is similar to the proposed model, it outputs neither chroma features nor MFCCs and only uses the Viterbi decoding to obtain results.

4.2 Experimental Results

Table 1 shows the evaluation results. In the labeling accuracy, the proposed method outperformed the other methods that have the labeling ability. Compared with the cascade model using the labeling results of the BLSTM in the post-processing, the proposed model had better performance in segmentation and labeling. This indicates the effectiveness of joint segmentation and labeling in the unified probabilistic framework. In addition, compared with the baseline model using the Viterbi decoding only, the proposed model achieved better performance in all metrics. This revealed the effectiveness of piece-specific Bayesian learning based on the prior distributions. In contrast, the proposed method did not always achieve the state-of-the-art performance except for labeling. It may be because the proposed method tended to yield unnatural repetitions of the same label with various lengths. In general, sections of the same label have approximately the same length. Such a constraint could be incorporated by introducing a duration probability distri-

Figure 3. Example results by proposed, baseline, and cascade model (RWC-MDB-P-2001 No. 25)

bution specific for each label.

Example results are shown in Fig. 3. The cascade model yielded some mislabeled sections with correctly estimated boundaries because the clustering errors of the HSMM were propagated. In contrast, because the proposed method performs segmentation and labeling simultaneously, such errors were reduced effectively. While the baseline model yielded errors originating from the errors of the BLSTM, such errors were corrected in the result of the proposed method. This suggested that the proposed method has the ability to prevent such errors by focusing on the homogeneity of MFCCs and repetitiveness of chroma features. We found that the proposed method erroneously estimated "chorus A" at the beginning of this song as "intro". Such errors could be avoided by adjusting the weights of the initial and emission probabilities or training the BLSTM with the connectionist temporal classification (CTC) loss function [42] to remove frequent musically unnatural label switching.

5. CONCLUSION

We have presented a deep generative approach to music structure analysis based on a Bayesian LSTM-HSMM hybrid model. The model represents the essential characteristics of sections, homogeneity, repetitiveness, and regularity, with MFCCs, chroma features, and mel spectra. Music segmentation and section labeling are performed jointly by unsupervised Bayesian learning of the model. The experimental results showed that the proposed method is effective for musical structure analysis.

The proposed method considers homogeneity, repetitiveness, and regularity, but not novelty, which has been emphasized in conventional research [1]. Exploiting this aspect remains an avenue for future work. It is also important to deal with further hierarchies [17], as music has a hierarchical structure moving from motives and phrases to sections and section groups [43].

ABSTRACT

Music copyright lawsuits often result in multimillion dollar damage awards or settlements, yet there are few objective guidelines for applying copyright law in infringement claims involving musical works. Recent research has attempted to develop objective methods based on automated similarity algorithms, but there remains almost no data on the role of perceived similarity in music copyright decisions despite its crucial role in copyright law. We collected perceptual data from 20 participants for 17 adjudicated copyright cases from the USA and Japan after editing the disputed sections to contain either full audio, melody only, or lyrics only. Due to the historical emphasis in legal opinions on melody as the key criterion for deciding infringement, we predicted that listening to melody-only versions would result in perceptual judgements that more closely matched actual past legal decisions. Surprisingly, however, we found no significant differences between the three conditions, with participants matching past decisions in between 50-60% of cases in all three conditions. Automated algorithms designed to calculate melodic and audio similarity produced comparable results: both algorithms were able to match past decisions with identical accuracy of 71% (12/17 cases). Analysis of cases that were difficult to classify suggests that melody, lyrics, and other factors sometimes interact in complex ways difficult to capture using quantitative metrics. We propose directions for further investigation of the role of similarity in music copyright law using larger and more diverse samples of cases and enhanced methods, and adapting our perceptual experiment method to avoid relying for ground truth data only on court decisions (which may be subject to selection bias). Our results contribute to important practical debates, such as whether jury members should be allowed to listen to full audio recordings during copyright cases.

1. INTRODUCTION

Music copyright law protects the lawful rights and interests of music creators and performers, but in some music copyright infringement cases, its application has caused bitter controversy. As litigation becomes more frequent,

inappropriate music copyright lawsuits not only inhibit music creativity but also waste millions of taxpayer dollars annually to cover the adjudication of these disputes. The legal system and music industry could both benefit from automated methods that could reduce subjectivity in music copyright decisions, and several recent studies have proposed such automated methods [1-4]. While the accuracy of some algorithms have been tested against previous court decisions, they have not yet been tested against perceptual data to determine how different musical and extra-musical factors interact in copyright law.

"Substantial similarity" and "protectable expression" are central concepts in US copyright law, the understanding of which could potentially be supplemented through automated and/or perceptual analyses. The concept of "substantial similarity" requires not only that the defendant can be shown to have copied musical material, but that this copying of protected musical expression was so extensive that the two works are substantially similar [5]. Data on degrees of computed and/or perceived similarity can help to determine objective standards for how much copying is required to be considered "substantial".

Evaluating what is considered "protectable expression" is more qualitative and complex. Many musical aspects such as scales, certain rhythmic patterns, and timbres are considered to be such basic and commonplace musical ideas as not to be copyrightable. For example, many blues songs all use very similar blues scales, 12-bar harmonic progressions, vocal styles and instrumentation, but copying these aspects is not considered copyright infringement. Instead, melody (i.e., the sequence of pitches) and lyrics have traditionally played predominant roles against other musical factors [6-7]. However, it has been disputed whether jury members should be allowed to listen to full-audio or melody-only versions of musical works because people may perceive and judge differently when comparing pairs of melodies or other musical features [8]. For example, a core issue in the recently concluded case involving the Blurred Lines [9] was whether the jury should be allowed to listen to a full audio recording including lyrics and background instrumentation of the complaining work, or whether it should only be exposed to the sheet music that was deposited with the US Copyright Office [6].

To quantitatively compare the effects of melody, lyrics, and other factors, we designed a controlled experiment where we constructed versions of a disputed musical work containing the full audio (including lyrics, melody, and other factors such as instrumentation), melody only (pitches and rhythms in MIDI representation), and lyrics

only (text representation). Because of the historical dominance of melody, we predicted that participants would most accurately match past decisions when presented with melody-only versions, and that automated algorithms based on melodic data would more accurately match past decisions than ones based on full-audio data.

Section 2 discusses related research. Section 3 discusses the data selection for our study. In Section 4, we demonstrate the design and details of the perceptual experiment. In Section 5, we show how the melodic and audio similarity are calculated by automated algorithms (PMI and Musly, respectively). In Sections 6, 7, and 8, we discuss the performance of the two automated methods, compare the automated and perceptual methods, summarize current results, and discuss future directions for improvement.

2. RELATED WORK

2.1 Perceptual Experiments

In one previous experimental study, Lund used two past court cases (*Swirsky v. Carey* and *Gasté v. Kaiserman*) and manipulated MIDI representations of the works to change aspects such as tempo, rhythm, and instrumentation [8]. Lund found that such manipulations reduced the accuracy of participants' judgements of copyright infringements even though it was assumed that such non-melodic features should not play a role in decisions. Lund argued that this demonstrated that the "lay listener test" was flawed because it relies on subjective listening to audio recordings that may differ in non-melodic aspects. However, Lund did not compare full audio recordings with these MIDI representations, so it remains unknown whether listeners are in fact more accurate when listening to MIDI representations than when listening to full audio recordings.

2.2 Automatic Analysis

Müllensiefen and Pendzich developed an algorithm for judging melodic similarity that compares the profile of successive pitch intervals in two disputed songs against each other, while weighting them against a database of comparable profiles from 14,063 pop songs using a weighting formula for estimating perceptual salience [1]. When they applied this algorithm to a database of 20 past music copyright decisions focused on melodic similarity, they found the best-performing version of their algorithm was able to accurately identify 90% (18/20) of past cases.

Savage et al. later developed a Percent Melodic Identity (PMI) method for quantifying melodic evolution based on automatic sequence alignment algorithms used in molecular genetics to measure melodic similarity [10]. When they applied this method to the same set of cases as Müllensiefen & Pendzich, it accurately predicted 80% (16/20) of cases, despite being a simpler method that didn't require calibration to an existing database of popular songs [3].

While the related task of cover song detection has a long history of study in music information retrieval [11-12], to our knowledge no audio similarity algorithms have yet been tested for their ability to evaluate copyright infringement. However, many general audio similarity algorithms have been evaluated through the Music Information Retrieval Exchange (MIREX) competition. We thus chose the audio similarity algorithm implemented in Musly, an open-source library of audio music similarity algorithms, because it has consistently performed at or near the top of audio similarity algorithms as evaluated in MIREX [13].

3. DATASET OF MUSIC COPYRIGHT INFRINGEMENT CASES

We chose a set of 17 court decisions whose main copyright issue focused on substantial similarity of the melodies (Table 1). 14 of these 17 cases are from the US, and these 14 represent a subset of 20 cases from the Music Copyright Infringement Resource [14] that were previously analyzed [1, 3] for which full audio recordings were available for both of the disputed musical works (the remaining 6 cases were not included because one or both musical works were represented only by sheet music and/or MIDI files). We also included 3 court decisions from Japan in order to increase cultural diversity in the dataset for further study on adaptability to music other than Western music. Of the 17 cases courts found no infringement in 8 cases, and infringement in 9.

4. PERCEPTUAL EXPERIMENT

4.1 Experiment Design

We conducted an online perceptual experiment where participants were each asked to judge substantial similarity for the 17 cases. The disputed segments of the musical works (mean length: 22s; range: 3-55s) were presented in one of three different versions: full-audio (the recorded versions including all instrumental and/or vocal parts), melody-only (MIDI rendition of the pitches and rhythms of the main melody), and lyrics-only (lyrics shown as visual text, without any accompanying audio). For the melody condition, in order to control for all non-melodic factors including instrumentation, key, and tempo, transcribed melodies from the original audio recordings were edited as necessary to exactly correspond to the audio recordings[1]: these transcribed melodies were transposed to have a tonic of C, and were then recorded using the MIDI piano in MuseScore played back at a tempo that was the average of the tempi from the plaintiff and defendant recordings. For the lyrics condition, the three instrumental works without lyrics (cf. Table 1) simply showed "[no lyrics]". These three types of presentations were repeated twice: once using the originally disputed pair of musical works, and once using the original defendant work but comparing it against a randomly selected plaintiff work from the other 16 cases.

---

[1] While preparing the audio files for experiments we noticed several minor inconsistencies between the audio files and the transcriptions provided by the authors of [1]. In some cases, these were small errors in pitch/rhythm; in others, only one half of a larger section was transcribed. The original transcriptions were not initially published but have now been uploaded to https://github.com/pesavage/copyright/tree/master/MIDIs_plagiarismcases_MullensiefenPendzich2009 to allow comparison as necessary. The corrected transcriptions are available at https://github.com/compmusiclab/music-copyright.

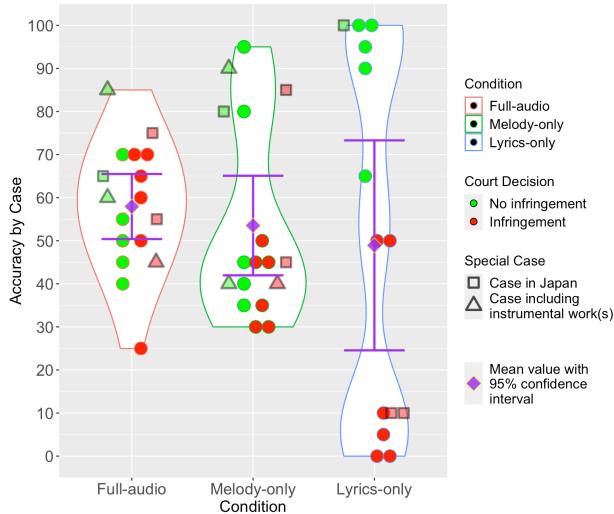
Table 1. The 17 music copyright infringement cases analyzed and respective melodic similarity (PMI), audio music similarity (Musly), and perceptual experiment results. Cases are ordered by increasing PMI values. In "Court Decision" column, "0" represents no infringement, and "1" represents infringement. Cases in italics are those PMI failed to accurately classify, and bold indicates those Musly failed to classify. Columns highlighted in light blue are the accuracy of perceptual judgement for the 17 court cases judged by the 20 participants for full-audio, melody-only, and lyrics-only, corresponding to the data in Figure 1. Columns highlighted in light green are perceptual similarity values used for comparison between automatic methods and perceptual judgement in Section 6, corresponding to the data in Figures S2 and S3. Three defending works marked in orange text are instrumental.

This gave a total of 102 different pairs of musical works to evaluate (17 cases × 3 presentations [full, melody, lyrics] × 2 pairings [original plaintiff vs. random plaintiff]), presented in fully random order (without separate blocks for different conditions; i.e., any given sample might be full-audio, melody-only, or lyrics-only; original case or not). Each experiment took approximately 2 hours for one participant to complete evaluations for these 102 pairs.

For each pair, the participant is given a pair of music excerpts, "A" and "B". "A" is always a plaintiff's work while "B" is always a defendant's work. After listening to the full-audio or MIDI or reading the lyrics of the two music works, the participant needs to answer two questions: 1) How similar are A and B? (5-point Likert scale: "not at all similar", "a little similar", "somewhat similar", "very similar", and "extremely similar"). 2) Do you think the second music work ("B") infringed the copyright of the first one's ("A")? (Yes/no answer.) The following criteria for infringement were provided, taken from [8] (which was in turn adapted from real instructions given to juries [details of the adaptation were not provided]):

To find music copyright infringement between plaintiff's and defendant's songs, you must find that the songs are substantially similar. Two works are substantially similar if the original expression of ideas in the plaintiff's (Song #1) copyrighted work and the expression of ideas in the defendant's work (Song #2) that are shared are substantially similar. Original expression are those unique aspects of plaintiff's song that are not common or ordinary to the genre or to music generally. The amount of similarity must be both quantitatively

and qualitatively significant, that is the defendant's song copied either a substantial portion of the original expression of the plaintiff's song, or copied a smaller but qualitatively important portion of the plaintiff's song.

In short, this investigation imitates the lay listener test used to see whether an ordinary observer recognizes that the defendant appropriated something belonging to the plaintiff [8, 15].


4.2 Results

We collected perceptual data from 20 participants from our institution. 9 were male, and 11 were female. 17 were between 17-28 years old, 1 was between 29-50, and 2 were over 50. The native languages of participants were Chinese (13 participants), Japanese (6) and English (1). 11 reported substantial music experience while 9 did not. Table 1 summarizes all results for perceptual and automated experiments.

Figure 1 and S1 show how accurately the 20 participants' judgement of infringement matched the official court decisions when they were given full-audio, melody-only, or lyrics-only versions of music pieces from the 17 court cases. Note that accuracy is measured as how likely participants were to match court decisions, whether that decision was of infringement or no infringement. Although the perceptual data were collected for the three cases including instrumental works, these cases were omitted from the lyrics-only analyses because infringement of lyrics is clearly impossible for instrumental works. In Figure S1,

individual data points represent mean accuracy for individual *participants* (n = 20) across the 17 cases, while in Figure 1 individual data points represent mean accuracy for individual *cases* (n = 17) across the 20 participants.

Surprisingly, the accuracy numbers by participants of the three condition groups distributed quite closely, with mean accuracy of 58%, 54%, and 49% for full-audio, melody-only, and lyrics-only groups respectively. Not only was our predicted difference between melody-only and full-audio not significant (paired t = 1.7, df = 19, one-tailed p = 0.95), but what small difference there was between full-audio and melody-only was in the opposite direction from our predictions (participants were slightly *more* accurate when presented with full-audio than with melody alone). However, randomized control pairs had modal accuracies of 100% for all three conditions (cf. Figure S1), confirming that participants were able to perform all three tasks much more accurately than by chance. In addition, participants who self-reported as musicians showed no significant differences in accuracy compared to non-musicians (full: t = 0.63, df = 11, 1-sided p-value = 0.27; melody: t = 1.20, df = 17, 1-sided p-value = 0.12; lyrics: t = 0.68, df = 14, 1-sided p-value = 0.25).

Figure 1. Accuracy of perceptual judgement for each of the 17 court cases, as measured by the percentage of the 20 participants whose judgements of music copyright infringement matched court decisions.

Figure 1 plots the accuracy of perceptual judgement for the 17 court cases judged by the 20 participants. As in Fig. S1, the means of the three conditions are similar. Interestingly, however, the accuracy values are approximately normally distributed for the full-audio condition, while the melody-only and lyrics-only conditions have bimodal, hourglass-shaped distributions. Furthermore, full-audio cases show no major differences in the distribution of infringing vs. non-infringing cases, while melodic cases show some skewing toward higher accuracy for non-infringing cases and lyrics show a strong dichotomy between high accuracy for non-infringing cases and low accuracy

for infringing cases. No clear differences are notable for the small subsets of cases from Japan or those involving instrumental works.

5. AUTOMATIC ANALYSIS

We performed automatic similarity analysis of these cases using two different automated algorithms focused on melodic and audio similarity, respectively.

5.1 Melodic Similarity (Percent Melodic Identity [PMI])

We chose the PMI (Percent Melodic Identity) method to calculate melodic similarity because it has been validated in previous research using a similar sample of copyright cases. Like Judge Learned Hand's "comparative method" [6] to test musical similarity, the PMI method begins by transposing two melodies transcribed in staff notation into a same key, eliminating rhythmic information by assigning all notes equal time values, and then aligning and counting the confluence of notes[1]. Following the procedure, we prepared note sequences of disputed melodies all transposed to a C tonic for consistency (just as was done when preparing MIDI files). The PMI algorithm then automatically aligns each sequences pair, and counts the number of identical notes (*ID*). The percentage of identical notes shared between the pair of melodies, named percent melodic identity (*PMI*) [3], is calculated by dividing *ID* by the average length of the melodies pair (L_1 and L_2), as follows:

$$PMI = 100\left(\frac{ID}{\frac{L_1 + L_2}{2}}\right)$$

5.1.1 Melodic Similarity Results

The PMI values computed for all 17 music copyright infringement cases are shown in Table 1. Receiver Operating Characteristic (ROC) analysis was used to assess the prediction given by PMI values. The area under the ROC curve (AUC) is 0.61. The optimal cutoff PMI value is 46.8% with sensitivity = 0.89 and specificity = 0.50. Using this cutoff, PMI method was able to accurately classify 12 out of the 17 cases (71%) to match their court decisions. The five cases highlighted by italic font in Table 1 are those that the PMI method failed to classify correctly, discussed further below.

5.2 Audio Similarity (Musly)

Musly currently implements two music similarity algorithms. One implements Mandel-Ellis audio similarity algorithm [16]. The other one, which is the default one, improves Mandel-Ellis algorithm to compute audio similarity for best results. Specifically, it computes a representation of each song's audio signal based on 25 Mel-Frequency Cepstral Coefficients (MFCCs) to estimate a Gaussian model and finally a single timbre model to be compared, computes similarity between each pair of timbre models using Jensen-Shannon approximation, and normalizes the

---

[1] Note that rhythms are not eliminated for the perceptual stimuli, only for the PMI calculation (see [10] for discussion of treatment of rhythm in the PMI method).

similarities with Mutual Proximity [17-18]. We used the default algorithm because it has been found to have higher accuracy [17].

We prepared the full-audio version of the music excerpts from the dataset of court cases and fed them to the default algorithm of Musly to compute similarity. The output of the Musly algorithm is a distance matrix where distances, i.e. differences, between every two songs are listed. Because the Musly default algorithm normalizes the results, all the distances range between 0 and 1. Consequently, we calculated the audio music similarity by subtracting distance values from 1 and multiplying by 100 to convert the results into percentage terms for consistency with our other methods.

5.2.1 Audio Similarity Results

The results of Musly-calculated audio music similarity values for all 17 tested cases are shown in Table 1, appended next to the column of PMI values. The area under the ROC curve (AUC) is 0.69. The optimal cutoff threshold of Musly-calculated similarity is 32.8% with sensitivity = 0.67 and specificity = 0.75. Using this cutoff, Musly algorithm was also able to accurately classify 12 out of the 17 cases (71%) to match the court's decisions. The five failure cases are highlighted by bold font in Table 1 and briefly analyzed below.

6. AUTOMATED VS. PERCEPTUAL JUDGEMENTS

6.1 PMI vs. Perceptual Data

Mean perceptual similarity of each court case was calculated by averaging participants' individual ratings of similarity. The perceptual similarity values for the 17 court cases are listed in Table 1 and highlighted by light green. Figure S2 shows the relationship between PMI values and perceptual similarity under the three different conditions. Regression analyses show that the PMI melodic similarity is significantly correlated with perceptual similarity for both full-audio and melody-only conditions (full: R = 0.58, p = 0.014; melody: R = 0.59, p = 0.012), but not for the lyrics-only condition (R = -0.058, p = 0.84).

6.2 Musly vs. Perceptual Data

We also compared the Musly-calculated audio music similarity with the perceptual data collected. Figure S3 shows the correlation between Musly similarity and perceptual similarity of the 17 tested court cases under three different conditions for perceptual judgement. Regression analyses indicate that the Musly audio similarity has no significant correlations with perceptual similarity for all three condition groups of "full-audio", "melody-only", and "lyrics-only" (full: R = 0.26, p = 0.32; melody: R = 0.082, p = 0.76; lyrics: R = 0.059, p = 0.84).

7. DISCUSSION

Overall, our analyses showed moderate agreement between automated and perceptual judgements of music copyright infringement. Both automated similarity algorithms – PMI for symbolic data and Musly for audio data – matched past court decisions with relatively high accuracy (both 71%). The fact that PMI was significantly correlated with perceptual similarity for both melody-only and full-audio provides validation for PMI as a perceptually relevant measure of melodic similarity and is consistent with the idea that melodic similarity plays a role in judgements of overall musical similarity [19].

The lack of correlation between Musly's audio similarity algorithm and perceptual similarity was surprising given that Musly's algorithm has previously performed well in evaluations of general musical similarity. This may be partly explained by Musly's reliance on MFCCs to capture timbral and rhythmic similarity, not melodic similarity. Previous studies have shown that limited inter-rater reliability in judgements of musical similarity can limit the performance of automated algorithms [13]. Future analyses using supervised learning or other algorithms for capturing melodic similarity [1] may be able to improve performance, although the subjective nature of musical similarity will still place limits on the ability of any algorithm to match human judgements.

Surprisingly, both automated methods had higher accuracy than that of perceptual judgement, with both automated methods able to accurately predict 71% (12/17) of previous court decisions while perceptual accuracy were 58% and 54% under full-audio and melody-only conditions respectively. We suspect that allowing the algorithms to optimize the similarity threshold via the ROC analysis helped to improve - and probably overfit - the automated analyses[1]. Future analyses with larger data samples should consider calibrating parameters on a training subset before evaluating them on a separate test subset.

There are several possibilities for the low levels of perceptual accuracy. The fact that participants showed very high levels of accuracy (almost 100%) for randomized plaintiff samples suggests that the results were not merely random, but the inclusion of such samples might conceivably have skewed judgements by including levels of dissimilarity rarely included in real court cases. The fact that musicians performed similarly to non-musicians suggests that lack of musical expertise is also unlikely to explain the low performance. Although we cannot rule out effects of participants' familiarity because we failed to collect such data, any familiarity effects when participants were aware of the cases would be predicted to increase, rather than decrease, accuracy.

Instead, some past court decisions (e.g., the cases involving "He's So Fine" and "Blurred Lines") have been so controversial as to be debatable whether they were in fact "correct" [6]. Indeed, it seems likely that the dynamics of copyright lawsuits create a type of selection bias in which cases where infringement or lack of infringement are obvious are more likely to be resolved out of court[2] without a final court decision, while only the most ambiguous

---

[1] The chance of getting an accuracy of 12 or more correct by chance is actually 26%.

[2] One case (HarumakiGohan v. Mori) was settled out of court, and this case displayed some of the highest levels of participant accuracy.

cases require the court to make a final adjudication. In the future, rather than relying for ground truth only on court decisions and the selection bias they may create, our perceptual experiment may provide an alternative source of ground truth for disputes that were resolved out of court and thus tend to lack objective legal documentation.

Our prediction that listening to melody-only would provide superior accuracy than listening to full-audio was not supported. The fact that our prediction was not only not significant but was in the wrong direction suggests that limited statistical power cannot explain this result. Instead, despite legal arguments suggesting that non-melodic factors should generally be ignored and the sample having been selected based on the criteria of melodic similarity [1], individual cases are always complex and factors such as lyrics, instrumentation, and other non-melodic factors did in fact play roles in past decisions [14]. Overall, participants tended to judge melody-only versions as less similar than full-audio, with accuracy tending to be lower for cases judged as infringing. This suggests that participants have more difficulty detecting infringement using melody only. Since including non-melodic information appears to help (or at least not hurt) improve accuracy even for this sample emphasizing melodic similarity, this may suggest that allowing juries to hear full audio recordings without restricting them to sheet music depositions could actually help improve accuracy in legal cases. However, this hypothesis remains speculative until it can be more rigorously tested at larger scales (and the issue discussed above of determining "correct" decisions more thoroughly addressed).

The average results for each case shown in Figure 1 displayed a normal distribution for full-audio but were hourglass-shaped/bimodal for melody-only and lyrics-only. For the lyrics-only condition, this distribution reflects that most participants judged non-infringement for most cases, which is consistent with the fact that this sample was not selected to include many example of lyrics infringement. The melody-only condition led to higher accuracy for some cases (as predicted), but lower accuracy for others (contra predictions).

The accuracy of the PMI algorithm for the current study of 71% (12/17 cases) was slightly lower than the value of 80% (16/20 cases) reported in a previous study using a similar dataset. There are two reasons for this: 1) The sample was different – this study excluded 6 cases without matching full audio recordings and added 3 new Japanese cases (the new Japanese cases were not selected based on PMI values or any quantitative criteria, but they all were correctly classified by the PMI algorithm). 2) In the process of preparing controlled audio files for the experiment that were exactly matched, we noticed that several of the transcriptions used in [1] and [3] either did not exactly match the audio recordings, or had mismatched lengths.

Compared with the previous published study on PMI [3], the current PMI method successfully classified two case that were not accurately classified in the 2018 testing (*Three Boys Music v. Michael Bolton* and *Grand Upright v. Warner*), but three cases previously classified successfully now failed to be successfully classified (*Swirsky v. Carey*, *Granite Music v. United Artists*, and *Jean et al. v. Bug Music*). Two cases (*Selle v. Gibb* and *Fantasy v.*

Fogerty) remained failures in both studies, but these two exceptions were not due primarily to a failure of the melodic similarity algorithm but rather to the complex nature of musical copyright law [3]. These discrepancies show how results from the PMI method can be affected by errors and uncertainties in the transcription process.

While the Musly algorithm resulted in the same overall accuracy as the PMI method (71%), 4 of the 5 mis-classified cases were different between the two methods. Both methods mis-classified *Fantasy v. Fogerty* as infringing when the court decision was non-infringement (see [3] for discussion of legal details). The four cases uniquely misclassified by the Musly but not PMI method largely seemed to be of the type predicted by the melody-centric view of copyright in which non-melodic similarities or differences interfered with assessment of melodic similarity. For instance, *Herald Square Music v. Living Music* showed low audio similarity via Musly despite high melodic similarity and a finding of infringement. In this case, the different timbres where one melody is performed by a saxophone with background noise while the other is sung by a vocalist with piano accompaniment seem to obscure similarities in the two melodies.

The fact that both algorithms failed for different sets of cases, and the fact that participants who made judgements only based on audio similarity without information about the historical/legal context performed even lower than the algorithms, suggests that the complexities of copyright law are difficult to fully capture through objective measurement of similarity alone. The relative emphasis on melody, lyrics, other musical aspects, and extra-musical legal factors changes from case to case, limiting the power of any single objective method. This supports previous caveats that, while objective quantitative methods may help supplement traditional qualitative analysis, "Trial by algorithm will never replace trial by jury, nor should it." [3].

8. FUTURE DIRECTIONS

The primary limitation of our study at present is its limited size and scope, with a dataset of only 17 court decisions (17 from USA) and perceptual ratings from only 20 participants. Furthermore, some of the cases include non-musical aspects that make it difficult for current automated methods focusing on musical similarity to identify those exceptions. Thus, we plan to expand the testing data by including more usable cases which have court decisions and have no non-musical factors that have affected the court decisions. Preliminary screening of the 238 cases at the Music Copyright Infringement Resource [14], we found 50 potentially usable court cases we plan to investigate in future studies. To increase diversity and cross-cultural generalizability, we also plan to identify more non-US cases, particularly from Japan and China where music industry revenues are substantial.

One promising direction may be to expand from a focus purely on music copyright infringement to also include the related domain of cover-song detection. Because there are larger databases and more sophisticated algorithms being developed for cover-song detection, these may provide more powerful methods that could be adapted to copyright infringement in future research [11-12].

9. DATA/CODE AVAILABILITY

Musical stimuli, data and analysis code are available at https://github.com/compmusiclab/music-copyright. The full experiment can be accessed at https://music.keio.moe/experiments/copyright/full.

ABSTRACT

Investigating music with a focus on the similarity relations between songs, albums, and artists plays an important role when trying to understand trends in the history of music genres. In particular, representing these relations as a similarity network allows us to investigate the innovation presented by these entities in a multitude of points-of-view, including disruption. A disruptive object is one that creates a new stream of events, changing the traditional way of how a context usually works. The proper measurement of disruption remains as a task with large room for improvement, and these gaps are even more evident in the music domain, where the topic has not received much attention so far. This work builds on preliminary studies focused on the analysis of music disruption derived from metadata-based similarity networks, demonstrating that the raw audio can augment similarity information. We developed a case study based on a collection of a Brazilian local music tradition called Forró, that emphasizes the analytical and musicological potential of the musical disruption metric to describe and explain a genre trajectory over time.

1. INTRODUCTION

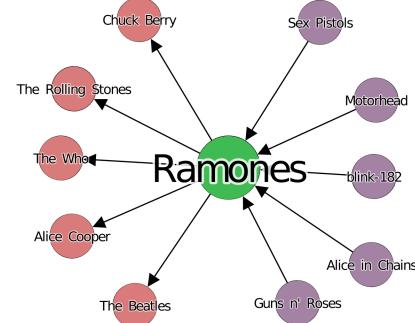
Inflections on creative threads are prevalent events that can be observed multiple times throughout music history [1]. The emergence of punk rock in the early seventies, for example, changed the traditional rock and roll in many aspects to create a unique music expression [2]. The music branch of the punk culture brought heavy lyrics, aggressive looks, and even deep acoustic changes to the songs, which were more aroused and noisier than songs from previous decades. Such music aspects were replicated over time, as evidenced for example in the expert-curated influences credited in the AllMusic guide [3] to artists from the early stages of the punk rock (e.g. *Ramones*, *Bad Religion*, *Sex Pistols*). The guide attributes to these bands influence over more recent ones, such as *Green Day* and *The Offspring*.


Figure 1. Network topology for a disruptive artist.
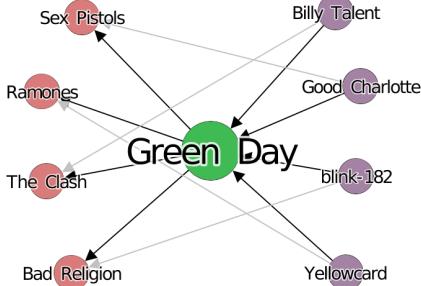

Regarding the different creative roles played by artists during the genre trajectories, the AllMusic guide defines the *Ramones* as *"inarguably the most relevant band in punk history, creating the stylistic prototype that would be followed by countless bands who emerged in their wake"* [1] . That points out to a particular innovative case where an artist had a significant and primary influence over the rupture of some well-established guidelines. Thus, an artist can be considered *disruptive* when your music contribution is developed in a self-sufficient way, abruptly shifting the present creative thread.

Conversely, AllMusic suggests a different nature of innovation when describes *Green Day* as *"influenced by the late-'70s punk predecessors, they went on to introduce a new, younger generation to the genre"* [2] . On the opposite of the disruptive movement by the *Ramones*, this excerpt allows describing *Green Day*'s creative potential as a consolidation of the previous practices, including their particular musical signature in the meantime.

Both musical creative natures can be represented by a network model, where the nodes represent artists and the edges symbolize the influence relation of one artist over another. Figure 1 shows a disruptive innovation by the *Ramones* based on influences metadata extracted from AllMusic, where edges indicate an "influenced by" relation. Predecessors (i.e., one that chronologically preceded another) of a focal node (in green) are represented by red

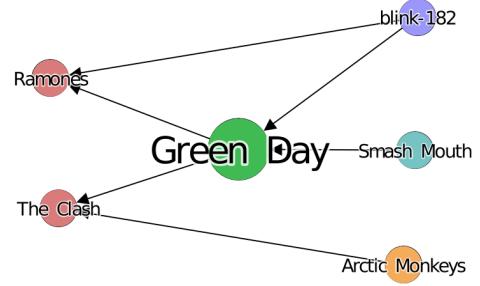
Figure 2. Network topology for a consolidator artist.

Figure 3. Demonstration for different types of influence.

nodes, whereas purple nodes represent the successors.

Due to its self-sufficient nature, one may expect that most of the artists (nodes) that succeed and are influenced by a disruptive artist connect to this artist, but not to its predecessors. A similar explanation can be given to describe the network topology for artists that consolidate the genres over time (Figure 2 for *Green Day*): these artists reaffirm a thread of influences, as their successors are usually influenced by both them and their predecessors.

Despite its simple semantics and noticeable potential in enriching musicological analyses about the history of genres, there is limited research that measures the disruption of songs over time. In particular, this work is based on the disruption quantification using a metric derived from audio similarity networks. Specifically, we model a network of similarity among songs and use their temporal precedence to explore patterns of similarity that reveal creative aspects and disruption over time.


Features extracted from raw audio are reportedly a rich source of similarity information [4], as they cover many music aspects, such as timbre [5, 6], harmony [7, 8], and rhythm [9]. Therefore, consider such types of data to construct similarity networks can be valuable in understanding how songs of the same genre are acoustically related. In this work, a musical disruption analysis is proposed over this similarity network, allowing to unveil some interesting findings of the disruption of songs over time. To promote a better interpretation of results, we collected a new audio dataset comprising songs of a definite style, called Forró.

In this analysis we represent songs as Mel-Frequency Cepstral Coefficients (MFCCs), using these representations to build a similarity network that connects songs with similar acoustics. Next, we process this network's topology to calculate the disruption metric for all songs, summarizing the most disruptive music pieces. This analysis allows us to validate the disruption metric in the music context. Both the dataset and the network representations generated during the experiments are made available for further studies.

2. BACKGROUND

2.1 Music Innovation & Corpora

Music innovation is not a popular main research topic, being usually mentioned in studies focused on modeling mu-

sic influence [10–12]. In particular, Shalit et al. [13] proposed a dynamic topic model to represent music influence over time using metadata and audio. In their work a song is considered influential if its language gets replicated by subsequent works, while innovation is modeled as the extent of which the model accounts for a song when trained only with data from the past. Their findings leveraged the Million Song Dataset [14] to point to correlations between influence and innovation only during some short periods in the early 70's and mid-90's.

Associations between music influence and innovation were also investigated by Noyer and his collaborators [15]. Using a network to represent influences between artists, the authors tried to find topological differences between innovative and non-innovative artists. Their approach analysed artists data from 1951 to 2008, measuring innovation as the number of Grammy awards won by each artist. Conclusions identify that innovation in fact impacts network topology, showing that artists with more awards presented considerably more structural holes on their sub-networks.

Corpora plays a major role when representing the influence relations between artists, albums and songs. Both the Million Song Dataset [13,16] and the information available on the AllMusic music catalogue [15, 17, 18] have been used as audio and metadata source for many MIR tasks, including influence modeling.

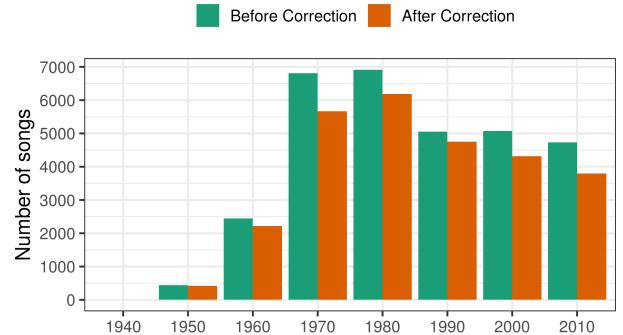
2.2 Disruption Index

This present work builds on a network metric proposed by Funk & Owen-Smith [19] to measure destabilizing and consolidating influences of inventions over existing technology streams. Their CD_t index assumes that the degree of destabilizing influence (disruption) of an invention within an influence network should be measured in terms of "how future inventions make use of the technological predecessors cited by a focal patent". Given that notion, Figure 3 depicts an example of the three types of music influences for a focal node a (*Green Day* in the example) used for measuring disruption according with CD_t: Let n_i be the number of nodes i that reference only a and none of its predecessors (*e.g., Smash Mouth*), n_j be the number of nodes j that reference both a and at least one of its predecessors (*e.g., blink-182*), while n_k accounts for the number of nodes k that do not reference a but reference at least one of its predecessors (*e.g., Arctic Monkeys*). Disruption

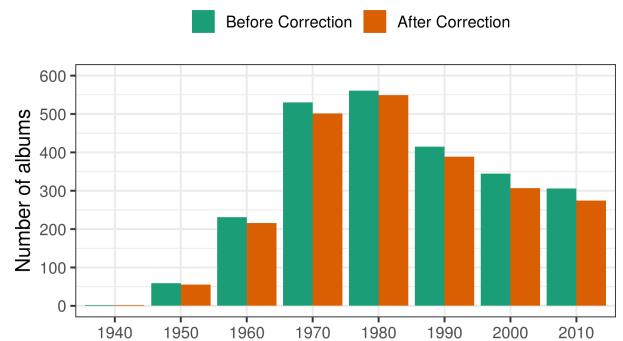
(henceforth referenced as D) is then measured as:

$$D = \frac{n_i - n_j}{n_i + n_j + n_k} \tag{1}$$

D ranges from -1 to 1, where values close to 1 indicate nodes with highly disruptive potential whereas measures around the negative extreme denote nodes that mostly consolidated influences over time and therefore were cited in parallel with their predecessors.

The original case study for D was developed over a database of patents granted in the US between 1977 and 2005. Their findings indicate that disruptive inventions are usually boosted by federal research funding initiatives, while commercial ties are more related to the consolidation of the *status quo*. Such validation was later expanded by Wu et al. [20], that enriched the dataset with scientific papers and software repositories, accounting now for a total of 65 million observations. The study concluded that disruptive products are associated with smaller teams, while larger groups mostly consolidated knowledge.


The disruption metric was recently experimented in the music context by Figueiredo and Andrade [17]. They leveraged influence metadata from AllMusic to create a network linking 32,568 artists according with their influence relations (i.e. a "link from artist a to b denotes that a has been influenced by b"). Disruptions are then extracted for all the network components, triggering discussions regarding disruptive and consolidator potential. In particular, they confirm the results of [13] about the lack of correlation between influence and disruption, also concluding that D translates structural insights that are not derived from any existing network metrics.

3. COLLECTED MUSIC DATA


Our musical disruption analysis uses audio data from a Brazilian cultural manifestation called Forró (composed by music, dance, and festivities), native from the northeast of Brazil during the second half of the 19th century. The Forró music genre is composed of three preponderant instruments: accordion, triangle, and a percussive drum called *zabumba*. *Luiz Gonzaga* is the most prominent representative of this genre and is responsible for spreading his music to other regions of Brazil.

The audio data was obtained from the collaborative site *Forró em Vinil* [21], which organize and publish contents that register the history of Forró (e.g. albums, books, and pictures). The audio collection is maintained by media collectors that own long play records and CD's that are no longer produced by record labels. These collectors digitize their media and provide the audio files to the site's administrators, responsible for curating the collection. We built a dataset covering Forró songs ranging from the years 1945 to 2016, by scraping the site via a web crawler. Overall, 2,449 distinct albums were collected, grouping a total of 31,485 songs, each one annotated with artist, album, and release year.

To ensure that the collected data is only comprised of Forró songs, we excluded other genres found on a descrip-

Figure 4. Histogram for number of songs over decades.

Figure 5. Histogram for number of albums over decades.

tive analysis phase. Moreover, to guarantee a chronological information required by the nature of this study, we filtered out albums without release year informed. These data corrections were necessary to satisfy genre-specific and time constraints requirements. Figures 4 and 5 show the song and album distribution over decades before and after dataset correction, respectively. Out of the original 2,449 albums, 2,293 satisfied the constraints, accounting for 27,352 songs which we considered.

4. MUSIC & SIMILARITY REPRESENTATIONS

We leverage Mel-Frequency Cepstral Coefficients (MFCCs) as feature for audio similarity estimation. MFCCs are robust music representations often used in many music information retrieval tasks [22], including genre classification [23], music recommendation [24, 25] and audio similarity [26, 27]. Moreover, given its reported ability to model timbre information [28], we expect that this feature will also capture relevant audio events when iterating over our data. In particular, we look for disruptive episodes when an artist included new instruments to the basic setup discussed on Section 3, which is something that actually happened during the history of Forró.

Similarly to what is proposed by Choi et al. [22] for their baseline feature, we employ as our audio feature the means and standard deviations for 20 MFFCs and their first order derivatives over the entire song. Audio processing techniques are aided by the Librosa package [29]. The result of this feature extraction methodology is a collection

32

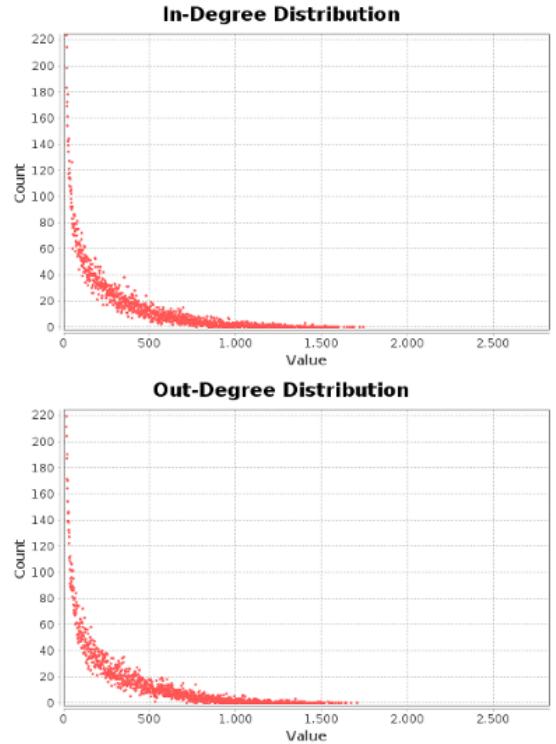
Task #	# of classes (n in top-n)	Max. items per class	Sample size	Precision
1	20 classes	500 items	6572 items	**0.79**
2	50 classes	25 items	1125 items	**0.88**

Table 1. Sampling settings and reported precisions for artist (#1) and album (#2) classification tasks.

of 27,352 vectors (henceforth referenced as *feature vectors*), each one containing 80 elements that represent audio information.

An extra validation step is also conducted to confirm those feature vectors encode enough audio information to generate comprehensible music similarities. Two multiclass audio classification tasks are designed to measure the precision of machine learning classifiers when trained with feature vectors from the *Forró em Vinil* Dataset:

- Task 1: Artist classification: classification of artists among the *top-n* (those with more songs);

- Task 2: Album classification: classification of albums among the *top-n* (those with more songs);


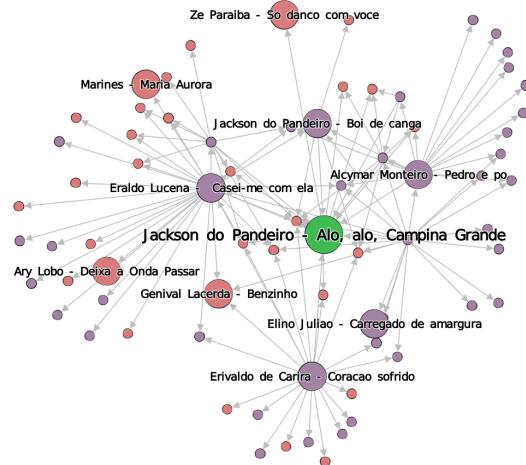
SVM classifiers are used in both cases, given their efficiency in tasks with small training sets. Model training was done using scikit-learn [30] and experiments are run with 10-fold cross-validation using stratified splits. Models have their parameters optimized upon the use of gridsearch on the validation phase and reported precision values are related to the best classifier after all splits are done. Table 1 summarizes both the dataset sampling strategies and scores for artist and album classifiers, indicating high precisions for both cases (79% and 88%, respectively).

These partial results present two interesting findings that support the next steps. First we can now fairly assume that our vector representations encode enough audio information to derive similarity measures. The second conclusion refers to the best performing kernel function considered by the grid-search routine for both classifiers: the Radial Basis Function (RBF) kernel. The RBF kernel models vector distance, and its mathematical definition [31] assigns to itself a similarity interpretation [32] (i.e., values ranging from 0 to 1, inversely proportional to the vector distance). Given its potential on providing similarity insights for sequential data, we opt for using the RBF kernel as similarity measure for pairs of feature vectors.

5. SIMILARITY NETWORK

To measure disruption we first need to construct a directed network connecting similar objects. When it comes to song similarity networks, the nodes are the songs and an edge between any pair of songs represent a similarity relationship. We now describe how our network was built.

Each song from the *Forró em Vinil* Dataset is a single node in this network. As for the edges, although the RBF kernel allows us to quantify the similarity between any pair of songs, the binary choice about whether or not we create

Figure 6. Distribution of in and out degrees.


an edge between two nodes depends on the definition of a similarity threshold above which we can safely ensure that a similarity edge exists. In order to empirically select this threshold, we leverage the fact that songs from the same album are arguably a fair ground truth for noticeable similarity (i.e., these songs usually share the same instrument and voice settings). Thus, we iterate over the whole dataset checking the average similarities between each song s from album a and every other song s' from a. This analysis informs an average similarity of ≈ 0.90, which from now on is used as threshold when creating edges.

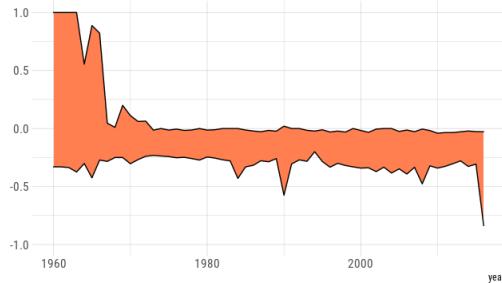
To create our network, for each song s we query the similarity matrix among all songs and create an edge from s to a predecessor s' if their similarity is greater than or equal the threshold. Additionally, to limit our analysis to a timeframe where stylistic movements are observable, we enforce a time window within which two songs must fall to in order to enable connections between them. Here the size of this time window is 10 years, as it seems reasonable in this context and was also used in [20] when deriving influences between scientific papers.

Out of the 27,352 original songs from the dataset, 26,452 are included in the resulting graph, connected by 5,728,466 directed edges. This minimal difference from the original songs count is explained by the removal of disconnected nodes (i.e. songs that do not sound similar to any other). 98% of all nodes are densely connected to the same giant component and in and out-degrees distribution can be observed on Figure 6. Moreover, Figure 7 illustrates an ego-network extracted from the original structure.

Song	Artist	Album (year)	Disruption Index & Comments
Padrinho Cícero do Juazeiro	*Trio Juazeiro*	*Pedaço de fulô (1982)*	$D = 1$ ($n_i = 37, n_j = 0, n_k = 0$). A fast song (140bpm) with a clear and complex accordion arrangement. The sub-network focused around its node evidences connections with multiple songs from same albums, what might indicate the emergence of a new (disruptive) acoustic setting that was adopted by following artists, like *Clemilda* and *Roberto do Acordeon*.
Namorada de João	*Coroné Narcisinho*	*Forró do Serrado (1969)*	$D = 1$ ($n_i = 28, n_j = 0, n_k = 0$). The song brings a very audible triangle as part of its percussive setup, what can't be perceived in most of the songs from the same epoch. Dominant triangles can also be heard in many of the songs that succeded *Namorada de João*, as in *Esse forró eu danço* (*Abdias* - 1977).
Sem vergonheira	*Marinês*	*Canção da fé (1972)*	$D = 1$ ($n_i = 24, n_j = 0, n_k = 0$). Marinês is one of the first female Forró singers. *Sem vergonheira*, as many of her songs, presents a combination of a strong lead singing voice and effective backing vocals, an unusual practice back then. Similar strategy is used by some of its succeeding songs, like *Quebra-cabeça* (*Trio Nordestino - 1981*).
Derramaro o gai	*Luiz Gonzaga*	*O nordeste na voz de Luiz Gonzaga (1962)*	$D = 1$ ($n_i = 22, n_j = 0, n_k = 0$). The refined accordion melodies are undoubtedly the strongest aspect of *Luiz Gonzaga*'s work, and this song is proof of that. *Derramaro o gai* has multiple disruptive connections with other songs from its very same album, as well as similarities with songs from *Severino Januário*, his brother.
Lembranças	*Flávio José*	*Só confio em tu (1977)*	$D = 1$ ($n_i = 19, n_j = 0, n_k = 0$). The song empowers the acoustic guitar among the original Forró instrumentation, what was rare back in the late seventies. Similar songs by *Flávio José* solidify this new creative branch, imitated by artists like *Marinês* and *Genival Lacerda*.

Table 2. Top-5 of disruptive songs according to the D measure.

Figure 7. Ego-network for *Alô, alô, minha Campina Grande* by *Jackson do Pandeiro* ($D = -0.07$). Red nodes preceded and purple succeeded the focal, green, node.

6. DISRUPTION ANALYSIS


We can now combine the disruption metric D with the similarity network proposed in the previous section to trigger discussions regarding the disruptive potential of songs over the history of Forró. Since disruption as modeled by Equation 1 depends on preceding data (i.e., n_j and n_k nodes), we decide to use songs prior to 1960 only as comparison data for the following decades, hence no disruptions for these are reported. In other words, the songs from the forties and fifties are a part of the graph (they impact the disruption of future songs), we just do not report their disruption. All the other songs have their disruption indexes

derived according to the i, j and k as described on Section 2.2.

Table 2 depicts data from the disruption ranking and summarizes the five most disruptive songs of the *Forró em Vinil* Dataset, trying to support these findings with specifics related to the songs acoustics and their similarity relations. Although artist influence is not a mandatory requirement when determining disruption, it's meaningful to evidence that music pieces from representative artists such as *Luiz Gonzaga*, *Marinês* and *Flávio José* are considered disruptive according to our analysis.

We draw special attention to songs from *Sivuca* that are included among the most disruptive ones (eight songs with $D \geq 0.5$). This musician, widely acclaimed for his work both in Brazil and the United States, was a multi-instrumentalist with strong accordion and acoustic guitar skills. Many of his songs with high disruption in the network combine elements from a variety of genres other than Forró, like *Choro*, *Frevo*, Jazz and Blues. The acoustic richness assigned to his work as well as the uniqueness of the music performed by *Sivuca* generate a lot of internal similarity relations between his own songs, causing the high disruptions. To put it another way, when it comes to Forró, *Sivuca* was disruptive in the sense that his work was mostly influenced by himself, and himself only. This peculiar finding is a representative example of how the disruption metric can actually help to identify meaningful events hidden inside the history of genres.

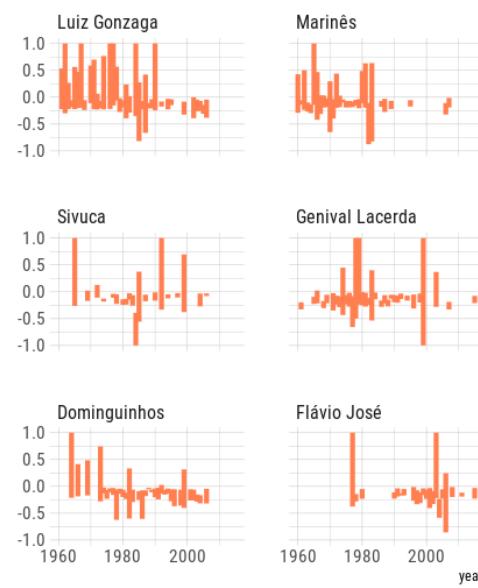
Next, we leverage the disruption information to model how the creative thread for Forró was developed during the past seven decades. With this analysis we aim at finding exactly when the genre presented creative inflections and how often these events happen during its history. Due


Figure 8. 5 to 95 percentile range of D over the years.

to the large number of songs with D around zero, caused by the dense network, we opt to summarize this disruption distribution in Figure 8 using 5 to 95 percentile ranges over the years. In overall, the higher disruptions of Forró are mostly concentrated on its first years, specially in the interval between 1960 and 1970. While at a first glance this may look like a natural consequence of these being the first songs in the dataset, recall that we omit an entire decade from Figure 8 (i.e., to filter out biases due to first mover advantage, songs from the 1950's impact the disruption of future songs but are not present in our analysis).

We further queried the ranking to understand what happened in the 1960's. Firstly, we see that this high creative load is guided by multiple disruptive songs from pioneers of the history of Forró, like *Luiz Gonzaga*, *Jackson do Pandeiro* and *Marinês*. When we investigate the biographies of these artists (from the AllMusic Guide), we point out facts such as: *Jackson do Pandeiro*[3] is considered: *"one of the most inventive and influential Brazilian musicians"*, *Luiz Gonzaga*[4] is cited as '*"one of the most influential figures of Brazilian popular music in the twentieth century"*. Finally, *Marinês* was the first woman to have a Forró group[5]. Biographies were last accessed in August 2020.

Nevertheless, we do point out that the following decades were also presented with disruptive songs. In particular, we propose an artist by year investigation to unveil some insights regarding artists who have unsettled the creative structure of Forró. Figure 9 uses the same percentile approach as Figure 8 to summarize the disruption information for the six artists with higher averaged D for aggregated data (i.e., all songs from the artist in the network). Again we see *Luiz Gonzaga* and *Marinês* figuring as very disruptive artists, with a high creative production specially until 1980, when their careers came to an end (*Luiz Gonzaga* died in 1989 and *Marinês* reduced her production after late 1980). Their creative legacy seems to have been inherited by *Genival Lacerda* and *Flávio José*, other disruptive artists that have been active since the seventies and which often perform disruptive songs since then. These other artists provide further evidence that our ranking is not entirely explained by first mover advantage.

Figure 9. 5 to 95 percentile range of D for disruptive artists over the years.

7. FUTURE WORK & CONCLUSIONS

The present study proposed an audio-based approach to extend the experimentation of a disruption metric in the music context. A new dataset comprised of songs from a Brazilian music tradition was collected to allow for a specific case study. The data supported the generation of an audio similarity network that models the creative flow of songs over time. Results derived from the disruption index underline the semantic potential attached to it, by triggering discussions about specific times when the genre had creative inflections and even which artists were responsible for these events. We argue in favor of applying similar approaches to different contexts, as this may unveil interesting findings about the history of many music genres.

A complementary research direction encourages some enhancements on Equation 1. In particular, we advocate that this formula should also account for the nodes similarities encoded on the edges, instead of simply dealing with creative relations in a binary fashion. That would prevent future studies from having to define a similarity threshold to choose whether or not similarity edges are included in the network, as suggested by this work.

Reproducibility: Both the MFCCs for the *Forró em Vinil* Dataset and the generated similarity network (Graph Exchange XML Format)[6], as well as the code used during the experiments[7] are publicly available.

ABSTRACT

Music arrangement generation is a subtask of automatic music generation, which involves reconstructing and re-conceptualizing a piece with new compositional techniques. Such a generation process inevitably requires reference from the original melody, chord progression, or other structural information. Despite some promising models for arrangement, they lack more refined data to achieve better evaluations and more practical results. In this paper, we propose POP909, a dataset which contains multiple versions of the piano arrangements of 909 popular songs created by professional musicians. The main body of the dataset contains the vocal melody, the lead instrument melody, and the piano accompaniment for each song in MIDI format, which are aligned to the original audio files. Furthermore, we provide the annotations of tempo, beat, key, and chords, where the tempo curves are hand-labeled and others are done by MIR algorithms. Finally, we conduct several baseline experiments with this dataset using standard deep music generation algorithms.

1. INTRODUCTION

Music arrangement, the process of reconstructing and re-conceptualizing a piece, can refer to various *conditional* music generation tasks, which includes *accompaniment generation* conditioned on a lead sheet (the lead melody with a chord progression) [1–4], transcription and *re-orchestration* conditioned on the original audio [5–7], and *reduction* of a full score so that the piece can be performed by a single (or fewer) instrument(s) [8,9]. As shown in Figure 1, arrangement acts as a bridge, which connects lead sheet, audio and full score. In particular, *piano arrange-*

Figure 1: Illustration of the role of piano arrangement in the three forms of music composition, where ① and ② are covered by our POP909 dataset.

ment is one of the most favored form of music arrangement due to its rich musical expression. With the emergence of player pianos [10] and expressive performance techniques [11, 12], we expect the study of piano arrangement to be more meaningful in the future, towards the full automation of piano composition and performance.

In the computer music community, despite several promising generative models for arrangement, the lack of suitable datasets becomes one of the main bottlenecks of this research area (as pointed by [19, 20].) A desired arrangement dataset should have three features. First, the arrangement should be a style-consistent re-orchestration, instead of an arbitrary selection of tracks from the original orchestration. Second, the arrangement should be paired with an original form of music (audio, lead sheet, or full score) with precise time alignment, which serves as a supervision for the learning algorithms. Third, the dataset should provide external labels (e.g., chords, downbeat labels), which are commonly used to improve the controllability of the generation process [21]. Until now, we have not seen such a qualified dataset. Although most existing high-quality datasets (e.g., [13, 15]) contain at least one form of audio, lead melody or full score data, they have less focus on arrangement, lacking accurate alignment and

Table 1: A summary of existing datasets.

labels.

To this end, we propose POP909 dataset.[1] It contains 909 popular songs, each with multiple versions of piano arrangements created by professional musicians. The arrangements are in MIDI format, aligned to the lead melody (also in MIDI format) and the original audios. Furthermore, each song are provided with manually labeled tempo curves and machine-extracted beat, key and chord labels using music information retrieval algorithms. We hope our dataset can help with future research in automated music arrangement, especially task ① and ② indicated in Figure 1:

Task 1: Piano accompaniment generation conditioned on paired melody and auxiliary annotation. This task involves learning the intrinsic relations between melody and accompaniment, including the selection of accompaniment figure, the creation of counterparts and secondary melody, etc.

Task 2: Re-orchestration from audio, i.e., the generation of piano accompaniment based on the audio of a full orchestra.

Besides those main tasks, our dataset can also be used for unconditional symbolic music generation, expressive performance rendering, etc.

2. RELATED WORK

In this section, we begin with a discussion of different modalities of music data in Section 2.1. We then review some existing composition-related datasets in Section 2.2 and summarize the requirements of a qualified arrangement dataset in Section 2.3. Again, our focus is piano arrangement and this dataset is designed for task ① and ② indicated in Figure 1, i.e., *piano accompaniment generation* based on the lead melody or the original audio.

2.1 Modalities of Music Generation

As discussed in [22], music data is intrinsically multi-modal and most generative models focus on one modality. In specific, music generation can refer to: 1) *score generation* [23–26], which deals with the very abstract symbolic representation, 2) *performance rendering* [4, 19, 20], which regards music as a sequence of controls and usually involves timing and dynamics nuances, and 3) *audio synthesis* [27, 28], which considers music as a waveform or

---
[1] The dataset is available at https://github.com/music-x-lab/POP909-Dataset

spectrogram. The POP909 dataset is targeted for arrangement generation in the modality of score and performance.

2.2 Existing Datasets

Table 1 summarizes the existing music datasets which are the potential resources for the piano arrangement generation tasks. The first column shows the dataset name, and the other columns show some important properties of each dataset.

Lakh MIDI [13] is one of the most popular datasets in symbolic format, containing 176,581 songs in MIDI format from a broad range of genres. Most songs have multiple tracks, most of which are aligned to the original audio. However, the dataset does not mark the lead melody track or the piano accompaniment track and therefore cannot be directly used for piano arrangement.

Maestro [15] and E-piano [29] contains classical piano performances in time-aligned MIDI and audio formats. However, the boundary between the melody and accompaniment is usually ambiguous for classical compositions. Consequently, the dataset is not suitable for the arrangement task ①. Moreover, the MIDI files are transcription rather than re-harmonization of the audio, which makes it inappropriate for the arrangement task ② either.

Nottingham Database [18] is a high-quality resource of British and Irish folk songs. The database contains MIDI files and ABC notations. One drawback of the dataset is that it only contains monophonic melody without polyphonic texture.

RWC-POP [17], CrestMuse [16], and JSB-Chorale [14] all contain polyphonic music pieces with rich annotations. However, the sizes of these three datasets are relatively small for training most deep generative models.

2.3 Requirements of Datasets for Piano Arrangement

We list the requirements of a music dataset suitable for the study of piano arrangement. The design objective of POP909 is to create a reliable, rich dataset that satisfies the following requirements.

- **A style-consistent piano track**: The piano track can either be an re-orchestration of the original audio or an accompaniment of the lead melody.

- **Lead melody or audio**: the necessary information for the arrangement task ① and ②, respectively.

- **Sufficient annotations** including key, beat, and chord labels. The annotations not only provide structured information for more controllable music generation, but also offer a flexible conversion between score and expressive performance.

- **Time alignment** among the piano accompaniment tracks, the lead melody or audio, and the annotations.

- **A considerable size**: while traditional machine learning models can be trained on a relatively small dataset, deep learning models usually require a larger sample size (expected 50 hours in total duration).

3. DATASET DESCRIPTION

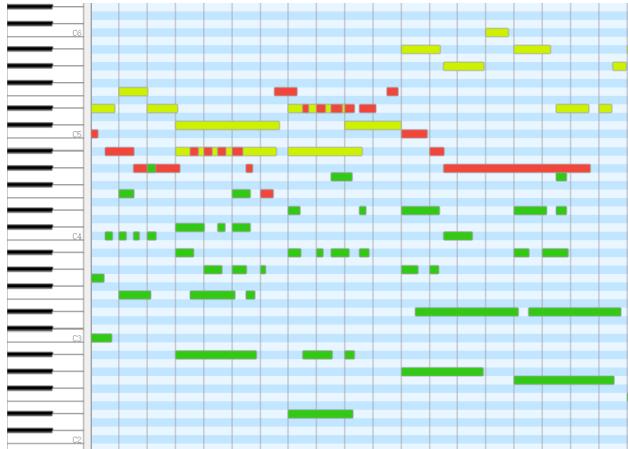
POP909 consists of piano arrangements of 909 popular songs. The arrangements are time-aligned to the corresponding audios and maintain the original style and texture. Extra annotation includes beat, chord, and key information.

3.1 Data Collection Process

We hire professional musicians to create piano arrangements. In order to maintain a high-quality standard of the arrangements, we divide the musicians into two teams: the *arranger team* and the *reviewer team*. The collection is finalized through an iterative procedure between two teams. For each song, each iteration goes through three steps:

1. Arrangement: the arranger team creates an arrangement from scratch, or revise the previous version of arrangement.

2. Review: the reviewer team decides whether the current version is qualified and comments on how to improve the arrangement in case further revisions are required.

3. Discussion: musicians from both teams catch up with the progress, discuss and improve details of arrangement standards.


We start the process from a list of 1000 popular songs and finally select 909 songs with high arrangement quality. We not only present the last revision (i.e., the qualified version) of each song but also provide the unqualified versions of each song created during the iterative process. This multi-version feature may potentially offer a broader application scenario of the dataset.

3.2 Data Content and Format

In POP909, the total duration of 909 arrangements is about 60 hours. The songs are composed by 462 artists. The release of all songs spans around 60 years (from the earliest in 1950s to the latest around 2010).

Each piano arrangement is stored in MIDI format with three tracks. Figure 2 shows an example of a three-track MIDI file, in which different tracks are labeled with different colors. The three tracks are:

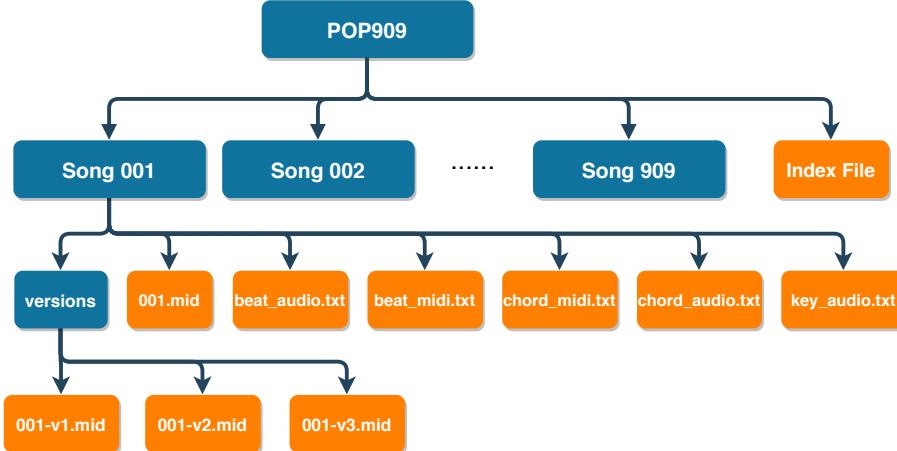
- MELODY: the lead (vocal) melody transcription.

Figure 2: An example of the MIDI file in a piano roll view. Different colors denote different tracks (red for MELODY, yellow for BRIDGE, and green for PIANO).

- BRIDGE: the arrangement of secondary melodies or lead instruments.

- PIANO: the arrangement of main body of the accompaniment, including broken chords, arpeggios, and many other textures.

Here, the combination of BRIDGE and PIANO track forms the piano accompaniment arrangement of the original song. Each MIDI file is aligned with the original audio by manually labeled tempo curve. Moreover, each note event contains expressive dynamics (i.e., detailed velocity control) based on the original audio.

Beat, chord, and key annotations are provided in five separate text files for each song. Annotations for beat and chord have both MIDI and audio versions while key changes annotations are merely extracted from audios.[2] The relevant music information retrieval algorithms are discussed in Section 4.


3.3 Data Folder Structure

Figure 3 demonstrates the folder structure of POP909. In the root directory, there are 909 folders, corresponding to 909 songs. In each folder, we provide the MIDI format arrangement, text format annotations, and a folder of all arrangement versions produced during the iterative processes.

The annotation files contain beat, chord and key annotations in plain text format. Table 2 shows the partial annotations of the song `003` in table format for better illustration purposes. For the beat annotation, `beat_audio` and `beat_midi` are the annotation files extracted from audio and MIDI, respectively. The source of chord and key annotations are indicated in a similar way.

Finally, we provide an index file in the root directory containing the song name, artist name, number of modified times and other useful metadata of the dataset.

---

[2] For annotations from MIDI files, the qualified (final) version of arrangements is used.

Figure 3: The folder structure of POP909. The blue boxes denote the folder and the orange boxes denote the file.

4. ANNOTATION METHODS

In this section, we discuss how we annotate the beat, chord and key information. For each of the three tasks, different algorithms are applied to extract information from MIDI or audio.

4.1 Beat & Downbeat Estimation

We first extract beat information from MIDI files by taking advantage of two features of the MIDI performance: (1) human-annotated tempo curves, and (2) the accompaniment figure of arrangements which shows a significant sign of beat and downbeat attacks.

Our method can be seen as a modification of the beat-tracking algorithms used in [30, 31]. First, we estimate the initial beat position and use the tempo curve to deduce subsequent beat positions. Second, we estimate the number of beats in a measure by calculating the auto-correlation of the extracted beat features (MIDI onset and velocity), assuming time signature is in general consistent within one song except for some infrequent phase changes. Finally, we search among all the possible phase shifts and find the optimal beat track that has the highest correlation with the extracted features.

We also provide the beat and downbeat annotations extracted from the audio using the algorithm introduced in [32] and compare them with the annotations extracted from MIDI.

For beat position estimation, the two algorithms have more than 90% consistency when the maximum error tolerance is 100 ms, which is acceptable in the data collection process. For downbeat estimation, the two algorithms have 80% agreement. We provide both extraction results in our annotation files.

4.2 Chord Label Extraction

We also provide the chord labels extracted from both MIDI and audio files. For the audio chord recognition, we adopt a large-vocabulary chord transcription algorithm by [33]. As chord changes in popular music are most likely to happen

at beat positions, we post-process the chord boundaries by aligning them to beats to produce the final chord labels.

file	beat time	downbeat_1	downbeat_2
	0.02	1.0	0.0
	0.75	0.0	0.0
	1.49	1.0	1.0
beat_midi	2.22	0.0	0.0
	2.95	1.0	0.0
	3.68	0.0	0.0
	...	...	...

file	beat time	beat order
	1.46	1.0
	2.18	2.0
beat_audio	2.92	3.0
	3.66	4.0
	...	...

file	start time	end time	chord
	0.02	0.75	N
	0.75	1.49	N
chord_midi	1.49	4.41	G:min7
	4.41	7.34	Eb:sus2
	...	...	...

file	start time	end time	chord
	0.00	1.46	N
	2.46	4.39	G:min7
chord_audio	4.39	7.31	Eb:maj(9)
	...	...	...

file	start time	end time	key
key_audio	1.46	226.00	Bb:maj

Table 2: The first several lines of the annotation files for song `003`. "downbeat_1" and "downbeat_2" in `beat_midi` are the two downbeat extractors under simple meter and compound meter assumptions, respectively.

For MIDI chord recognition, we adopt a method similar to the one proposed in [34]. We made two minor changes based on the original algorithm. First, the chord segmentation is performed on the beat level. Second, we alter the chord templates to include more chord qualities

used by pop songs: (1) triads (`maj`, `min`, `dim`, `aug`) with inversions, (2) basic sevenths (`maj7`, `min7`, `7`, `dim7`, `hdim7`) with inversions, (3) suspended chords (`sus2`, `sus4`, `sus4(b7)`), and (4) sixth chords (`maj6`, `min6`).

Note that the arrangement and its original audio may have different chord progressions. For example, a `C:maj` chord may be arranged into `C:sus2`, if necessary. Therefore, both annotations are reasonable and they are not necessarily consistent with each other. To compare the extraction accuracy, we compute the matching rate of the root notes of the chords extracted from both methods. Results show that the matching degree of more than 800 songs in POP909 are above 75%. On the other hand, there are still a few songs whose matching degrees are below 40%. The main reasons are: (1) some of these audio recordings are slightly out of tune, and (2) some parts of the audio have complicated sound effects, in which case our teams decide to re-arrange the chord progression.

4.3 Key Signature Extraction

We also provide key signature annotation from the audio files. We adopt an algorithm very similar to [35]. The original algorithm performs the key classification for a whole song based on the averaged frame-wise feature. In our modified algorithm, we also allow key changes in the middle of the song using a median filter to post-process the frame-level labels.

5. EXPERIMENTS

In this section, we conduct two baseline experiments on music (score-modality) generation with the POP909 dataset: 1) polyphonic music generation (without melody condition), and 2) piano arrangement generation conditioned on melody. For both tasks, we use the Transformer architecture [36] for its advantages in capturing long-term dependencies on time-series data.

5.1 Polyphonic Music Generation

We use a transformer encoder with relative positional encoding [19, 37] to model the distribution of polyphonic music. We adopt a MIDI-like event-based representation slightly modified from [19, 38] to encode the polyphonic music. Each piece of music is represented as a series of events, including note onsets, offsets, velocity changes, and time shifts. We further quantize time shifts tokens under the resolution of $\frac{1}{4}$ beat. In total, we use 16 time-shift events, ranging from $\frac{1}{4}$ beat to 4 beats. Longer notes or rests can be represented by multiple time-shift tokens in a sequence. Table 3 shows the details of our data representation.

We split the dataset into 3 subsets: 90% for training, 5% for validation, and 5% for testing. We set the maximum sequence length $L = 2048$, transformer hidden size $H = 512$, the number of attention heads $h = 6$, and the number of attention layers $N = 6$. Cross Entropy loss is used as the loss function and early stopping is applied.

Event type	Tokenization
Note-On	0-127 (MELODY & BRIDGE track) 256-383 (PIANO track)
Note-Off	128-255 (MELODY & BRIDGE) 384-511 (PIANO track)
Time-Shift	512-527
Velocity	528-560

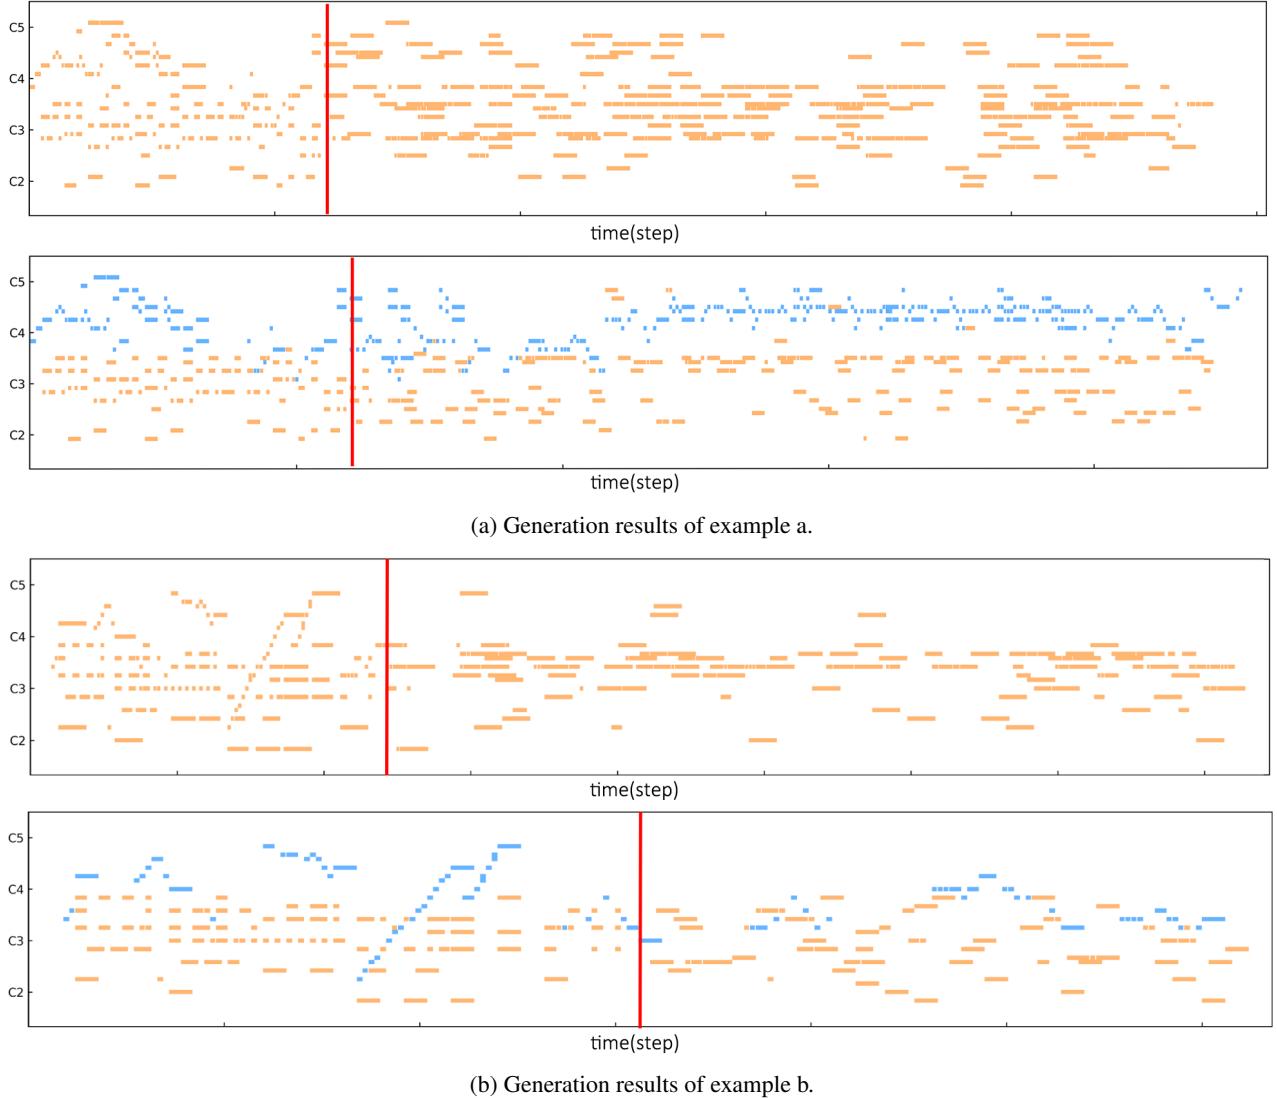
Table 3: The tokenization of the modified MIDI-like event sequence representation.

GPT-2-based transformer in POP909			
Train Loss	Train Acc.	Test Loss	Test Acc.
2.08978	0.62021	2.38122	0.54529

Table 4: The report of training and test loss and prediction accuracy of MIDI event tokens.

We use Adam optimizer [39] with hyperparameters $\beta_1 = 0.9, \beta_2 = 0.998$. We further adopt the warm-up schedule to control the learning rate. Formally, at the i-th warm-up step, the learning rate

$$lr = \frac{1}{\sqrt{H}} \times \min(\frac{1}{\sqrt{i}}, \frac{i}{S\sqrt{S}}), \tag{1}$$

where $S = 4000$ is a hyperparameter controlling the number of warm-up steps. The training result is presented in Table 4.


5.2 Piano Arrangement Generation

In the second experiment, we design an automatic piano arrangement task: piano accompaniment generation conditioned on the melody. In the data processing step, we first merge the MELODY track and the BRIDGE track into the *main melody* and regard PIANO track the *piano accompaniment*.

We use the same (trained) model in Section 5.1 to model the joint distribution of the main melody and piano accompaniment. During the inference, we force the generated melody to match the given melody condition, generating the most likely accompaniment conditioned on the melody. (A similar conditional generation method has been used in [20].)

5.3 Experiment Results

Figure 4 shows several examples generated by the trained model. In each subfigure, the top piano roll shows the polyphonic music generation (introduced in Section 5.1) result and the bottom piano roll shows the piano arrangement generation (introduced in Section 5.2) result conditioned on the main melody (the blue track). In both cases, the first 500 MIDI-event tokens are given as the context; the red line separates the given context and the generated outputs. We see that the generated pieces capture basic harmonic relationships between the melody and accompaniment and contain consistent rhythmic patterns. Although the quality is still far from the music generated by state-of-the-art

(a) Generation results of example a.

(b) Generation results of example b.

Figure 4: Generation examples with POP909 dataset. Unconditioned polyphonic music generation and piano arrangement generation (blue for the melody, orange for the accompaniment) of the two selected examples are displayed.

algorithms [19, 40], they serve as a baseline to illustrate our dataset usage. We believe that the model can produce better and more structured results with the development of deep generative models.

6. CONCLUSION

In conclusion, we contributed POP909, a tailored dataset for music arrangement. It contains multiple versions of professional piano arrangements in MIDI format of 909 popular songs, together with precise tempo curve aligned to the original audio recordings. We also provide annotations of tempo, beat, downbeat, key, and chord labels. To guarantee a high data quality, the dataset was collected via the collaboration of two groups of professional musicians, arrangers and reviewers, in an interactive process. Apart from the arrangement problem, the POP909 dataset serves as a high-quality resource for structural music generation and cross-modal music generation.

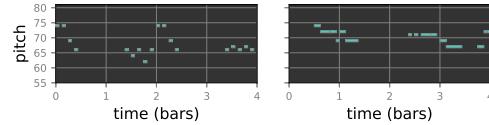
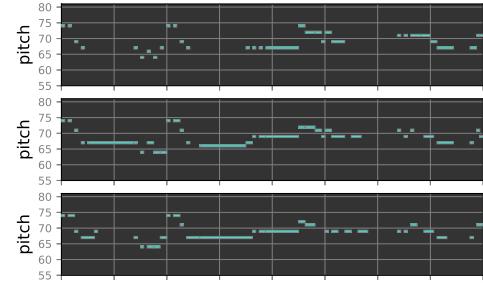
CONNECTIVE FUSION:
LEARNING TRANSFORMATIONAL JOINING OF SEQUENCES
WITH APPLICATION TO MELODY CREATION

Taketo Akama

Sony Computer Science Laboratories, Tokyo, Japan

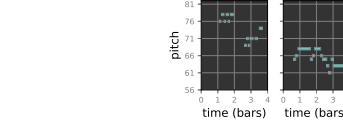
`taketo.akama@sony.com`


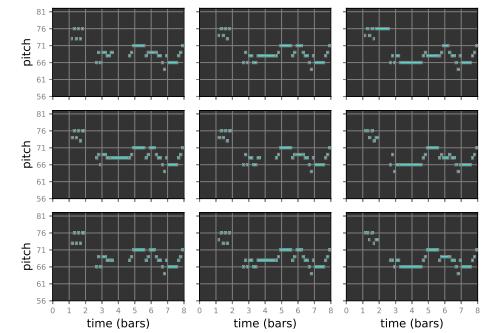
ABSTRACT

We present *Connective Fusion*, a music generation scheme by transformational joining of two musical sequences for creative purposes. Given two shorter sequences as inputs, our model transforms each of them such that their concatenation is more coherent to form a longer sequence, while each of the transformed shorter sequences retains meaningful similarity with the corresponding input sequence. In short, our model connects and fuses two contextually unrelated sequences in a coherent way. This transformation can be applied iteratively to gradually fuse the input sequences. The *style latent space* is simultaneously learned, allowing users to control how the two sequences are merged. Our approach comprises two steps of unsupervised learning: a deep generative model with a latent space is learned, followed by adversarial learning of the transformation function in the latent space. We demonstrate the usefulness of our method through the task of melody creation using a symbolic music dataset.


1. INTRODUCTION

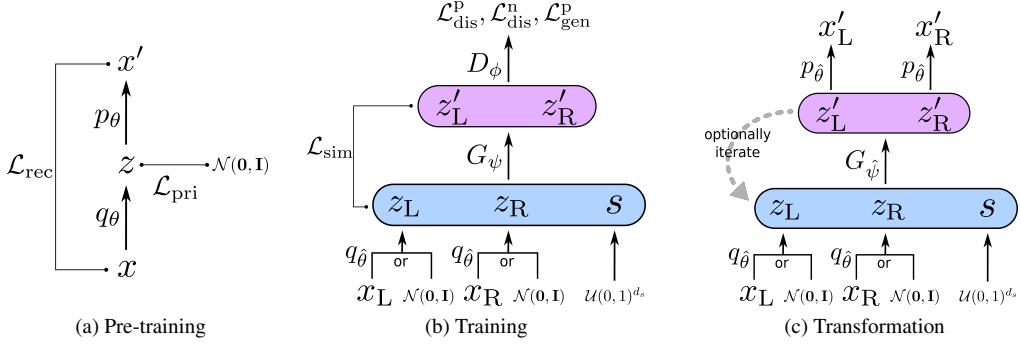
Spurred by the progress of deep neural networks, symbolic music generation systems, especially the ones with user controllability have gathered renewed interests these days. Most of the systems with controllability can be categorized into generating continuation [1], regenerating arbitrary positions [2, 3], unsupervised conditional generation [4, 7], or transforming musical sequences such that musical attributes, concepts, or styles are altered [4–8].

In this paper, we seek another category, generation by fusing input musical sequences as ideas. Specifically, we propose *Connective Fusion*, a generative transformation scheme which allows two input musical sequences to be transformed such that the concatenated musical sequence is musically plausible (See Fig.1 for the illustration). After the transformation, each of the two sequences has meaningful similarity with the one before the transformation. Two input musical sequences can also be transformed it-


(a) Given inputs: random combination of two sequences


(b) Transformed outputs of iteration 1, 2, and 3

Figure 1: Iterated application of transformation.

(a) Given inputs: random combination of two sequences


(b) Transformed outputs

eratively to gradually increase the coherency of joining (Fig.1). Our generative transformation differs from pure transformation in that it permits users to explore or sample from the *style space* of how the two sequences are combined (Fig.2). The application of Connective Fusion includes i) providing users with musical ideas based on not

Figure 3: Connective Fusion schematic diagrams.

necessarily polished ideas on hand, and ii) creating novel musical flows by combining and fusing musical fragments of different characteristics in a coherent way.

Technically, our approach is training a transformation function in an unsupervised learning manner, consisting of two steps: the pre-training step and the training step. In the pre-training step, a Variational Auto-Encoder (VAE) [9] is trained to obtain mappings between the *data space* and the *latent space*. A given pair of musical sequences are fed into the encoder of the VAE to be mapped to the corresponding latent vectors in the latent space. In the following training step, models are trained upon the representation of the VAE latent space. The transformation function, the *generator* is trained adversarially [10] such that transformed results are indistinguishable from the human-made musical sequences. Together with the adversarial loss, the similarity loss, consisting of the latent space distance before and after the transformation, is simultaneously taken into account in order to train models with desired amount of transformation.

In experiments, we empirically demonstrate that our method outperforms a baseline method with various parameter settings in terms of reality and five musical statistics at each transformation amount. We also quantitatively show that iterated application of our transformation allows gradual transformation while having comparable to or better performance than single (non-iterative) transformation.

Our contributions of this paper are: i) proposing a new problem setting/task and its solution, ii) presenting a model and procedure for learning style space, iii) introducing iterated application of transformation for gradual transformation, and iv) demonstrating the performance and the application for melody creation.

2. METHODOLOGY

2.1 Problem Scenario

Suppose we have a dataset of sequences $\mathcal{D}_y = \{y^{(i)} = x_{\mathrm{L}}^{(i)} \oplus x_{\mathrm{R}}^{(i)}\}_{i=1}^{N}$, where $y^{(i)} \in \mathcal{Y}$ is the concatenation of two subsequences $x_{\mathrm{L}}^{(i)} \in \mathcal{X}$ and $x_{\mathrm{R}}^{(i)} \in \mathcal{X}$. We can consider $\mathcal{D}_y$ as a sequence pair dataset $\mathcal{D} = \{(x_{\mathrm{L}}^{(i)}, x_{\mathrm{R}}^{(i)})\}_{i=1}^{N}$. For instance, $y^{(i)}$ is a musical sequence of 8 bars, whereas $x_{\mathrm{L}}^{(i)}$

and $x_{\mathrm{R}}^{(i)}$ are musical sequences of 4 bars.

Using the dataset $\mathcal{D}$, the scheme of Connective Fusion basically solves the following task: given two sequences $x_{\mathrm{L}}, x_{\mathrm{R}} \in \mathcal{X}$, transforming x_{L} to x_{L}' and x_{R} to x_{R}' such that the concatenated sequence $x_{\mathrm{L}}' \oplus x_{\mathrm{R}}'$ becomes more probable to be a sample in $\mathcal{Y}$ than $x_{\mathrm{L}} \oplus x_{\mathrm{R}}$, while the transformed sequences $x_{\mathrm{L}}', x_{\mathrm{R}}'$ retain meaningful similarity to the given sequences $x_{\mathrm{L}}, x_{\mathrm{R}}$, respectively. For example, this serves as a solution for generating longer musical sequences given shorter musical sequence pairs of any combinations as inspiration, which is useful for composing new music based on unpolished musical ideas on hand.

2.2 Approach

Schematic diagrams of pre-training, training, and transformation of Connective Fusion are depicted in Fig.3.

2.2.1 Pre-training

Our approach is first training a Variational Auto-Encoder (VAE) model for obtaining bidirectional mappings between each sequence $x \in \mathcal{X}$ and its latent vector $z \in \mathcal{Z} \subset \mathbb{R}^{d_z}$, which has the compressed information of x.

2.2.2 Training

Then we train a generator G that transforms any pair $(z_{\mathrm{L}}, z_{\mathrm{R}}) \in \mathcal{Z} \times \mathcal{Z}$ to $(z_{\mathrm{L}}', z_{\mathrm{R}}') \in \mathcal{Z} \times \mathcal{Z}$ that are indistinguishable from the pairs in the dataset. The generator also takes a style vector $s \in \mathcal{S}$ from the style space $\mathcal{S} = [0, 1]^{d_s}$ as an additional input. Formally, the generator can be written as $(z_{\mathrm{L}}', z_{\mathrm{R}}') = G(z_{\mathrm{L}}, z_{\mathrm{R}}, s)$ and $G \colon \mathcal{Z} \times \mathcal{Z} \times \mathcal{S} \to \mathcal{Z} \times \mathcal{Z}$. The generator G is trained together with the discriminator $D \colon \mathcal{Z} \times \mathcal{Z} \to [0, 1]$ with the adversarial learning framework [10]. In addition to the adversarial loss, we add the similarity loss in order to adjust the degree of similarity before and after the transformation.

2.2.3 Transformation

Given two sequences x_{L} and x_{R}, these sequences are first fed to the encoder of the VAE to obtain z_{L} and z_{R}, respectively. The latent vectors z_{L} and z_{R} together with a style vector $s \in \mathcal{S}$ sampled from $\mathcal{S} = [0, 1]^{d_s}$ are then fed to the

generator G to transform z_L, z_R to z'_L, z'_R, respectively. Finally, the transformed latent vectors z'_L, z'_R are fed to the decoder to generate x'_L, x'_R, respectively. The concatenation $x'_L \oplus x'_R$ is the generated sequence. Instead, z_L and z_R can also be sampled from the prior distribution $p(z)$, providing users with scratch generation functionality followed by the transformation functionality.

The style space $\mathcal{S}$ allows us to control *how the two sequences are connectively fused*. For example, as illustrated in Fig.2 and explained in the experiments Sec.3.3, users can choose preferred styles of fusion among interpolated styles on a 2D plane.

We also propose iterated transformation with G, which consists in applying G repeatedly, drawing two interrelated trajectories in the latent space. The higher the number of iterations becomes, the farther the latent vectors tend to move from the original position. This is useful for users to control the degree of similarity in transformation.

2.3 Advantage of Approach Using Latent Space

Using the representation in $\mathcal{Z}$ but not the one in $\mathcal{X}$ i) is useful for defining similarity before and after the transformation, ii) is computationally inexpensive, and iii) bypasses the difficult problem of back-propagating through discrete sampling of sequences.

2.4 Pre-training Detail: Encoder and Decoder Training with Auto-Encoding VB algorithm

To train the VAE, another dataset $\mathcal{D}' = \{x^{(j)}\}_{j=1}^{2N}$ is derived from the dataset $\mathcal{D} = \{(x_L^{(i)}, x_R^{(i)})\}_{i=1}^{N}$, where $x^{(2i-1)} = x_L^{(i)}$ and $x^{(2i)} = x_R^{(i)}$. The encoder model $q_\theta(x|z)$ and the decoder model $p_\theta(z|x)$ in the VAE are trained with the following optimization problem:

$$\max_\theta \mathbb{E}_{x \sim \mathcal{D}'} \left[\mathbb{E}_{z \sim q_\theta(z|x)} \left[\log p_\theta(x|z) \right] - KL\left(q_\theta(z|x) || p(z) \right) \right],$$
(1)

which is the maximization of the variational lower bound [9], the lower bound of the marginal log likelihood. Here, KL denotes the Kullback-Leibler (KL) divergence. Note that the sampling operation $z \sim q_\theta(z|x)$ is differentiable using the reparametrization trick. For the purpose of visualization in Fig.3, we name the two terms in the optimization problem $\mathcal{L}_{rec} = -\mathbb{E}_{x \sim \mathcal{D}'} \left[\mathbb{E}_{z \sim q_\theta(z|x)} \left[\log p_\theta(x|z) \right] \right]$ and $\mathcal{L}_{pri} = \mathbb{E}_{x \sim \mathcal{D}'} \left[KL\left(q_\theta(z|x) || p(z) \right) \right]$. For the rest of this paper, $\hat{\theta}$ denotes the estimated model parameter after the optimization of Eq.1. We use normal distribution for the encoder model $q_\theta(z|x)$.

2.5 Training Detail: Generator and Discriminator Training with Adversarial Learning

For notational simplicity, we introduce datasets of latent vectors $\mathcal{D}_z = \{(z_L^{(i)}, z_R^{(i)})\}_{i=1}^{N}$ and $\mathcal{D}'_z = \{z^{(j)}\}_{j=1}^{2N}$ corresponding to $\mathcal{D} = \{(x_L^{(i)}, x_R^{(i)})\}_{i=1}^{N}$ and $\mathcal{D}' = \{x^{(j)}\}_{j=1}^{2N}$ respectively, where $z_L^{(i)} = \text{argmax}_z q_{\hat\theta}(z|x_L^{(i)})$, $z_R^{(i)} =$

$\text{argmax}_z q_{\hat\theta}(z|x_R^{(i)})$, and $z^{(j)} = \text{argmax}_z q_{\hat\theta}(z|x^{(j)})$. The generator G and the discriminator D are parametrized by ψ and ϕ, respectively. In the following, we use short hand $\mathcal{L}_{D_\phi}^p(z_L, z_R) = -\log D_\phi(z_L, z_R)$, $\mathcal{L}_{D_\phi}^n(z_L, z_R) = -(1 - \log D_\phi(z_L, z_R))$, and $\mathcal{U} = \mathcal{U}(0,1)^{d_s}$.

2.5.1 Discriminator Loss

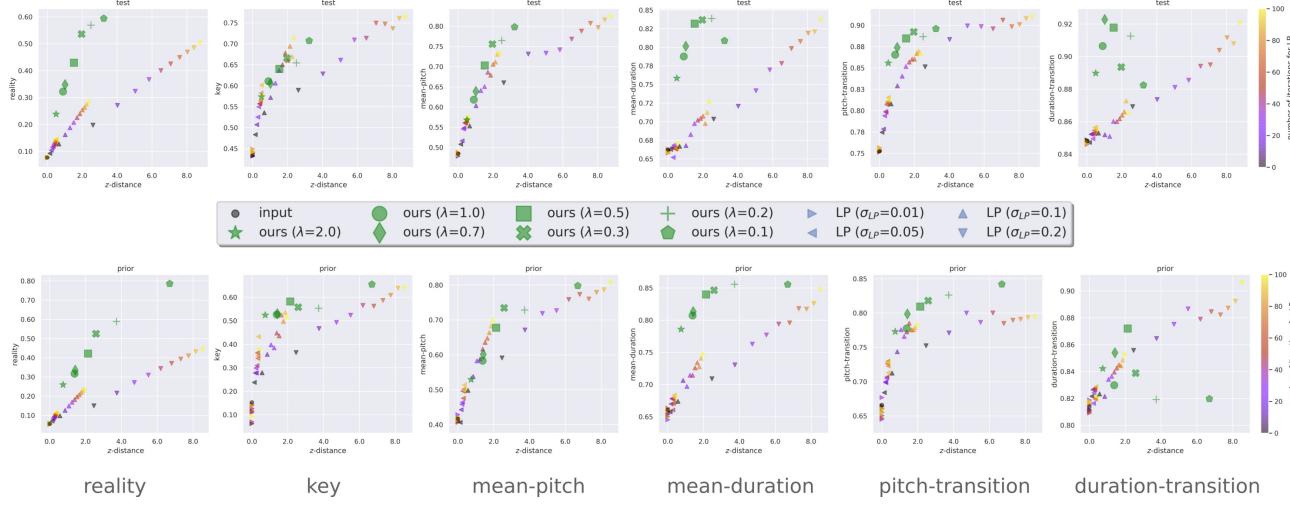
In the adversarial learning framework, the discriminator classifies two sets of samples: the *real class* and the *fake class*. In Connective Fusion, samples in the real class are latent vector pairs (z_L, z_R) sampled from the dataset $\mathcal{D}_z$. Formally, the loss function for the real class of the discriminator is

$$\mathcal{L}_{dis}^p = \mathbb{E}_{(z_L, z_R) \sim \mathcal{D}_z} \left[\mathcal{L}_{D_\phi}^p(z_L, z_R) \right].$$
(2)

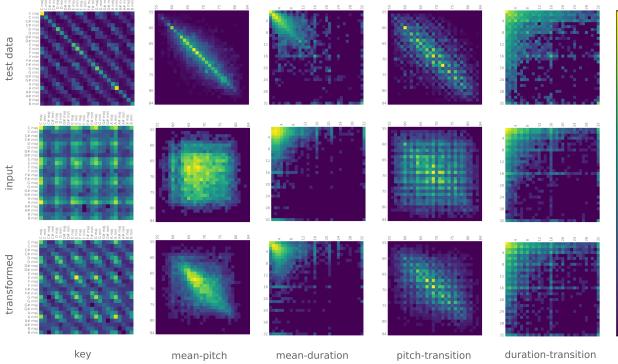
The fake class for the discriminator are latent vector pairs (z_L, z_R) which are obtained by i) sampling independently with the uniform distribution over the dataset $\mathcal{D}'_z$ (1st term of Eq.3), ii) sampling independently from the prior $p(z)$ (2nd term of Eq.3), iii) the generator G transforming samples (z_L, z_R, s), where z_L, z_R are sampled in the same way as i, while s are sampled from $\mathcal{U}$, the uniform distribution over $\mathcal{S} = [0,1]^{d_s}$ (3rd term of Eq.3), and iv) the generator G transforming samples (z_L, z_R, s), where z_L, z_R are sampled in the same way as ii, while s are sampled from $\mathcal{U}$ (4th term of Eq.3). Formally, the loss function is

$$\begin{aligned}
\mathcal{L}_{dis}^n = {} & \mathbb{E}_{z_L \sim \mathcal{D}'_z} \mathbb{E}_{z_R \sim \mathcal{D}'_z} \left[\mathcal{L}_{D_\phi}^n(z_L, z_R) \right] \\
& + \mathbb{E}_{z_L \sim p(z)} \mathbb{E}_{z_R \sim p(z)} \left[\mathcal{L}_{D_\phi}^n(z_L, z_R) \right] \\
& + \mathbb{E}_{z_L \sim \mathcal{D}'_z} \mathbb{E}_{z_R \sim \mathcal{D}'_z} \mathbb{E}_{s \sim \mathcal{U}} \left[\mathcal{L}_{D_\phi}^n(G_\psi(z_L, z_R, s)) \right] \\
& + \mathbb{E}_{z_L \sim p(z)} \mathbb{E}_{z_R \sim p(z)} \mathbb{E}_{s \sim \mathcal{U}} \left[\mathcal{L}_{D_\phi}^n(G_\psi(z_L, z_R, s)) \right].
\end{aligned}$$
(3)

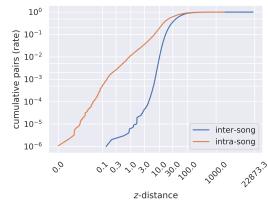
Finally, the overall loss function for the discriminator becomes

$$\mathcal{L}_{dis} = \mathcal{L}_{dis}^p + \mathcal{L}_{dis}^n.$$
(4)


2.5.2 Generator Loss

Based on the discriminator, a generator is trained such that the generated samples become more like the real samples rather than the fake samples. We consider two kinds of generated samples which are sampled in the same way as iii and iv in the previous section 2.5.1. Formally, the loss function is


$$\begin{aligned}
\mathcal{L}_{gen}^p = {} & \mathbb{E}_{z_L \sim \mathcal{D}'_z} \mathbb{E}_{z_R \sim \mathcal{D}'_z} \mathbb{E}_{s \sim \mathcal{U}} \left[\mathcal{L}_{D_\phi}^p(G_\psi(z_L, z_R, s)) \right] \\
& + \mathbb{E}_{z_L \sim p(z)} \mathbb{E}_{z_R \sim p(z)} \mathbb{E}_{s \sim \mathcal{U}} \left[\mathcal{L}_{D_\phi}^p(G_\psi(z_L, z_R, s)) \right].
\end{aligned}$$
(5)

Additionally, we introduce the similarity loss which is the latent space distance between samples before and after the transformation:


$$\begin{aligned}
\mathcal{L}_{sim} = {} & \mathbb{E}_{z_L \sim \mathcal{D}'_z} \mathbb{E}_{z_R \sim \mathcal{D}'_z} \mathbb{E}_{s \sim \mathcal{U}} \left[\mathcal{L}_{dist}(z_L, z_R, s) \right] \\
& + \mathbb{E}_{z_L \sim p(z)} \mathbb{E}_{z_R \sim p(z)} \mathbb{E}_{s \sim \mathcal{U}} \left[\mathcal{L}_{dist}(z_L, z_R, s) \right],
\end{aligned}$$
(6)

Figure 4: Evaluation of our model on six metrics vs z-distance. The upper/lower rows are transformation results where inputs are randomly created pairs of test/generated (sampled from prior) data. The color gradient corresponds to the number of iterations for LP. For all metrics, higher values are better. See Sec.3.5.

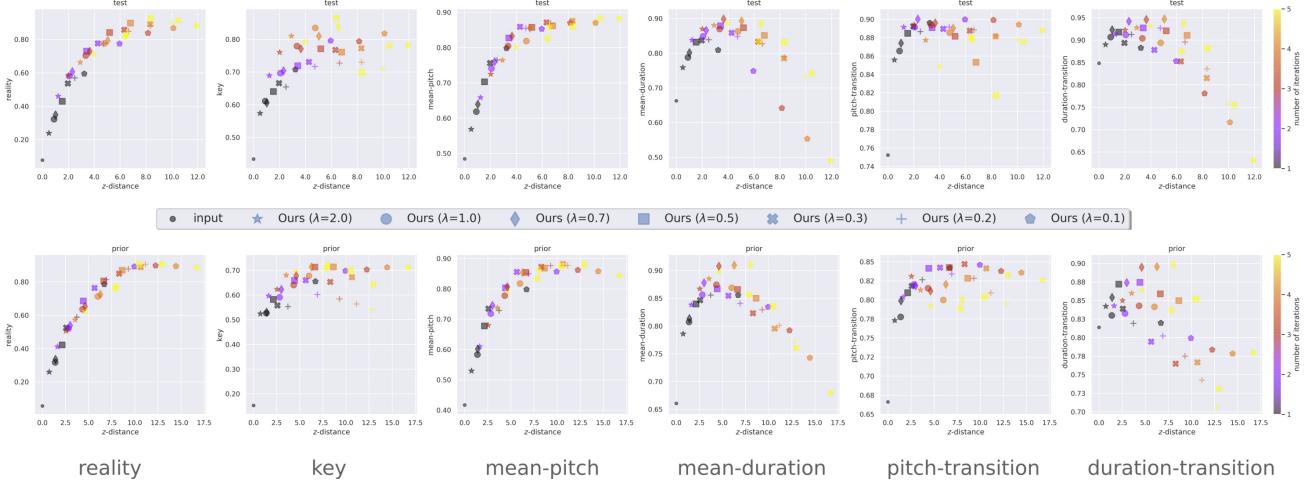
Figure 5: Musical statistics are corrected after our transformation. Brighter color indicates higher probability. See the second paragraph of 3.4.

Figure 6: Analysis of z-distance in the latent space $\mathcal{Z}$. See the last paragraph of 3.4.

where

$$\mathcal{L}_{\text{dist}}(z_{\text{L}}, z_{\text{R}}, s) = \frac{1}{d_z} \left\| \frac{1}{\bar{\sigma}_z^2} \log\left(1 + (z'_{\text{L}} - z_{\text{L}})^2\right) \right\|_1$$
$$+ \frac{1}{d_z} \left\| \frac{1}{\bar{\sigma}_z^2} \log\left(1 + (z'_{\text{R}} - z_{\text{R}})^2\right) \right\|_1$$
$$\text{with } (z'_{\text{L}}, z'_{\text{R}}) = G_\psi(z_{\text{L}}, z_{\text{R}}, s). \tag{7}$$

Following the latent constraint paper [6], $\bar{\sigma}_z \in \mathbb{R}^{d_z}$ is chosen to be the standard deviation $\sigma(x) \in \mathbb{R}^{d_z}$ of the encoder model $q_{\hat{\theta}}(z|x) = \mathcal{N}\left(\mu(x), \text{diag}\left(\sigma^2(x)\right)\right)$ av-

eraged over all the training dataset. Precisely, $\bar{\sigma}_z = 1/|\mathcal{D}'| \sum_{x \in \mathcal{D}'} \sigma(x)$. Finally, the overall loss function for the generator becomes


$$\mathcal{L}_{\text{gen}} = \mathcal{L}_{\text{gen}}^{\text{p}} + \lambda \mathcal{L}_{\text{sim}}. \tag{8}$$

3. EXPERIMENTS

3.1 Dataset

We create datasets from LMD-matched of Lakh MIDI dataset [11], comprising 45,129 files matched to the song identity entries in the Million Song Dataset [12]. Each song has one or several different versions of MIDI files. We first extract files with 4/4 time signature, use accompanying tempo information to determine beat locations, and quantize each beat into 4. We then split the song identities into the proportion of 11:1:6:1:1 to create train-1, validation-1, train-2, validation-2, and test dataset, respectively. Train-1 and validation-1 datasets are for training proposed and baseline models, whereas train-2 and validation-2 datasets are for training evaluation models. We filter out non-monophonic tracks, bass or drum tracks, and the tracks outside the pitch range of [55, 84]. We conduct data augmentation by transposing tracks to all possible keys if the transposed tracks stay within the pitch range of [55, 84]. We retrieve 8-bar sliding windows (with a stride of 1 bar) from each track followed by filtering out windows that have more than one bar consecutive rests. Finally, for each split of train-1, validation-1, train-2, validation-2, and test dataset, we create a dataset $\mathcal{D} = \{(x_{\text{L}}^{(i)}, x_{\text{R}}^{(i)})\}_{i=1}^N$ by assigning the first 4-bars and the last 4-bars of each 8-bar window to $x_{\text{L}}^{(i)}$ and $x_{\text{R}}^{(i)}$, respectively. For encoding musical sequences, we use Melodico-rhythmic encoding proposed in [3].

Figure 7: Evaluation of iterated application of our model. Iterated application of models with larger λ tends to compare favorably with others. The upper/lower rows are transformation results where inputs are randomly created pairs of test/generated (sampled from prior) data. The color gradient corresponds to the number of iterations for our method. For all metrics, higher values are better. See Sec.3.6.

3.2 Implementation Details

2-layered long short term memory (LSTM) [13] is used for the encoder and the decoder of the VAE, with the number of latent dimensionality $d_z = 64$. 5-layered multilayer perceptron (MLP) is used for the generator and the discriminator, where input vectors are simply concatenated and ReLU activation is employed. Following the latent constraint paper [6], we use the gating mechanism for each of the outputs z'_L and z'_R. For the decoder to generate sequences, argmax operation is utilized at each time step greedily for sampling each token. In the adversarial learning, the parameter updates of the model are alternating between updating the discriminator 10 times and updating the generator once. Adam optimizer [14] is used for training with the parameters $(\alpha, \beta_1, \beta_2) = (0.000005, 0, 0.9)$.

3.3 Transformation Examples

Fig.1 and Fig.2 are the transformation examples for $\lambda = 2.0$ and $\lambda = 0.3$, respectively. In Fig.1b at iteration 1, the used pitch set of x_L becomes aligned to that of x_R, and the note at time around 4 transforms to the one with longer duration to join two input sequences. As the number of iterations increases, the note durations become more uniform, while retaining similarity to the input sequences in terms of pitch contours or rhythmic properties. In Fig.2b, four corners are generated by feeding s randomly sampled from $\{0, 1\}$ for each dimension and the others are interpolations. Interestingly, the time 4 to 8 of the bottom left sequence is the exact transposition of the right input of Fig.2a, whereas other sequences has variations and transpositions.

3.4 Evaluation Metrics

We use *reality*, correlations of five musical statistics evaluated against the test data, and *z-distance* as evaluation metrics. Reality is defined as the probability that a generated sequence is classified as human-made. Two-layered transformer binary classification model is trained on train-2 and validation-2 datasets, where the pair sequences from the dataset $\mathcal{D}$ are labeled as positive, while the randomly shuffled pair sequences from the same dataset are labeled as negative. The mean of output values of this classification model and its accuracy are 0.959 and 0.953 on the test dataset. Reality is a holistic metric of quality which quantifies how likely a sequence is human-made.

As musical statistics, we choose to use key, mean-pitch (MP), mean-duration (MD) for evaluating whether the first and the last 4-bars are more musically consistent after transformation. We also employ pitch-transition (PT) and duration-transition (DT) for evaluating if transitions between the first and the last 4-bars are smooth and natural. Fig.5 illustrates these five musical statistics. For key, MP, and MD, these values are estimated for the first and the last 4-bars, which are interpreted as Markov transitions of musical states, creating matrices as in Fig.5. For PT and DT, we extract two or three consecutive notes around the boundary of the first and the last 4-bars, and again compute Markov transition matrices of each statistics as states. Finally, as a quantitative metric, we compute Pearson correlation coefficient between the matrix made from the test dataset and the one from the samples outputted by models.

z-distance is a scaled squared Mahalanobis distance $dist(z', z) = 1/d_z(z' - z)\Sigma^{-1}(z' - z)^\intercal$, where $\Sigma = \mathrm{diag}(\bar{\sigma}_z^2)$. We analyze z-distance in the latent space $\mathcal{Z}$ using song id annotations of the dataset. We randomly sampled 1,000,000 pairs of 4-bar sequences from the entire dataset, where pairs are sampled either from the same or different song id, corresponding to intra- and inter-song in Fig.6. Pairs with identical sequences are filtered out to analyze the similarity rather than the identicality. Fig.6 shows

that sequences from different song ids are several orders of magnitude less likely to have smaller (say, less than 1.0 or 3.0) z-distances, compared with those from the same ids. The difference of z-distances probably comes from the fact that a lot of variations can be seen within each song id and similar themes are rarely seen among different song ids especially for melody, suggesting that smaller z-distances includes variations and that z-distance encodes musically meaningful similarity.

Algorithm 1 Latent Perturb (baseline method).

Input: z_L, z_R, and σ_LP

1: $S_\text{max} \leftarrow \text{argmax}_x\, p_{\hat{\theta}}(x|z_\text{L}) \oplus \text{argmax}_x\, p_{\hat{\theta}}(x|z_\text{R})$
2: $R_\text{max} \leftarrow$ estimate reality of S_max
3: **for** $i = 1$ to $NumIter$ **do**
4: $\quad \epsilon_\text{L}, \epsilon_\text{R} \sim \mathcal{N}(\mathbf{0}, \text{diag}(\sigma_\text{LP}^2))$
5: $\quad S_\text{L} \leftarrow \text{argmax}_x\, p_{\hat{\theta}}(x|z_\text{L} + \epsilon_\text{L})$
6: $\quad S_\text{R} \leftarrow \text{argmax}_x\, p_{\hat{\theta}}(x|z_\text{R} + \epsilon_\text{R})$
7: $\quad R_\text{tmp} \leftarrow$ estimate reality of $S_\text{tmp} = S_\text{L} \oplus S_\text{R}$
8: $\quad$ **if** $R_\text{tmp} > R_\text{max}$ **then**
9: $\quad\quad S_\text{max} \leftarrow S_\text{tmp}$; $R_\text{max} \leftarrow R_\text{tmp}$
10: $\quad\quad z_\text{L} \leftarrow z_\text{L} + \epsilon_\text{L}$; $z_\text{R} \leftarrow z_\text{R} + \epsilon_\text{R}$
11: $\quad$ **end if**
12: **end for**
13: **return** S_max

3.5 Comparisons of Methods

We introduce a naive but strong baseline method called *Latent Perturb (LP)*, which is summarized in Algorithm 1. Note that the reality estimation model is trained with the train-1 dataset, and the argmax operation is approximated with the greedy sampling scheme. Compared to data space, perturbation in the latent space can efficiently search similar samples with high reality.

Fig.4 shows the comparisons of baseline methods and ours evaluated on z-distance vs the other evaluation metrics, where z-distance is the average of the mean of z-distances for z_L and z_R. The reason for choosing LP with σ_LP in $[0.01, 0.2]$ is to make sure their resulting evaluation metrics span the range that the proposed technique "ours" spans. For samples from the prior as well as from the test dataset, our methods, especially with larger λ tend to outperform in all the metrics, even though LP methods use abundant computational budgets—100 forward computations of the decoder model and the classification model.

3.6 Evaluation of Iterated Transformation

Fig.7 illustrates the performance of iterated application of our transformation. Interestingly, performance of models with larger λ after several iterations are often comparable to or better than that of models with smaller λ. This means that a model with larger λ can be used for transformation with different distances, without sacrificing the performance. For example, as illustrated in Fig.1, the model with $\lambda = 2.0$, if iteratively applied, can be used for gradual transformations with several different distances. Their

quality is as satisfactory as single (non-iterative) transformation with models of smaller λ.

4. RELATED WORK

Concatenative Synthesis (CS) methods [15, 16] typically use a large database of source audio segmented into units, and search units that match each segment of the target audio by unit selection algorithms. Mashup methods [17, 18] combine two or more songs to create entertaining musical results. Typically tracks from different songs are superimposed and combined. Our Connective Fusion differs from CS and Mashup in that i) ours is generative rather than searching and using existing segments of music, ii) ours tries to combine any segments, whereas CS/Mashup typically combine some searched segments, iii) ours is unsupervised learning which does not need any human annotation in the dataset or musical expertise for training models, and iv) ours is symbolic which is often not the case in CS/Mashup.

Learning transformation in the latent space has been studied for image, texts, and music [6, 19–23]. Notably, Mueller et al. proposed to transform texts to have specified attributes based on optimization in the latent space [21]. Engel et al. proposed to transform image or music to become more realistic or to have specified attributes in the latent space by using adversarial learning [6]. Lore et al. and more recently Jahanian et al. instead proposed to transform image by learning latent space directions [22, 23].

Learning transformation with adversarial learning without paired data has been extensively studied. The input and output domain of transformation in these studies can be categorized into the same data domain with different classes [24] or attributes [6, 25], the semantic domain to the data domain [24], and semantically similar domain such as simulation to real [26, 27] and unsupervised language translation [28, 29]. On the other hand, the input and output domains of transformation in this paper are essentially the same except that they have different lengths/counts.

5. CONCLUSION

We introduced Connective Fusion, a new scheme of interactively generating sequences for creative purposes. Given two sequences of random combination, our model transforms each of them to similar one such that their concatenation is more indistinguishable from human-made sequences. The transformation model is adversarially learned in the latent space. Our model equips with user control—choosing the amount of transformation as well as exploring in the style space. In experiments of melody creation on a symbolic music dataset, we empirically demonstrated that our method outperforms a baseline method of various parameter settings, and that iterative gradual transformation not just introduced new functionality but also works as satisfactory as or sometimes better than non-iterative transformation.

ABSTRACT

As the field of Music Information Retrieval grows, it is important to take into consideration the multi-modality of music and how aspects of musical engagement such as movement and gesture might be taken into account. Bodily movement is universally associated with music and reflective of important individual features related to music preference such as personality, mood, and empathy. Future multimodal MIR systems may benefit from taking these aspects into account. The current study addresses this by identifying individual differences, specifically Big Five personality traits, and scores on the Empathy and Systemizing Quotients (EQ/SQ) from participants' free dance movements. Our model successfully explored the unseen space for personality as well as EQ, SQ, which has not previously been accomplished for the latter. R^2 scores for personality, EQ, and SQ were 76.3%, 77.1%, and 86.7% respectively. As a follow-up, we investigated which bodily joints were most important in defining these traits. We discuss how further research may explore how the mapping of these traits to movement patterns can be used to build a more personalized, multi-modal recommendation system, as well as potential therapeutic applications.

1. INTRODUCTION

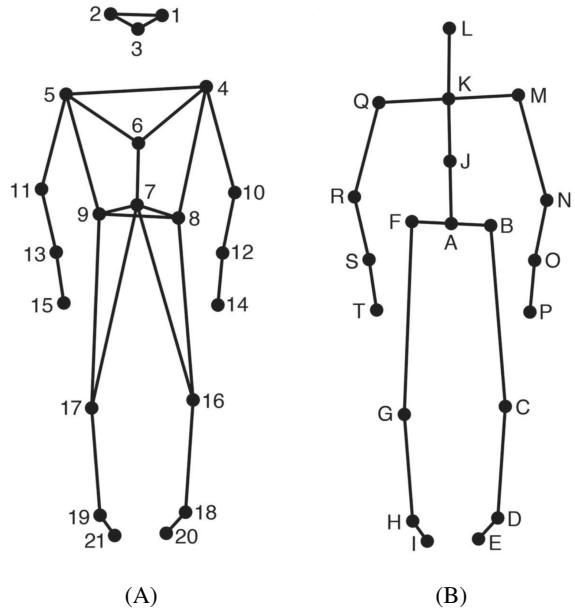
From the perspective of most computational analysis, music can be defined as sound, its important features yielding to the decomposition of waveforms. However, for the vast majority of history, musical sound could not be separated from its source; to whatever degree it may have evolved biologically to serve various human functions, music must be regarded as an embodied and socially embedded phenomenon [1–3]. Research has shown intimate links between musical features and human movement, including the reflection of hierarchical rhythmic structures in embodied eigen movements [4], the reflection of higher-level musical structures in group movement to Electronic Dance Movement [5], and reflection of spectral and timbral features of music in dance [6]. Bodily movement is one of the most commonly reported responses to music [7], and movement to music is one of very few universal features of music across cultures [8].

This paper towards Multimodal MIR takes into consideration the multi-modality of music, and takes into account one of the primary aspect of musical engagement, i.e, movement. It is therefore insufficient to consider music only in terms of sound when trying to understand human digital use and interaction with music. This may be especially true in terms of user experience and personalization; human movement in response to music reflects not only the music itself but characteristics of the individual, such as personality [9] and emotion [10]. Indeed, research has shown that music-induced movement is so individual that its features can be used in person-identification with a high degree of accuracy [11]. This is in line with previous research, such as that of Cutting et al. [12] demonstrating that friends can recognise each other from their walk with only point-light (stick figure) displays of movement, without the need for other distinguishing features. This paradoxical balance between universality and individuality in human motoric responsiveness to music poses a challenge for the creation of digital music interfaces which take music-induced movement into account in providing personalized music experiences. Although the concept of an interactive music system has long been proposed that allow music playback to be controlled and altered via human gestures [13], human-movement based interaction techniques and devices are fast gaining importance in the field of HCI [14]. In this context, it makes decoding aspects of a user/individual via human movements a key and useful endeavor, which would then aid in the design of more personalized experiences.

2. RELATED WORK

The specific features used in previous work associated movement with individual differences are quite varied. Satchell et al. [15] examined speed, relative and absolute rotation of the body and found relationships between relative movement of the upper and lower body during walk-

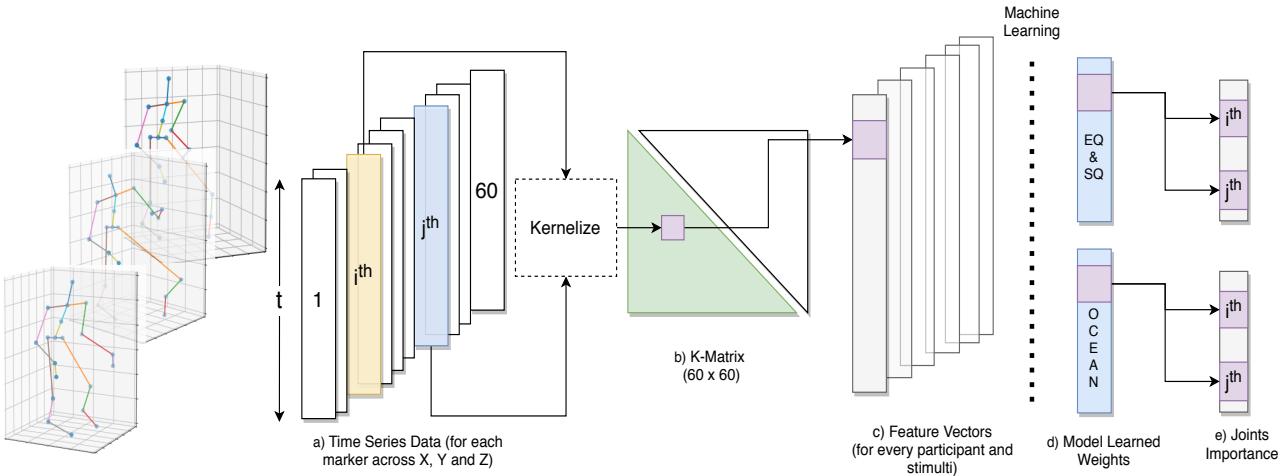
ing in both FFM personality traits and gait, while Micha-lak et al. [16] were able to associate low mood with lateral body sway and posture. In dance, relevant features have in-cluded amount of movement of the whole body relative to itself and to the environment, responsiveness to music fea-tures such as tempo [4, 17]. Another area for exploration of individual differences in movement patterns has been in the context of disorders that have altered or impaired movement [18–20]. These links allow us to postulate that movement patterns should give us information related to individual traits and tendencies which can be then linked to music preferences, mood or emotion in relation to mu-sic experiences and could have implications for music ther-apy as well as for music information retrieval. However, as an initial step, there exist no studies that predict per-sonality and empathy as a function of movement patterns. The current study focuses on identifying FFM personality traits, as well as scores on the Empathy Quotient (EQ) and Systemizing Quotient (SQ), from participants' free dance movements to various genres of music. The EQ measures participants' tendency to empathize with others [21], while the SQ measures the tendency to think in terms of sys-tems [22]. These two measures were originally developed to increase understanding of people with ASD, as in this population trait systemizing tends to be very high while empathy tends to be low. However previous work has also used the EQ/SQ to determine how these traits are dis-tributed in the general population. Although previous work has found relationships between empathy and responsive-ness to changes in heard music or in dance partner [23, 24], and between EQ/SQ scores and music preferences [25, 26], general movement patterns associated with empathy have not, to the knowledge of the authors, been explored using dance movement, nor have patterns related to systemizing tendencies.

3. METHOD


3.1 Participants

Data acquired was from a previous study [27] comprising data from 73 university students (54 females, mean age = 25.74 years, std = 4.72 years). Thirty-three reported hav-ing received formal musical training; five reported one to three years, ten reported seven to ten years, while sixteen reported ten or more years of training. Seventeen partici-pants reported having received formal dance training; ten reported one to three years, five reported four to six years, while two reported seven to ten years. Participants were of 24 different nationalities, with Finland, the United States, and Vietnam being the most frequently represented. For attending the experiment, participants received two movie ticket vouchers each. All participants spoke and received instructions in English. Fifteen participants were excluded from further analysis due to incomplete data. They were asked to listen to the music and move as freely as they de-sired, but staying within the marked capture space. The aim of these instructions was to create a naturalistic set-ting, such that participants would feel free to behave as

they might in a real-world situation.

3.2 Apparatus, Stimuli, and Procedure


Participants' movements were recorded using a twelve-camera optical motion-capture system (Qualisys Oqus 5+), tracking at a frame rate of 120 Hz, the three-dimensional position of 21 reflective markers attached to each partic-ipant. Markers were located as follows (L=left, R=right, F=front, B=back) 1: LF head; 2: RF head; 3: B head; 4: L shoulder; 5: R shoulder; 6: sternum; 7: stomach; 8: LB hip; 9: RB hip; 10: L elbow; 11: R elbow; 12: L wrist; 13: R wrist; 14: L middle finger; 15: R middle finger; 16: L knee; 17: R knee; 18: L ankle; 19: R ankle; 20: L toe; 21: R toe. The stimuli comprised sixteen 35-second excerpts from eight genres, in randomized order: Blues, Country, Dance, Jazz, Metal, Pop, Rap, and Reggae. The stimuli for the experiment were selected using a computa-tional process based on social-tagging and acoustic data. The selection pipeline was designed to select naturalistic stimuli that were uncontroversially representative of their respective genres, which would also be appropriate to use in a dance setting. Moreover, investigating movements to multiple genres of music further adds to the generalizabil-ity of our findings.

Figure 1: Marker and joint locations (A) Anterior view of the marker locations a stick figure illustration; (B) Anterior view of the locations of the secondary markers/joints used in animation and analysis of the data

3.2.1 Personality and Trait Empathy Measures

The Big Five Inventory (BFI) was used to capture the five predominant personality dimensions, namely, Openness, Conscientiousness, Extraversion, Agreeableness, and Neu-roticism [28]. Trait Empathy was measured using the EQ- and SQ-short form version, developed and validated by Wakabayashi et al. [29], as a result giving an EQ and SQ score per participant.

Figure 2: Overview of our Pipeline. Given the position of joints across time frames in 3D Euclidean space(a), we apply pairwise correntropy between time series x_i and x_j and calculate the K-matrix (b). Then, taking the lower triangular part of the symmetric covariance matrix, we get the feature vectors (c). After training the regression model on the feature vectors, we get the weight vector(d). Finally, corresponding weight values from the learned weight vector are mapped to the corresponding joints to get the per-joint importance (e).

3.3 Feature Extraction

The analysis and prediction pipeline is illustrated in Figure 2. To facilitate extraction of kinematic features using the MATLAB Motion Capture (MoCap) Toolbox [30], a set of 20 secondary markers, subsequently referred to as joints, was derived from the original 21 markers. The locations of these 20 joints are depicted in Figure 1. The locations of joints B, C, D, E, F, G, H, I, M, N, O, P, Q, R, S, and T are identical to the locations of one of the original markers, while the locations of the remaining joints were obtained by averaging the locations of two or more markers; Joint A: midpoint of the two back hip markers; J: midpoint the shoulder and hip markers; K: midpoint of shoulder markers; and L: midpoint of the three head markers. The instantaneous velocity of each marker in each direction was calculated. Instantaneous velocity was estimated by time differentiation followed by the application of a 2nd-order Butterworth filter with a cutoff frequency of 24Hz [30].

The features used in our analysis is the co-variances of position and velocity. The co-variances between all marker time series in each direction (X, Y and Z) within each participant for each stimulus. We used a non-linear measure to calculate covariance between the markers. This method, referred to as correntropy between time series x_i and x_j [31], is given by:

$$K(x_i, x_j) = e^{\frac{-||x_i - x_j||_2^2}{2\sigma^2 T^2}} \qquad (1)$$

where $||x_i - x_j||_2$ is L2-norm between x_i and x_j, σ is a constant, 12.0 in our case and T is the length of the time-series. The L2-norm is divided by T to normalize according to time series length since it has different lengths with varying stimuli. Since the number of joints are 20 and each joint has three coordinates, the dimension of K

would be 60×60. The lower triangular part excluding the diagonal elements of the symmetric covariance matrix was vectorised to produce a feature vector of length 1770 for each participant and for each stimuli.

We also run our experiments using the Normalized feature vectors calculated by using Position and Velocity, we employed standard Gaussian Normalization technique:

$$\hat{X} = \frac{X - \mu(X)}{\sigma(X)} \qquad (2)$$

where $\hat{X}$ is the feature vector, $\mu(X)$ is the mean and $\sigma(X)$ is standard deviation.

3.4 Model Regression

The most common regression model for value prediction tasks used is Linear Regression. The goal here is to find an optimal line that minimizes the total prediction error. But this model treats its parameters as unknown constants whose values must be derived. Moreover, the weights become sensitive when the dataset size is large. So to prevent the model from overfitting, we took principal components of the features to train the model (For the result sections, we will be considering 243 components for position data and 137 components for velocity data which gave us the best results). We also approached this problem by using Bayesian Regression other than Principal Component Regression (PCR) [1] .

In Bayesian Regression the parameters are treated as random variables belonging to an underlying distribution. Depending on the dataset, we can be more or less certain about the weights. Since, the parameters of the model belong to a distribution, the predictions of the model also belong to a distribution. So we have confidence bounds on

---

[1] Detailed analysis of Principal Component Regression (PCR) and Bayesian Regression are discussed in the supplementary.

our predictions. Therefore, they are better at representing the uncertainty of a model's predictions.

3.4.1 Personality and Trait Empathy Prediction

The features extracted are used to train five different Bayesian Regression models to predict each of the five personality traits - Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism (OCEAN). The features extracted are used to train both regression models to predict EQ and SQ respectively. The model is trained and evaluated on the described dataset.

3.5 Visualizing the Weight Vector

To interpret the coefficients (also known as the weights or model parameters) of the regression models, we add the value of the feature vector to the corresponding joints. In our algorithm, we first find the index in the 60×60 matrix and then add the absolute value to those joints.

The sign of the coefficient indicates the direction of the relationship but the magnitude preserves the importance. After that, Min-Max Normalization is applied to bring the values in the range (0, 1) for better visualizing the same variable across similar tasks.

$$\overline{JI}[i] = \left(\frac{JI[i] - min(JI)}{max(JI) - min(JI)} \right) \forall JI[i] \qquad (3)$$

where $\overline{JI}$ represent the normalized Joint Importance Vector. Algorithm 1 describes the pseudo-code to get the importance of joints from the weights of the trained regression model.

Algorithm 1 Joint Importance

Result: Calculate a vector J of 20 dimensions representing importance of each joint.

W is the weight vector; J is the importance vector initialised with 0; S contains lower triangular indices excluding diagonal indices; 0-indexing is followed;

1: $S \leftarrow LowerTriangularIndices(60 \times 60)$
2: $N \leftarrow S.length()$
3: **for** $k = 0 : N - 1$ **do**
4:     $(i, j) := S(k)$
5:     $(\hat{i}, \hat{j}) \leftarrow IndexToJoint(i, j)$
6:     $J(\hat{i}) := J(\hat{i}) + |W(k)|$
7:     $J(\hat{j}) := J(\hat{j}) + |W(k)|$
8: **end for**
9: **return** J

After getting a vector of 20 dimension, we reduce it to 12 before visualizing joint importance. We did this by taking the average of joints which occur in pairs eg. (L shoulder, R shoulder), (L wrist, R wrist).

3.5.1 Evaluation Metric

(a) Root Mean Square Error (RMSE): It computes a risk metric corresponding to the expected value of the root of squared (quadratic) error or loss.

(b) R^2 Score: It represents the proportion of the variance(of y) that has been explained by the independent variables in the model. [2]

As the square root of a variance, RMSE can be interpreted as the standard deviation of the unexplained variance, and has the useful property of being in the same units as the response variable and at the same time the R^2 helps us evaluate the goodness of fit in capturing the variance in training data. We calculate RMSE and R^2 on multiple splits so that we get an average estimate of the accuracy.

3.6 Results

3.6.1 EQ and SQ

The results for EQ prediction are in Table 1 and SQ prediction are in Table 2. The results are calculated using 5-fold cross validation. The range of EQ and SQ is 0-80. The boldface values represent the best score. The 'N' in the tables denote that Gaussian Normalization was applied on the features. We trained and evaluated two different models for each of the aforementioned tasks. We can see that using position data, instead of velocity data, to generate the feature vectors, gave us the best results. Also, we can see that the Bayesian Regression gave better results than Principal Component Regression on both metrics. So from here on, we will be using Bayesian Regression for other prediction and analysis tasks.

Input	PCR		Bayesian Ridge	
	RMSE	R^2	RMSE	R^2
Position	3.071	0.708	**2.722**	**0.771**
Position(N)	3.201	0.684	2.733	0.765
Velocity	4.938	0.249	4.343	0.423
Velocity(N)	4.583	0.353	4.015	0.503

Table 1: Prediction Results for Empathizing Quotient

Input	PCR		Bayesian Ridge	
	RMSE	R^2	RMSE	R^2
Position	2.398	0.781	**2.161**	**0.867**
Position(N)	2.363	0.786	2.502	0.838
Velocity	4.448	0.252	3.832	0.469
Velocity(N)	4.211	0.329	3.714	0.552

Table 2: Prediction Results for Systemizing Quotient

3.6.2 Personality Regression

The results for OCEAN value prediction on Dataset can be found in Table 3. The results are calculated using 5-fold cross validation. The range of the personality values is 1.0-5.0. We can see that using position data to extract features gave the best results on predicting all five personality traits on the dataset. We can concur that using position data instead of velocity data in the kernelized space is better for these regression tasks.

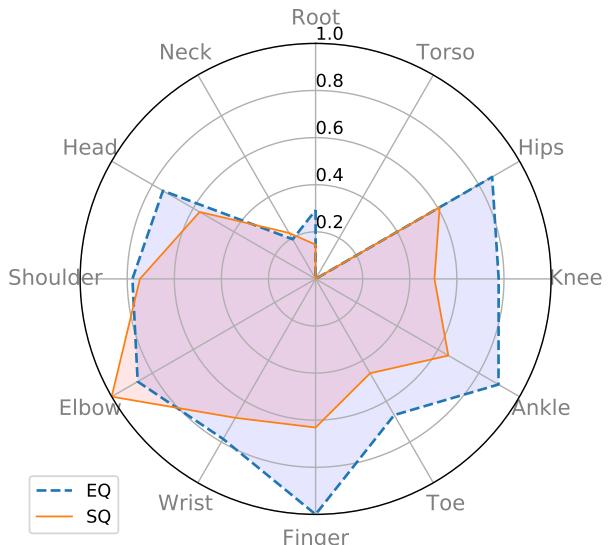
Table 3: Prediction Results for Five Personality Traits using Bayesian Regression

3.6.3 Joints' Importance

For evaluating joint importance we used learned weights of the model using position data across different tasks. For the purpose of analyzing the importance of the joints, we reduced them to 12 by taking the average for those joints which occur in pairs eg. (L shoulder, R shoulder). This was also done for hips, knee, ankle, toe, elbow, wrist, and finger. Altogether the results in characterizing an individual trait is dominated by the limbs than the core of the body.

From the relative joint importance depicted in Figure 3, we observe that 'Ankle', Elbow' and 'Shoulder' play an important role in determining EQ and SQ of an individual, whereas 'Neck' and 'Torso' have a negligible contribution. We also infer that 'Finger', 'Hip', and 'Knee' are more crucial joints for predicting EQ than for SQ whereas 'Elbow' holds significantly higher importance for predicting SQ than for EQ.

Figure 4 displays the relative joint importance of personality along with the mean plotted in each sub-figure. The farther away from the mean the joint importance value for an individual joint is, the more important it is in characterizing that trait. Some similarities in the joint importance profiles across the personality traits can be attributed to the inherent correlation that exists among them [3]. We observe that it is the 'Finger', 'Elbow', and 'Knees' that contribute to Feature Importance whereas 'Root', 'Neck' and 'Torso' have negligible contribution. For characterizing Conscientiousness, 'Shoulders', 'Knees' and 'Neck' play a crucial role while 'Head' and 'Toe' plays an important role for Extraversion. For Agreeableness, 'Neck' and 'Wrists' have relatively less importance as compared to other joints whereas, 'Wrists' play an important role in Openness. Finally, there are no significant defining features for Neuroticism, which indicates that their expression in Dance Movements through Music-Induced Movements are very limited.

4. DISCUSSION


Music experiences are highly embodied, making it necessary to consider individual embodied responses to music in developing more advanced personalized user experiences. The current study is among the first to the authors' knowledge to use participants' free dance movements to predict personality traits, and both the Empathizing and Systemizing Quotients (EQ/SQ).

Co-variance between joint velocities has previously been used to identify an individual from their free dance movements with a high degree of accuracy [11]. The results of the current analysis show co-variance to be a useful feature in predicting individual differences. However, we achieved considerably better prediction accuracy by using position data than velocity data.

Overall, the limbs of the body seemed to have more importance in predicting individual traits than the core body. This is in line with the fact that gesture plays an important role in communication [32], and as specifically regards the EQ/SQ, as these tests were originally developed in conjunction with studies of ASD, in which gesture and imitative movement appear to be compromised [33]. Although the sample used in the current study comprised typically functioning (non-ASD) participants, the accuracy of prediction of EQ/SQ scores in this analysis is worth highlighting in light of recent work suggesting the existence of motor signatures unique to ASD, detectable from whole body movements as well as data drawn from participants' interaction with tablets [19, 34].

The specific markers that were important in the prediction of individual traits in some cases corroborates previous work, and in some cases contradicts it. Luck et al. [9] found correlations between Extraversion and speed of head movement, which supports the current finding that the head is of particular importance in identifying Extraver-

Figure 3: Relative importance of Joints in EQ and SQ Tasks using the Position Data.

---

[3] The table for Spearman Correlation between the personality traits is provided in the supplementary material.

Figure 4: Relative importance of Joints of the five personality traits(Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism) using the Position Data. The black line indicates the mean importance of the corresponding joint marker. The red dotted line in the top left sub-figure indicates the standard deviation about the mean.

sion. Carlson et al. [17] found that, compared to Conscientiousness, the core body was more important in responsiveness to musical tempo in relation to Extraversion, which is partly supported by the slightly greater importance of the finger and wrist markers to Extraversion in our study, but partly contradicted by the importance of the shoulder marker in Extraversion. The difference between findings may relate to the use in the current study of position rather than velocity or acceleration data; that is, core body posture while moving to music may be more indicative of Conscientiousness than core body movement. EQ scores were more related to head, finger, hips and lower limb joints than SQ scores, which may be partly attributed to gender-typical movement patterns as females tend to score higher on the EQ than males [21, 35].

Several limitations of the current study should be noted. First, the majority of participants were from European or North American countries, and all eight music stimuli were of Western origin, limiting the degree to which results can be generalized cross-culturally. Secondly, There may exist potential bias due to gender imbalance. Future work could include separate analysis performed within gender categories. And lastly, participants' preferences for heard stimuli were not included in our model. This would be an important feature to focus on in future work, as preference

and enjoyment are highly relevant to personalized MIR.

Further extension of this work could help to make music recommendation systems more robust. Previous work has considered the relationship between personality and music preference [25, 36], while Greenberg et al. [26] explored the relationship between music preference and empathizing-systematizing theory, suggesting even that music may play a role in increasing empathy in people with empathy-related disorders, such as ASD. However, the relationship between embodiment, personality and musical experiences requires further exploration.

To conclude, this study represents an early step towards multimodal MIR. To make this approach applicable to personalized gesture-based retrieval systems, it can be extended to monocular video captured by accessible devices such as a mobile phone camera. This approach would be feasible due to recent progress in the area of 3D human pose estimation in predicting the body joint coordinates from a monocular video [37–39]. This would then allow future recommendation systems to take embodied processes into account, resulting in better and more responsive personalized experiences.

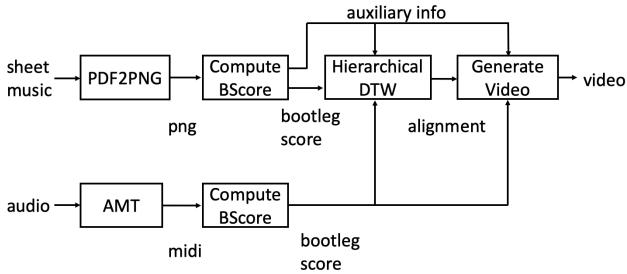
ABSTRACT

This paper studies the problem of automatically generating piano score following videos given an audio recording and raw sheet music images. Whereas previous works focus on synthetic sheet music where the data has been cleaned and preprocessed, we instead focus on developing a system that can cope with the messiness of raw, unprocessed sheet music PDFs from IMSLP. We investigate how well existing systems cope with real scanned sheet music, filler pages and unrelated pieces or movements, and discontinuities due to jumps and repeats. We find that a significant bottleneck in system performance is handling jumps and repeats correctly. In particular, we find that a previously proposed Jump DTW algorithm does not perform robustly when jump locations are unknown a priori. We propose a novel alignment algorithm called Hierarchical DTW that can handle jumps and repeats even when jump locations are not known. It first performs alignment at the feature level on each sheet music line, and then performs a second alignment at the segment level. By operating at the segment level, it is able to encode domain knowledge about how likely a particular jump is. Through carefully controlled experiments on unprocessed sheet music PDFs from IMSLP, we show that Hierarachical DTW significantly outperforms Jump DTW in handling various types of jumps.

1. INTRODUCTION


This paper tackles the problem of generating piano score following videos in a fully automated manner. Given an audio recording of a piano performance, our long-term goal is to build a system that can (a) identify the piece and automatically download the corresponding sheet music PDF from the International Music Score Library Project (IMSLP) website, and (b) generate a video showing the corresponding line of sheet music at each time instant in the audio recording. In this work, we focus exclusively on task (b), assuming that the correct sheet music PDF has been identified. This task requires us to perform audio–sheet music alignment on completely unprocessed PDF

files from IMSLP. This paper describes the key insights we have gained in building such a system, along with a novel alignment algorithm developed in the process.

Many previous works have studied cross-modal alignment between sheet music images and audio. Two general categories of approaches have been proposed. The first approach is to convert the sheet music images to a symbolic representation using optical music recognition (OMR), to collapse the pitch information across octaves to get a chroma representation, and then to compare this representation to chroma features extracted from the audio. This approach has been applied to synchronizing audio and sheet music [1] [2] [3], identifying audio recordings that correspond to a given sheet music representation [4], and finding the corresponding audio segment given a short segment of sheet music [5]. The second approach is to convert both sheet music and audio into a learned feature space that directly encodes semantic similarity. This has been done using convolutional neural networks combined with canonical correlation analysis [6] [7], pairwise ranking loss [8] [9], or some other suitable loss metric. This approach has been explored in the context of online sheet music score following [10], sheet music retrieval given an audio query [11] [8] [9], and offline alignment of sheet music and audio [8]. Recent works [12] [13] have also shown promising results formulating the score following problem as a reinforcement learning game. See [14] for an overview of work in this area.

The main difference between our current task and previous work is that we are working with totally unprocessed data "in the wild." All of the above works make one or more of the following assumptions, which are untrue in our task. First, many works focus primarily on training and testing with synthetic sheet music. In our case, we are primarily working with digital scans of physical sheet music. Second, most works assume that the data has been cleaned and preprocessed in various ways. For example, it is commonly assumed that unrelated pages of sheet music have been removed. Many works further assume that each page has been segmented into lines, so that the data is presented as a sequence of image strips each containing a single line of sheet music. In our task, the raw PDF from IMSLP may contain unrelated movements, pieces, or filler pages like the title page or table of contents. We also obviously cannot assume that each page has already been segmented perfectly. Third, all of the above works assume that the music does not have any jumps or repeats. In our

Figure 1. Architecture of proposed system. The sheet music and audio are both converted into bootleg scores, and then aligned with the Hierarchical DTW algorithm.

task, we have to be able to handle common discontinuities like repeats, D.C. al coda, D.S. al fine, etc.

In attempting to build a system that can handle messy, real-world data, we discovered two things. First, we found that most of the above issues can be resolved to a reasonable degree by suitably combining existing tools in the MIR literature. However, we also discovered that a significant bottleneck in system performance was handling jumps and repeats. In particular, we found that a previously proposed Jump DTW alignment algorithm [15] does not yield satisfactory performance when jump locations are unknown a priori.

There are several existing offline algorithms for aligning two feature sequences in the presence of jumps or repeats. Jump DTW [15] is a variant of dynamic time warping (DTW) where additional long-range transitions are allowed in the cost matrix at potential jump locations. Mueller and Appelt [16] and Grachten et al. [17] also propose variants of DTW for partial alignment in the presence of structural differences. One limitation of these latter two works is that repeated sections are handled by simply skipping or deleting sections of features, so that the actual alignment of the repeated section is not known. Joder et al. [18] frame the alignment problem as a conditional random field with additional transitions inserted at known jump locations. Jiang et al. [19] use a modified Markov model that allows arbitrary jumps to follow a musician during a practice session with lots of do-overs and jumps. There are also several real-time score following algorithms that handle various types of jumps [20] [21] [22] [23], though our focus in this work is on the offline context. In this study, we primarily focus on Jump DTW as the closest match to our target scenario: it is an offline algorithm, targeted at performances rather than practice sessions, and it provides a complete estimated alignment in the presence of jumps.

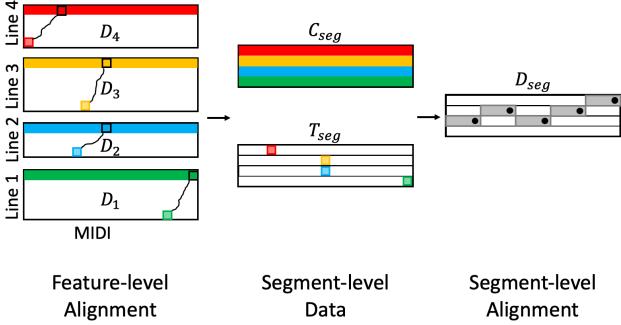
The main conceptual contribution of this paper is a novel alignment algorithm called Hierarchical DTW. Unlike Jump DTW, it does not require knowledge of jump locations a priori, but instead considers every line transition as a potential jump location. The algorithm is called Hierarchical DTW because it first performs an alignment at the feature level with each sheet music line, and then uses the results to perform a second alignment at the segment level. By performing an alignment at the segment level, we can encode domain knowledge about which types of jumps

are likely. The algorithm is very simple and only has two hyperparameters, which both have very clear and intuitive interpretations. Through carefully controlled experiments on unprocessed PDFs from IMSLP, we show that Hierarchical DTW significantly outperforms Jump DTW on the piano score following video generation task. [1]

2. SYSTEM DESCRIPTION

Figure 1 shows a high-level overview of our proposed system. We will explain its design in three parts: feature extraction, alignment, and video generation.

2.1 Feature Extraction

The first step is to convert both the sheet music and audio into bootleg score representations. The bootleg score [24] is a recently proposed feature representation for aligning piano sheet music images and MIDI. For sheet music, it encodes the position of filled noteheads relative to the staff lines. The bootleg score itself is a $62 \times N$ binary matrix, where 62 indicates the total number of possible staff line positions in both the left and right hands, and where N indicates the total estimated number of simultaneous note events. For MIDI files, each note onset can be projected onto the bootleg score using the rules of Western musical notation. Ambiguities due to enharmonic representations or left-right hand attribution are handled by simply setting all possible positions to 1.


We computed the bootleg score representations in the following manner. We convert each PDF into a sequence of PNG images at 300 dpi, compute a bootleg score for each page, and then represent the entire PDF as a sequence of bootleg score fragments, where each fragment corresponds to a single line of music. Note that these fragments may include lines of music from other unrelated movements or pieces in the same PDF, or may even represent nonsense features coming from filler pages. Next, we transcribe the audio recording using the Onsets and Frames [25] automatic music transcription system, and then convert the estimated MIDI into its corresponding bootleg score. In this work, we treat the bootleg score computation and music transcription as fixed feature extractors.

2.2 Alignment

The second main step is to align the bootleg score representations. We propose a novel alignment algorithm called Hierarchical DTW to accomplish this task. Figure 2 shows an overview of the algorithm, which consists of three stages.

The first stage is to perform feature-level alignment. We do this using a variant of DTW called subsequence DTW, which finds the optimal alignment between a short query sequence and any subsequence within a reference sequence. We perform subsequence DTW between each sheet music bootleg score fragment (each corresponding to one line of music) and the entire MIDI bootleg score, as

---

[1] Code, data, and example score following videos can be found at https://github.com/HMC-MIR/YoutubeScoreFollowing.

Figure 2. Overview of Hierarchical DTW. Subsequence DTW is performed at the feature level on each sheet music line. The results are used to generate the segment-level data matrices, and then a second alignment is performed at the segment level. Only a few selected elements of T_{seg} are shown for illustration.

shown on the left side of Figure 2. [2] We use the normalized negative inner product distance metric proposed in [24] along with allowable transitions $\{(1,1),(1,2),(2,1)\}$ with weights $\{1,1,2\}$. For a more detailed explanation of subsequence DTW, we refer the reader to [26].

The second stage is to construct the segment-level data matrices. There are two matrices that need to be constructed. The first matrix is formed by taking the last row in every cumulative cost matrix D_i from stage 1 and stacking them into a matrix of size $L \times M$, where L indicates the total number of lines of music in the PDF and M indicates the total number of features in the MIDI bootleg score. This matrix contains subsequence path scores and is denoted as C_{seg} in Figure 2. It will play a role analogous to the pairwise cost matrix when we do dynamic programming at the segment level. The second matrix T_{seg} is the same size as C_{seg} and indicates allowable transitions at the segment level. Each element $T_{seg}[i,j]$ is computed by identifying the jth element in the last row of D_i, and then backtracking from this element to determine the beginning location of the matching path. $T_{seg}[i,j]$ thus indicates the starting location of the best matching path in the ith line of sheet music ending at position j in the MIDI bootleg score. In Figure 2, a few selected elements in T_{seg} are shown as colored boxes to illustrate this process. Note that, in order to construct T_{seg}, we need to backtrace from every possible location for every line of sheet music.

The third stage is to perform segment-level alignment. Here, we use dynamic programming to find the optimal path through C_{seg} using transitions in T_{seg}. We construct a segment-level cumulative cost matrix D_{seg} by filling out its entries column-by-column using dynamic programming. The first column of D_{seg} is initialized to all zeros, which ensures that the matching path can start on any line of music without penalty. Note that, unlike regular DTW where the set of allowable transitions and weights is the same at every location, here the set of allowable transitions and weights is different for each element of D_{seg}.

Since the transitions are all unique, we simply encode the previous location rather than the transition type (e.g. the previous location $(i-1, j-1)$ instead of the transition $(1,1)$). When computing $D_{seg}[i,j]$, there are two types of allowable transitions. The first type of transition is skipping elements. This means transitioning from $(i, j-1)$ and moving directly to the right by one position without accumulating any score. Here, the candidate path score is $D_{seg}[i,j] = D_{seg}[i, j-1]$. The second type of transition is matching the ith line of music (ending) at this position. In this case, we can transition from the end of any line of music immediately before the matching segment begins. If we let $k \triangleq T_{seg}[i,j]$ be the beginning of the matching subsequence path, then there are L different possible transitions from $(n, k-1), n = 0, \ldots, L-1$ where n indicates the line of music. Here, the candidate path scores are $D_{seg}[i,j] = D_{seg}[n, k-1] + w_{n,i} \cdot C_{seg}[i,j] + p_{n,i}$, where $w_{n,i}$ is a multiplicative weight and $p_{n,i}$ is an additive penalty for jumps. We can summarize the dynamic programming rules for the segment-level alignment as

$$k \triangleq T_{seg}[i,j] \tag{1}$$

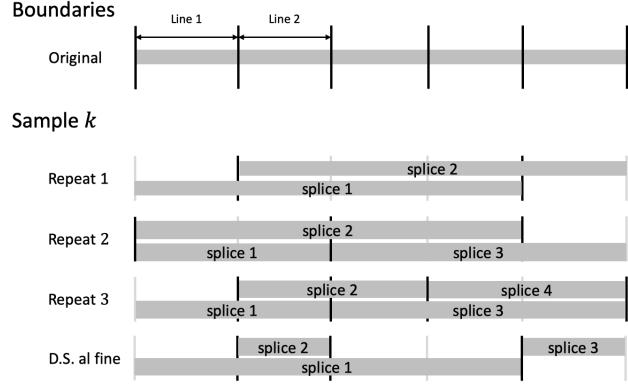
$$D_{seg}[i,j] = min \begin{cases} D_{seg}[i, j-1] \\ D_{seg}[0, k-1] + w_{0,i} \cdot C_{seg}[i,j] + p_{0,i} \\ D_{seg}[1, k-1] + w_{1,i} \cdot C_{seg}[i,j] + p_{1,i} \\ \ldots \end{cases}$$
$$\tag{2}$$

where the minimum is calculated over all sheet music lines $n = 0, \ldots, L-1$. When filling out the entries of D_{seg} using dynamic programming, we also keep track of backtrace information in a separate matrix. Once D_{seg} has been constructed, we identify the element in the last column of D_{seg} with the lowest path score, and then backtrace from that position to determine the optimal alignment path. Figure 2 shows the optimal alignment path as a series of black dots and the induced segmentation of the MIDI bootleg score as gray rectangles.

The real power of Hierarchical DTW comes from setting $w_{n,i}$ and $p_{n,i}$ in an intelligent way that encodes musical domain knowledge. These values can be adapted to allow no jumps, allow arbitrary jumps, or anything in between. For example, disallowing jumps means setting $p_{n,i} = \infty \cdot \mathbb{1}(i \neq n+1)$. The system described below is one possible instantiation based on three assumptions: (a) the performed lines of music will form a contiguous block (e.g. we will not go from page 13 to 34 to 19), (b) backwards jumps (from repeats) are to lines of music we have seen before, and (c) forward jumps (from D.S. al fine) are to one line past the furthest line of music that has been seen before (which we refer to as the "leading edge"). For the allowed jump transitions, multiplicative weights are set to 1 and additive penalties are set to $-\gamma \cdot p_{avg}$, where γ is a hyperparameter and p_{avg} is the result of calculating the best subsequence path score for each line of sheet music and averaging the scores across all lines. So, if $\gamma = 1$, the jump penalty approximately offsets 1 line of matching music. Note that we can keep track of which lines have been seen

before by defining two matrices R_{lower} and R_{upper} which are the same size as C_{seg} and keep track of the range of lines that have been seen in the optimal path ending at any position (i, j). R_{lower} and R_{upper} can be updated along with D_{seg} and the backtrace matrix during the dynamic programming stage. For regular forward transitions, we allow moving to the next line, staying on the current line (slowing down), or skipping one line (speeding up). These three transitions have multiplicative weights 1, α, and α and additive penalties of 0 (all), respectively. We found that allowing additional time warping at the segment level with multiplicative penalty $\alpha = 0.5$ allows the algorithm to recover from large mistakes more easily.

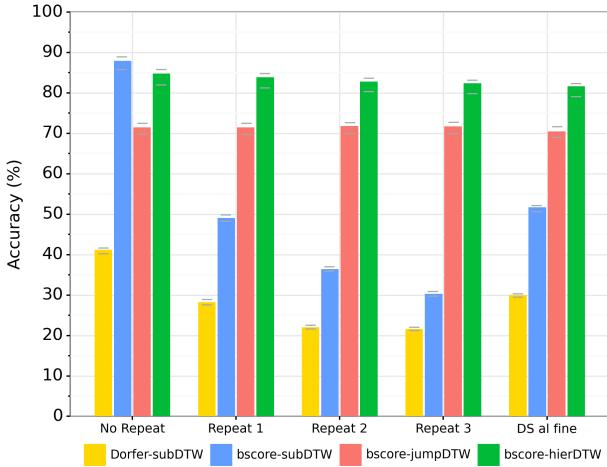
Hierarchical DTW is simple yet flexible. The version described above only has two hyperparameters that correspond to a multiplicative penalty for speeding up/slowing down (α) and an additive penalty for jumps (γ). Yet, the framework of Hierarchical DTW makes it possible to selectively allow very specific types of jumps that obey common musical conventions.

2.3 Video Generation


The third main step is to generate the score following video. In order to translate the predicted segment-level alignment into a score following video, we need additional auxiliary information from the bootleg score feature computation. For the audio recording, we need to keep track of the correspondence between each MIDI bootleg score feature column and its corresponding time in the audio recording. For the sheet music, we need to keep track of the correspondence between each sheet music bootleg score feature column and its corresponding page and pixel range in the sheet music images. We modified the original code provided in [24] to return this information, in addition to the bootleg score features. Given this auxiliary information and the predicted segment-level alignment, we can generate the score following video in a very straightforward manner: we simply show the predicted line of sheet music at every time instant in the audio recording.

3. EXPERIMENTAL SETUP

In this section, we explain the datasets and metrics used to evaluate our proposed system.

Our data is a derivative of the Sheet MIDI Retrieval dataset [24]. We will first describe the original dataset, and then explain how we used it to generate the data for this current work. The original dataset contains scanned sheet music from IMSLP for 200 solo piano pieces across 25 composers. The sheet music comes with manual annotations of how many lines of music are on each page, and how many measures are on each line. For each of the 200 pieces, there is a corresponding MIDI file and ground truth annotations of measure-level timestamps.


We derived our dataset in the following manner. We synthesize the MIDI files to audio using the FluidSynth library. By combining the sheet music and MIDI annotations, we determine the time intervals in the audio record-

Figure 3. Generating audio with repeats. The original audio recording is segmented by lines of sheet music. We sample k boundary points without replacement, and then splice and concatenate audio segments to generate the data with repeats.

ing that correspond to each line of sheet music. For each sheet music PDF in the Sheet MIDI Retrieval dataset, we retrieved the original PDF from the IMSLP website. The only difference between these two files is that the original IMSLP PDF contains other unrelated movements, pieces, and filler pages that were removed during the preparation of the Sheet MIDI Retrieval dataset. For example, one PDF in the test set contains 127 pages, of which only 17 correspond to the piece of interest. Because we want to test how well our system handles this type of noise, we use the original PDF with no preprocessing or data cleaning whatsoever. We augmented the sheet music annotations by converting the original IMSLP PDFs into PNG files at 300 dpi and manually annotating the vertical pixel range for every line of sheet music played in the audio recording. This required annotating a total of 1090 pages with $11,556$ pixel positions. By combining all of our annotations together, we can determine the page and pixel range of the line of sheet music that is currently being played at every point in the audio recording. In total, there are 13.0 hours of annotated audio. Because there are no repeats or jumps in the sheet music, we call this data the "No Repeat" dataset.

We also generate several synthetic datasets to test how well our system handles jumps and repeats. The process of generating a synthetic dataset consists of three steps, as shown in Figure 3. The first step is to identify the $L + 1$ boundary positions of the L lines of sheet music that are played in the audio recording. The second step is to randomly sample k boundary points without replacement. The value of k depends on the types of jumps we want to simulate. In this work, we consider four schemas: 1 repeat ($k = 2$), 2 repeats ($k = 3$), 3 repeats ($k = 4$), and D.S. al fine ($k = 3$). The third step is to splice and concatenate the audio to generate a modified audio recording as shown in Figure 3. Note that all of the synthetic datasets have the exact same sheet music, but their audio recordings have been spliced to reflect the desired schema. Since the process of sampling is random, we generate five different samples for every audio recording. The four syn-

Figure 4. Comparison of system performance on benchmarks with various types of jumps. The bar levels indicate accuracy with a scoring collar of 0.5 sec. The short gray lines indicate accuracy with scoring collars of 0 and 1.0 seconds.

thetic datasets described above have 84, 94, 100, and 81 hours of audio, respectively. The ground truth annotations are modified accordingly.

We evaluate system performance using a simple accuracy metric. Because our goal is to generate score following videos, we want to use an evaluation metric that correlates with user experience. The accuracy simply indicates the percentage of time that the correct line of music is being shown to the user. When calculating accuracy, we use a scoring collar, in which small intervals $(t_i - \Delta t, t_i + \Delta t)$ around the ground truth transition timestamps t_i are ignored during scoring. This is a standard practice in evaluating time-based segmentation tasks like speech activity detection [27]. By using a range of scoring collar values, we can also gain insight into what fraction of our errors occur very close to the transition boundaries.

For all experiments, we use (the same) 40 pieces for training and 160 pieces for testing. This results in 160 test queries for the No Repeat benchmark (10.6 hours of audio) and $160 \times 5 = 800$ test queries for the benchmarks with jumps (69.2, 76.9, 81.8, and 66.1 hours). Since we treat the bootleg score computation and automatic music transcription as fixed feature extractors, our system has no trainable weights and only 2 hyperparameters (α, γ). So, we only use a small fraction of the data for developing the algorithm, and we reserve most of the data for testing.

4. RESULTS

In this section, we present our experimental results on the piano score following video generation task.

We compare our proposed system to three other baseline systems. The first baseline system ('bscore-subDTW') is identical to our proposed system in Figure 1 except that it replaces the Hierarchical DTW with a simple subsequence DTW. The second baseline system ('bscore-jumpDTW') is also identical to our proposed system except that it replaces

the Hierarchical DTW with Jump DTW [15]. Because Jump DTW was designed to handle jumps and repeats, we expect this system to provide the most competitive baseline results. The third baseline system ('Dorfer-subDTW') is based on Dorfer et. al [9]. This system approaches the audio–sheet music alignment task by training a multimodal CNN to project chunks of sheet music and chunks of audio spectrogram into the same feature space where similarity can be computed directly. We used the pretrained CNN provided in [9] as a feature extractor, and then apply subsequence DTW. Finally, our proposed Hierarchical DTW system is indicated as 'bscore-hierDTW.'

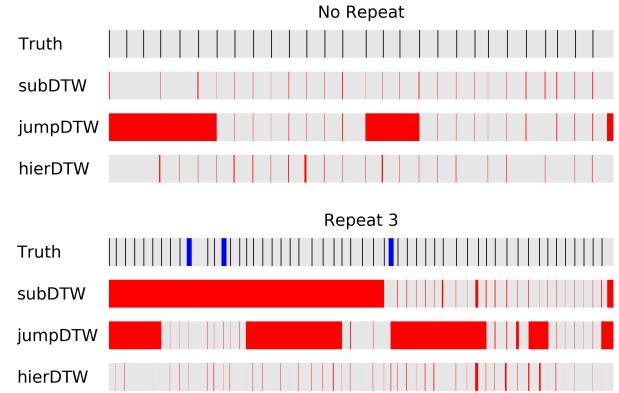
Figure 4 shows the results of these four systems. The histogram bars indicate the accuracies with a scoring collar of $\Delta t = .5$ sec. There are four things to notice about these results. First, the Dorfer-subDTW system performs poorly on all benchmarks. This indicates that this system does not generalize well to the scanned sheet music from IMSLP. Second, the bscore-subDTW system performs well on the No Repeat benchmark (87.9% accuracy), but performs poorly on all other benchmarks (e.g. 30.3% on the Repeat 3 benchmark). This is to be expected, since subsequence DTW cannot handle jumps and repeats. Third, Jump DTW is significantly worse than subsequence DTW on the No Repeat benchmark (71.5% vs. 87.9%), but it has consistent performance across benchmarks with repeats and jumps (71.5%, 71.8%, 71.7%, and 70.5%). This indicates that Jump DTW is able to cope with discontinuities, but with a significant cost in performance. Fourth, the Hierarchical DTW system is only slightly worse than subsequence DTW on the No Repeat benchmark (84.8% vs. 87.9%), and its performance decreases only slightly on the other benchmarks (83.9%, 82.8%, 82.4%, 81.6%). We can see that the Hierarchical DTW system consistently outperforms Jump DTW by 10-13% across all benchmarks. These results indicate that Hierarchical DTW is able to handle repeats and jumps reasonably well, and with a much smaller performance cost than Jump DTW.

5. ANALYSIS

In this section, we conduct two different analyses to gain more insight into system behavior.

5.1 Failure Modes

The first analysis answers the question, "What are the failure modes for each system?" To answer this question, we identified the individual queries that had the poorest accuracy, and then investigated the reasons for the errors.

The Dorfer system has two primary failure modes. The first failure mode is that the system is not designed to handle jumps, so it performs very poorly on any datasets with jumps or repeats. Note, however, that this system also performs poorly on the No Repeat benchmark. When we investigated the reasons for this, we discovered the second major failure mode: page segmentation. The sub-system for segmenting each page into lines of music performed very poorly on many pages in the dataset. This is perhaps


not surprising, since the original system was developed and trained on synthetic sheet music, where staff lines are perfectly horizontal. In this case, the assumptions in this work do not translate well to our task of working with IMSLP scanned sheet music.

The subsequence DTW system also has two primary failure modes. The first is (again) that the system cannot handle jumps or repeats. When we investigated the reasons for major errors on the No Repeat benchmark, we find that the failures primarily come from mistakes in the bootleg score representation. The bootleg score does not account for octave markings or clef changes, and it does not detect non-filled noteheads (e.g. half or whole notes). When there are long stretches of sheet music that contain several of these elements at the same time, the bootleg score is a poor representation of the sheet music. For example, three of the pieces in the test set are Erik Satie's Gymnopedies, where the sheet music is almost entirely non-filled noteheads. These pieces had close to 0% accuracy and caused a decrease of several percentage points on the aggregate accuracy score.

The JumpDTW system has one primary failure mode: it often jumps to incorrect lines of music. This occurs when either (a) there are similar lines of music in multiple places (e.g. the recapitulation of a theme), or (b) significant bootleg score errors cause the system to match random lines of music elsewhere in the piece. This problem is most clearly seen in the No Repeat benchmark, where it often takes jumps when none are present.

The Hierarchical DTW system has two primary failure modes. The first failure mode is prolonged bootleg score failures, which cause the algorithm to insert spurious small jumps. Once the bootleg score becomes an accurate representation again, the system is usually able to recover. The second failure mode is when the sheet music contains very repetitive measures and lines. This problem is particularly bad when the sheet music is very short (e.g. 2-3 pages long) and has jumps or repeats.

Figure 5 shows a visualization tool for diagnosing failure modes. The top half of Figure 5 shows four gray strips, each representing the duration of a single audio recording in the No Repeat benchmark. The topmost strip contains black vertical lines indicating the location of the ground truth sheet music line transitions. The three strips below it show the predictions of the subsequence DTW, Jump DTW, and Hierarchical DTW systems, where errors are shown in red. The bottom half of Figure 5 shows the same information for a query in the Repeat 3 benchmark. The location of the jumps are indicated with blue vertical lines. We can see many of the failure modes described above. For example, Jump DTW has spurious jumps in both queries but is able to follow two of the repeats in the bottom query. Subsequence DTW is unable to handle the jumps in the bottom query, but matches well after the last jump occurs. Finally, we can see that the Hierarchical DTW system is able to follow the correct sequence of sheet music lines, and its errors primarily occur close to line transitions.

Figure 5. Visualizing system predictions for a query with no repeats (top half) and a query with three repeats (bottom half). Black lines show ground truth line transitions, red regions indicate errors, and blue lines show repeats.

5.2 Error Locations

The second analysis answers the question, "Where are the errors located?" One way we can answer this question is to calculate system performance across a range of values for the scoring collars. This can tell us how close the errors are to line transition boundaries. Figure 4 shows the results of each system with various scoring collar values. The histogram bar level indicates the default scoring collar $\Delta t = .5$ sec, and the results with Δt set to 0 sec and 1.0 sec are shown as short horizontal gray lines directly below and above the histogram bar level, respectively. Note that as Δt increases, the accuracy will increase monotonically.

There are two things to notice about the results with various scoring collars. First, we see that even with a generous scoring collar of $\Delta t = 1$ sec, the accuracies of all systems only increase about 1-2%. This indicates that most of the errors are not slight misalignments at the line transitions, but are instead large errors due to total alignment failures. Second, we observe that the results with Hierarchical DTW on benchmarks with jumps is only marginally worse than the No Repeat benchmark. This indicates that Hierarchical DTW is able to handle discontinuities reasonably well. Combining these two observations, the failures in the bscore-hierDTW system seem to primarily come from large misalignments due to prolonged bootleg score failures. This strongly suggests that the performance bottleneck is the bootleg score representation, not the Hierarchical DTW alignment.

6. CONCLUSION

We present a method for audio-sheet image alignment that combines a bootleg score representation with a novel alignment algorithm called Hierarchical DTW, which performs alignment at both the feature-level and the segment-level in order to handle repeats, jumps, and unknown offset in the sheet music. We show that Hierarchical DTW significantly outperforms Jump DTW in handling jumps and repeats on unprocessed sheet music.

ZERO-SHOT SINGING VOICE CONVERSION

Shahan Nercessian

iZotope, Inc.

`shahan@izotope.com`

ABSTRACT

In this paper, we propose the use of speaker embedding networks to perform zero-shot singing voice conversion, and suggest two architectures for its realization. The use of speaker embedding networks not only enables the capability to adapt to new voices on-the-fly, but also allows for model training on unlabeled data. This not only facilitates the collection of suitable singing voice data, but also allows networks to be pretrained on large speech corpora before being refined on singing voice datasets, improving network generalization. We illustrate the effectiveness of the proposed zero-shot singing voice conversion algorithms by both qualitative and quantitative means.

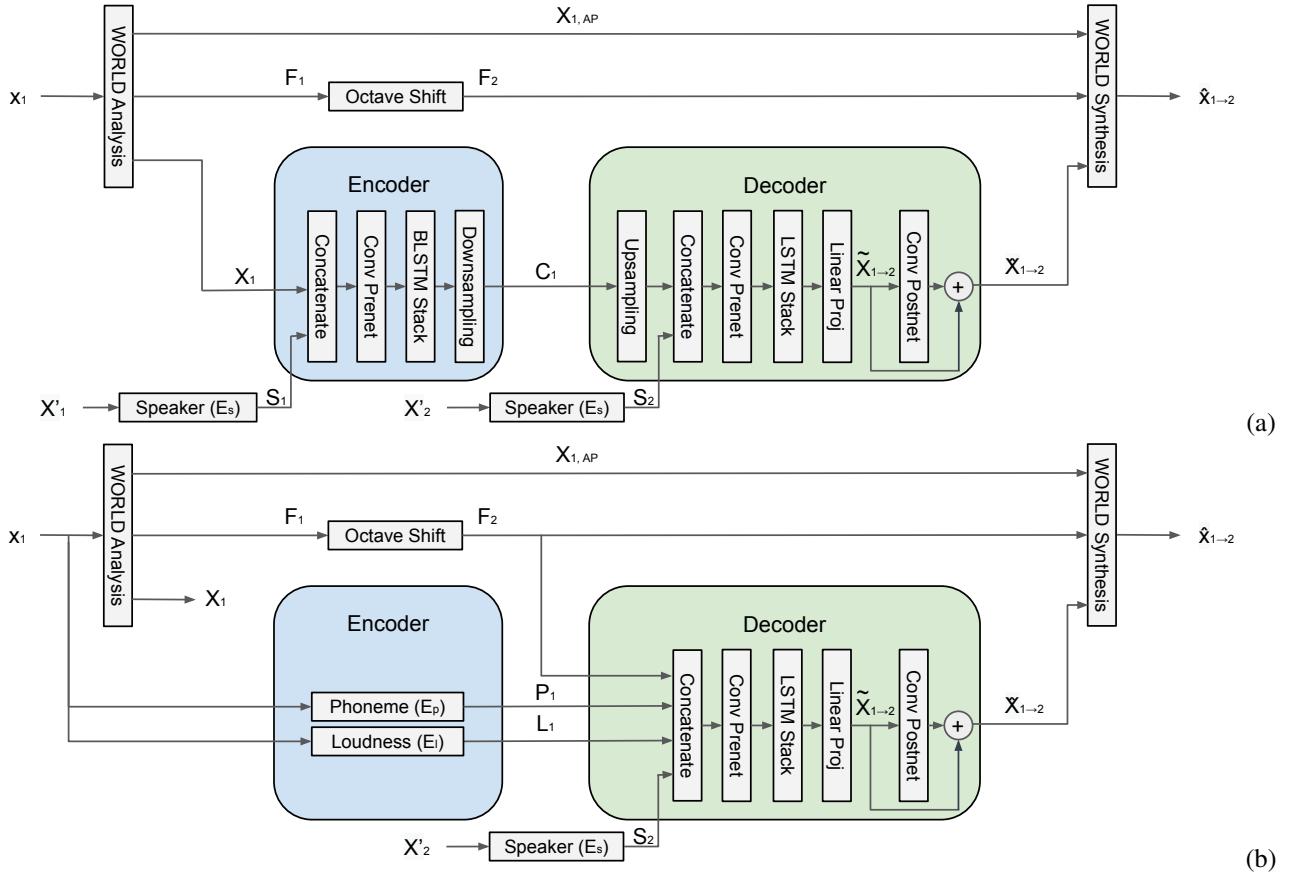
1. INTRODUCTION

Singing voice conversion (SVC) is the transformation of a singing performance from one vocalist to that of another. It can be used for creative manipulations of the voice that go far beyond traditional time stretching and pitch/formant shifting [1]. SVC methods must learn to disentangle speaker content from acoustic features [2], while accurately preserving input phonetic and pitch information in the converted output. Relative to similar methods applied to speech, the singing voice exhibits a larger pitch range and generally slower transitions between phonetic units, which conversion networks must be able to accommodate for [3, 4].

Most approaches to SVC rely on some form of vocoder which synthesizes vocal waveforms. The SVC task then becomes one of transforming vocoder features from a performance of a source singer to that of some target voice. Unlike approaches to voice conversion on speech, which usually leverage neural vocoders such as WaveNet [5] or WaveRNN [6] as their back-end speech synthesizer, SVC and singing synthesis algorithms tend to use hand-designed vocoders such as WORLD [7] for acoustic modeling and synthesis of the voice (with some exceptions, as in [8]). This is because they explicitly separate pitch from timbral components [3, 4, 9]. Accordingly, it is possible to learn timbral transformations while preserving pitch, which is not usually guaranteed when using neural vocoder [2].

This may come at the expense of reduced expressivity relative to neural vocoders, but is considered to be acceptable given its pitch-preserving characteristics [4].

Generative Adversarial Networks (GANs) [3, 9, 10] and Variational Autoencoders (VAEs) [11] have become popular choices for learning transformations of vocoder features for both SVC and singing synthesis. Different strategies have been investigated to model several target voices, and specifically, to adapt systems for new voices not seen during model training. One such strategy involves assigning a random embedding to the unseen voice, and resuming model training on data of the unseen voice so as to update this embedding and perform any necessary refinements to the model [12, 13]. More recently, conversion algorithms in the speech domain have used pretrained speaker embedding networks designed for speaker verification tasks [14] in order to encode speaker identity [15]. These approaches have the advantage that, upon having trained the speaker embedding network on many speakers, conversion algorithms can be adapted to new voices in a zero-shot manner, requiring no further training of the model and with as few as one sample of an unseen voice.

In this paper, we adapt zero-shot voice conversion methodologies [15] utilizing speaker embedding networks for the application of SVC. We use the WORLD vocoder and suggest two architectures for carrying out zero-shot SVC. We show that the zero-shot nature of the algorithm allows for SVC on unlabeled data. Moreover, we posit that SVC systems are amenable to initial training on large speech datasets which are more widely available, followed by model adaptation on smaller singing voice datasets. To the best of our knowledge, this is the first work to tackle zero-shot SVC. Unlike singing synthesis algorithms, such as [4, 10, 13], it does not require predefined annotations of phonetic transitions or pitch, as this information is extracted from acoustic features of the source performance.


The remainder of this paper is structured as follows: We suggest architectures for zero-shot SVC in Section 2. We evaluate model performance via qualitative and quantitative means in Section 3. Lastly, we draw conclusions and allude to future work in Section 4.

2. SVC ALGORITHMS

We use the WORLD vocoder for analysis and synthesis of singing voices due to its ability to separate timbral and pitch components. Specifically, the system decomposes a vocal signal into a harmonic spectral envelope and an aperiodicity envelope, based on a tonality-gated estimate

Figure 1. (a) Adapted AutoVC and (b) fixed encoder network architectures for zero-shot SVC.

of fundamental frequency. The conversion task primarily involves transformation of the harmonic spectral envelope, leaving the aperiodicity envelope unchanged. As in [4], we reduce the dimensionality of harmonic spectral envelopes to 60 coefficients at each time step, using truncated frequency warping in the cepstral domain with an allpole warping coefficient $\alpha = 0.45$ [16]. We consider two different architectures for SVC, as illustrated in Figure 1, drawing inspiration from [2, 15, 17, 18].

2.1 AutoVC

The first architecture is an adaptation of the AutoVC architecture [15] for singing voice, which operates on harmonic spectral envelopes extracted from WORLD (instead of Mel spectrograms which are ultimately fed into a WaveNet vocoder as in the original work). It is comprised of a speaker embedding network $E_s(\cdot)$ which takes as input a Mel spectogram and generates a single fixed-dimensional speaker embedding, a content encoder $E(\cdot)$ which takes as input the harmonic spectral envelope and speaker embedding from a source utterance and generates a latent encoding, and a decoder network $D(\cdot)$ which constructs the converted harmonic spectral envelope from a latent encoding and target speaker embedding.

The input to the encoder is the harmonic spectral envelope X_1 computed from a source utterance x_1. This is concatenated with a source speaker embedding $S_1 = E_s(X'_1)$ at each time step, where X'_1 is a Mel spectrogram of the

same or potentially different utterance x'_1 from the same source speaker. The encoder consists of a convolutional prenet, comprised of three 1D convolutional layers with 512 output channels and kernel size 5, each followed by batch normalization and ReLU activation. This result is passed through two bidirectional LSTM layers with forward and backward cell dimensions of 32, yielding an encoding of dimension 64. This is temporally downsampled by 32, yielding the content encoding C_1. The inclusion of S_1 in the encoder network helps the encoder to more easily learn a speaker-independent encoding.

The decoder begins by upsampling the latent encoding C_1 to its original temporal resolution. Given the Mel spectrogram X'_2 of some utterance x'_2 from the same target speaker as the target utterance x_2, the speaker embedding $S_2 = E_s(X'_2)$ is concatenated with the upsampled encoding. The concatenated features pass through a convolutional prenet similar to that in the encoder, followed by three LSTM layers with cell dimension 1024. The outputs of the LSTM layer are linearly projected to dimension 60, serving as an initial estimate $\tilde{X}_{1\rightarrow 2}$ of the converted harmonic spectral envelope. This initial estimate is refined by means of a convolutional postnet consisting of five 1D convolutional layers of kernel size 5. Batch normalization and Tanh are applied to the first four layers, and they each output 512 channels. The final layer applies no activation and outputs 60 channels. The converted harmonic spectral envelope $\hat{X}_{1\rightarrow 2}$ is produced by adding the output of the

postnet to $\tilde{X}_{1\rightarrow2}$.

During training, we set $x_1 = x_2$, $S_1 = S_2$, and accordingly, $X_1 = X_2$, $\tilde{X}_{1\rightarrow1} = \tilde{X}_{1\rightarrow2}$, and $\hat{X}_{1\rightarrow1} = \hat{X}_{1\rightarrow2}$. The objective function used for training AutoVC is

$$\begin{aligned}\mathcal{L} =& \mathrm{E}[|X_1 - \hat{X}_{1\rightarrow1}|_2^2] + \\ & \mu\mathrm{E}[|X_1 - \tilde{X}_{1\rightarrow1}|_2^2] + \\ & \lambda\mathrm{E}[|E(X_1, S_1) - E(\hat{X}_{1\rightarrow1}, S_1)|_1]\end{aligned} \qquad (1)$$

The first term is the reconstruction loss between the original and reconstructed harmonic spectral envelopes. The second term is a reconstruction loss between the original and initially estimated harmonic spectral envelopes, which empirically helps model convergence. The third term is a latent regressor loss [19] penalizing differences in encodings between the original and converted harmonic spectral envelopes. In practice, hyperparameters μ and λ can be set to 1 [15]. The model is trained as an autoencoder, with the hope that its bottleneck will be small enough to disentangle speaker identity but large enough to allow for an accurate reconstruction.

During inference, S_2 can be set to the speaker embedding of some target singer to perform a conversion. Given a source pitch contour F_1 extracted during WORLD analysis, the target pitch contour F_2 should be adjusted to accommodate the register of the target singer, and therefore, $F_2 = F_1 + F_{\Delta1\rightarrow2}$. The pitch shift $F_{\Delta1\rightarrow2}$ can be determined automatically by measuring the median pitches of source and target performances, and taking their difference rounded to the nearest octave. The aperiodicity spectral envelope of the source performance $X_{1,AP}$ is used as is. The converted audio waveform $\hat{x}_{1\rightarrow2}$ is computed by feeding the transformed harmonic spectral envelope, source aperiodicity spectral envelope, and target pitch contour F_2 as input to the WORLD synthesis engine.

2.2 Fixed encoder model

The second architecture is similar to AutoVC, but replaces the encoder $E(\cdot)$ with a number of conditioning signals, such as those found in [2]. By design, these conditioning signals encode the input in a speaker-independent way using explicit features, akin to the timbre transfer networks in [18]. We capture linguistic content using phonetic posteriorgrams (PPGs) extracted from a phoneme classifier $E_p(\cdot)$, as in [17]. The classifier passes 40 Mel frequency cepstral coefficients (MFCCs) per frame through two bidirectional LSTMs with 128 units per direction. A final dense layer with softmax activation yields the classifier output, which is compared to ground truth labels using a categorical cross-entropy loss during training. We trained the network on the TIMIT dataset [20], using its prescribed training and test sets. The dataset consists of audio and sample level timestamps of phonetic transitions from one of 61 classes (including a silence class). The output of the phoneme classifier is, therefore, a 61-dimensional vector at each time frame. The classification accuracy on the test set is 65%, which is found to be sufficient to act as a speaker-independent representation of linguistic content.

We extract loudness information (L) using the computational steps $E_l(\cdot)$ as in [21]. We compute an A-weighted power spectrum, which puts greater emphasis on higher frequencies. The result is aggregated across all frequencies and converted to decibels to produce a loudness value (in dbA) at each time step. Lastly, we include the target pitch contour F_2.

The decoder concatenates the target pitch contour F_2, $P_1 = E_p(x_1)$, $L_1 = E_l(x_1)$ with the target speaker embedding S_2. The inclusion of these different conditioning signals attempts to account for timbral changes which may vary as a function of the pitch and dynamics of a particular performance, while instructing the decoder of its underlying linguistic content. The decoder network is almost identical to that in AutoVC, except that we remove the upsampling operation as we no longer need to construct an information bottleneck for speaker disentanglement. We refer to this architecture as the fixed encoder model, because all conditioning signals are either computed without a neural network, or using a pretrained neural network whose weights are frozen during the training of the decoder network. The training objective is similar to that in Eqn. (1), except that the third term is no longer applicable and is therefore removed. Note that in this case, the source harmonic spectral envelope X_1 is never actually passed as input to the network, but is used as a target for reconstruction during training.

2.3 Architecture comparisons

We notionally discuss the potential advantages and disadvantages associated with the architectures proposed here. The main advantage of the AutoVC architecture is that it does not rely on a dedicated training set for extracting phonetic information. This information is learned by the encoder itself during model training. This could potentially have better implications for cross-lingual applications, in the case that the set of phoneme labels of a dataset itself introduces a language bias [22]. It does, however, incur some risk, as the encoder is solely responsible for learning all timbral variations in vocalization. It also requires a temporal downsampling/upsampling of its encoding to create an information bottleneck for speaker disentanglement, which has some additional latency implications in the decoder. The fixed encoder architecture is computationally less intensive, as the phoneme classifier is substantially smaller than the encoder network in AutoVC. It also avoids the need for temporal downsampling/upsampling. The main disadvantages of this architecture is the reliance on data to train a phoneme classifier, as well as the fact that its expressivity is limited to that provided by its conditioning signals.

2.4 Universal Background Model (UBM)

While we could simply train SVC networks "from scratch" on singing voice datasets, we consider leveraging the interesting fact that the use of speaker embeddings for encoding vocal identity (instead of one-hot labels) allows the system to be trained on unlabeled data. Arguably, any "clean"

speech or singing voice clip could now be used for training SVC systems. It is generally understood that there is significantly more speech data than their is singing voice data for research purposes. Borrowing nomenclature from the speech recognition community, an initial pretraining on large speech corpora is like training a UBM [23] from which other networks can be adapted for the more specific SVC task. We would hope that such a model would serve as a better initial condition for training a SVC network than random weights, and that the resulting system would at the very least generalize to more voices.

3. EXPERIMENTAL RESULTS

3.1 Experimental setup

Two datasets are used for training conversion networks in this work. We use the VCTK corpus, which consists of over 40 hours of speech from 109 speakers [24]. This corpus serves as both a supervised speaker dataset to compare performance between supervised and (unsupervised) zero-shot networks, as well as a sufficiently large dataset for training a UBM for further model fine tuning. As in [15], we retain 90% of the data of each speaker for training, and save the remainder as a test set. Additionally, we use a proprietary and unlabeled dataset consisting of 7 hours of singing voice data, which we simply call the SVC dataset. Again, we retain 90% of the data for training, and save the remainder as a test set. Note that the lack of labels in this dataset poses no problem for zero-shot network training.

We make use of an open-source speaker embedding network [1] pretrained to minimize the Generalized End-to-End Loss [14]. This speaker embedding network generates a 256-dimensional speaker embedding from a 40-band Mel spectrogram using an LSTM architecture and retaining only the output from the final time step. During training, we use an entire utterance for x'_1, whereas x_1 is a 2 second cut from the same utterance. The speaker embedding network and the phoneme classifier are pretrained and frozen during the training of the conversion networks.

All models operate at 16 kHz with a frame rate of 12.5 ms, and were trained with a batch size of 2 using the ADAM optimizer and a learning rate of 10^{-3}. We train four configurations for each model architecture described here. The first configuration, VCTK (one-hot), is trained on the VCTK corpus using the labels provided by the dataset, which are converted to a one-hot representation and fed as S_1 to the network. This configuration serves as a baseline to compare against its zero-shot counterpart. The second configuration, VCTK (zero-shot), is trained on the VCTK corpus using speaker embeddings for S_1. The first two configurations are each trained for 150,000 steps. In the third configuration, SVC (zero-shot), we train zero-shot architectures on the SVC dataset for 500,000 steps. In the final configuration, VCTK→SVC (zero-shot), the second configuration is used as an initial state, and training is resumed for 350,000 steps on the SVC dataset (for a total of 500,000 steps). For audio examples, please visit the

demo site [2] associated with this paper.

3.2 Performance assessment

We assess networks by both qualitative and quantitative means. The main goal of this paper is to illustrate that speaker embeddings networks can indeed be utilized for training zero-shot SVC networks. Since we are unaware of any other published methods for zero-shot SVC such as the ones introduced here, and in order to provide some form of comparative analysis, we focus our attention to analyzing differences in results between the training configurations outlined here. For our quantitative evaluation, we report the reconstruction loss for each network (the first term in Eqn. (1)), which when computed on harmonic spectral envelopes, effectively serves as a Mel cepstral distortion metric. For our qualitative evaluation, we conducted surveys with 15 participants within our organization who have some critical listening experience, and tabulated mean opinion scores (MOS). We conduct separate surveys for overall conversion quality and on similarity to the target voice. While we provide examples from both architectures in the supplementary material of this work, we restrict ourselves to samples generated from training variants of the fixed encoder architecture for subjective evaluations. The first reason for this restriction is simply to minimize the number of listening options so as not to overwhelm participants taking part in the survey. The second reason is because the inclusion of one-hot speaker labels for S_1 in the encoder network of AutoVC would require that input source samples come from its closed speaker set. Therefore, it is not practically possible to use the VCTK (one-hot) training configuration on AutoVC on singing voice examples without removing S_1 from the network, leading to a potentially unfair comparison.

The results of our quantitative analysis assessed on both the VCTK and SVC datasets are shown in Tables 1 and 2, respectively. Across both architectures, we can confirm that the replacement of one-hot labels with speaker embeddings does not dramatically hurt conversion performance.

	AutoVC	Fixed Encoder
VCTK (one-hot)	0.1837	**0.1882**
VCTK (zero-shot)	**0.1634**	0.1891
SVC (zero-shot)	0.2930	0.3590
VCTK→SVC (zero-shot)	0.2557	0.3232

Table 1. Reconstruction loss on the VCTK test set.

	AutoVC	Fixed Encoder
VCTK (one-hot)	N/A	N/A
VCTK (zero-shot)	0.3007	0.4314
SVC (zero-shot)	0.1650	0.1959
VCTK→SVC (zero-shot)	**0.1439**	**0.1850**

Table 2. Reconstruction loss on the SVC test set.

---

[2] https://sites.google.com/izotope.com/ismir2020-audio-demo

In fact, we see that for the AutoVC architecture, VCTK (zero-shot) actually outperforms VCTK (one-hot), while offering the added functionality of zero-shot adaptation to new unseen voices. This result is consistent with the findings in [15]. We note that there is a significant degradation in performance assessed quantitatively when applying either VCTK (zero-shot) directly to singing voice samples, or when applying SVC networks directly to VCTK samples, highlighting that there is indeed a mismatch between the speech and singing voice domains. There is a consistent improvement when using our proposed adaptation strategy, with VCTK→SVC (zero-shot) outperforming SVC (zero-shot), both in the speech domain and more importantly, in the singing voice domain of interest. Overall, the best performing approach for singing voice based on this quantitative evaluation is AutoVC trained using VCTK→SVC (zero-shot) training configuration, though the computationally lighter, fixed encoder model does perform comparably well. It is worth noting that the VCTK (one-hot) configuration is not applicable for evaluation on the SVC dataset as it does not have the immediate ability to adapt to new voices.

The results of our qualitative analysis, converting singing voice performances using target voices from both the VCTK and SVC test sets are shown in Tables 3 and 4, respectively. First and foremost, we observe that speaker embeddings networks can, in general, be used for zero-shot SVC. We note that conversion networks trained on speech can be used on singing voice, but they have some trouble maintaining consistent spectral envelopes over prolonged vowels. Lastly, while not formally a part of the subjective evaluation, we informally observe comparable performance between architectures, with a preference towards one architecture over the other on a per-case basis.

With target voices from VCTK, there is no remarkable difference between networks trained using one-hot speaker labels or using zero-shot speaker embeddings, but the latter naturally allows adaptation to new voices. While SVC (zero-shot) is trained to be adapted to properties of singing voice, it is trained on less data and has been exposed to fewer voices. Though it was able to generate voices resembling the VCTK target voices due to its zero-shot nature, and worked comparably to other methods, it understandably received the lowest MOS in this case. The networks trained on the SVC dataset are more successful when using target voices from the SVC test set (and again, are better adapted to the time scale of phonetic transitions in singing). In this case, there is some degradation in quality for the system trained using the VCTK (zero-shot) configuration, and the VCTK (one-hot) configuration is not even applicable. We again see an improvement for networks trained using VCTK→SVC (zero-shot) relative to SVC (zero-shot) in this scenario. In fact, the VCTK→SVC (zero-shot) training configuration outperforms other methods in terms of overall quality for both VCTK and SVC target voices. The VCTK (zero-shot) and VCTK→SVC (zero-shot) training configurations are the top performers in terms of voice similarity for VCTK and SVC target

	Quality	Similarity
VCTK (one-hot)	2.377	2.828
VCTK (zero-shot)	2.447	**3.051**
SVC (zero-shot)	2.289	2.549
VCTK→SVC (zero-shot)	**2.476**	2.664

Table 3. Mean opinion scores on singing voice with target voices from the VCTK test set with fixed encoder model.

	Quality	Similarity
VCTK (one-hot)	N/A	N/A
VCTK (zero-shot)	2.154	2.610
SVC (zero-shot)	2.477	2.772
VCTK→SVC (zero-shot)	**2.674**	**2.937**

Table 4. Mean opinion scores on singing voice with target voices from the SVC test set with fixed encoder model.

voices, respectively.

Lastly, we further exemplify the zero-shot nature of our proposed method by subjecting our system to target voices outside of the VCTK and SVC datasets. These examples were generated without any further training of models and using just 1-2 seconds of audio from a target voice in order to compute speaker embeddings. While quality and voice similarity could obviously be improved by further model fine tuning on more data from target voices, it is apparent that the system can generate reasonable conversions resembling the voices from the reference material in a zero-shot manner.

4. CONCLUSION

In this paper, we propose the application of speaker embedding networks for zero-shot SVC. We suggest two architectures for carrying out zero-shot SVC using the WORLD vocoder for modeling singing voice. Overall, we find that speaker embeddings can indeed be used directly for zero-shot SVC. Moreover, zero-shot networks replacing one-hot speaker labels with speaker embeddings perform as well as (or even better than) their supervised closed set counterparts, with the invaluable added benefits that they can be trained on unlabeled data and can potentially adapt to new voices without requiring further training. Furthermore, we show that there is some benefit to training zero-shot SVC networks by adapting an initial model trained on large amounts of speech data. In future work, we will investigate learning latent factors which can allow for further expressive manipulation of conversion results. While some initial progress to this end has been made using Gaussian Mixture VAEs (GMVAEs) [11], they have largely been limited to sung vowels. We can likely generalize this to more practical singing voice by utilizing the conditioning signals used in this work. We are also interested in replacing the WORLD vocoder with learned vocoders based on differentiable digital signal processing, as in [18, 25], in order to enable lightweight end-to-end training.

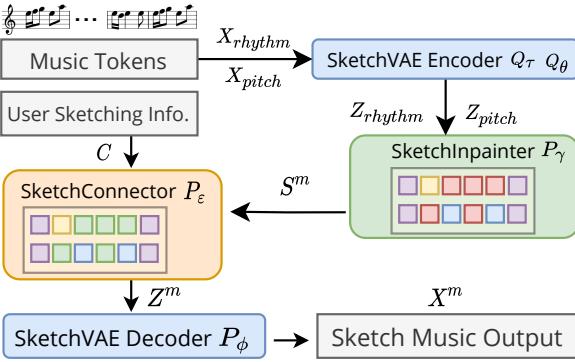
ABSTRACT

Drawing an analogy with automatic image completion systems, we propose Music SketchNet, a neural network framework that allows users to specify partial musical ideas guiding automatic music generation. We focus on generating the missing measures in incomplete monophonic musical pieces, conditioned on surrounding context, and optionally guided by user-specified pitch and rhythm snippets. First, we introduce SketchVAE, a novel variational autoencoder that explicitly factorizes rhythm and pitch contour to form the basis of our proposed model. Then we introduce two discriminative architectures, SketchInpainter and SketchConnector, that in conjunction perform the guided music completion, filling in representations for the missing measures conditioned on surrounding context and user-specified snippets. We evaluate SketchNet on a standard dataset of Irish folk music and compare with models from recent works. When used for music completion, our approach outperforms the state-of-the-art both in terms of objective metrics and subjective listening tests. Finally, we demonstrate that our model can successfully incorporate user-specified snippets during the generation process.

1. INTRODUCTION

As a research area, automatic music generation has a long history of studying and expanding human expression/creativity [1]. The use of neural network techniques in automatic music generation tasks has shown promising results in recent years [2]. In this paper, we focus on a specific facet of the automatic music generation problem on how to allow users to flexibly and intuitively control the outcome of automatic music generation. Prior work supports various forms of conditional music generation. MuseGan [3] allows users to condition generated results on full-length multi-track music. DeepBach [4] provides a constraint mechanism that allows users to limit the generated results to match composer styles. Music Trans-

Figure 1. The music sketch scenario. The model is designed to fill the missing part based on the known context and user's own specification.


former [5] supports a accompaniment arrangement from an existing melody track in classical music. However, all these approaches require the user preference to be defined in terms of complete musical tracks.

Inspired by the sketching and patching work from computer vision [6–10], we propose Music SketchNet [1] which allows users to specify partial musical ideas in terms of incomplete and distinct pitch and rhythm representations. More specifically, we generalize the concept of sketching and patching – wherein a user roughly sketches content for a missing portion of an image – to music, as depicted in Figure 1. The proposed framework will complete the missing parts given the known context and user input. To the best of our knowledge, there has been limited work on sketching in music generation. Some work [4,11] has used Markov Chain Monte Carlo (MCMC) to generate music with given contexts or generate music conditioned on simple starting and ending notes [12]. The most related task is music inpainting: completing a musical piece by generating a sequence of missing measures given the surrounding context, but without conditioning on any form of user preferences. Music InpaintNet, [13] completes musical pieces by predicting vector representations for missing measures, then the vector representations are decoded to output symbolic music through the use of a variational autoencoder (VAE) [14].

Our proposed music sketching scenario takes music in-

Figure 2. The Music SketchNet pipeline. The color patterns inside Inpainter and Connector correspond to the latent space transform and completion process in Figure 1.

painting a step further. We let users specify musical ideas by controlling pitch contours or rhythm patterns, not by complete musical tracks. The user input is optional: users can choose to specify musical ideas, or let the system fill in predictions without conditioning on user preferences.

Music SketchNet consists of three component, as depicted in Figure 2: (1) SketchVAE is a novel variational autoencoder that converts music measures into high dimensional latent variables. By the use of a factorized inference network, SketchVAE decouples latent variables into two parts: pitch contour and rhythm, which serve as the control parameters for users. (2) SketchInpainter contains stacked recurrent networks to handle the element-level inpainting prediction in the latent space. (3) SketchConnector receives users' sketches of pitch, rhythm, or both, combines them with the prediction from SketchInpainter, and finalizes the generation.

In this paper, we show that the proposed Sketch-VAE is capable of factorizing music input into latent variables meaningfully, and the proposed SketchInpainter/SketchConnector allows users to control the generative process. The novel training and evaluation methodologies of the SketchConnector are also presented.

2. MUSIC SKETCHING

We formalize the music sketching task as solving the following three problems: (1) how to represent music ideas or elements, (2) how to generate new materials given the past and future musical context and (3) how to process users' input and integrate it with the system. A visualization of the sketching scenario is depicted in Figure 1.

We propose three neural network components to tackle the three problems. The SketchVAE encodes/decodes the music between external music measures and the learned factorized latent representations. The SketchInpainter predicts musical ideas in the form of the latent variables given known context. And the SketchConnector combines the predictions from SketchInpainter and users' sketching to generate the final latent variables which are sent into the SketchVAE decoder to generate music output. A diagram

showing the proposed pipeline is shown in Figure 2.

2.1 Problem Definition

More formally, the proposed sketch framework can be described as a joint probability model of the missing musical content, X^m, conditioned on the past, future, and user sketching input. The joint probability breaks down into a product of conditional probabilities corresponding to subcomponents of the framework:

$$P_{\phi,\varepsilon,\gamma,\theta,\tau}(X^m, Z, S|X^p, X^f, C) =$$

$$P_\phi(X^m|Z^m) \qquad \text{(SketchVAE Decoder)}$$

$$* P_\varepsilon(Z^m|S^m, C) \qquad \text{(SketchConnector)}$$

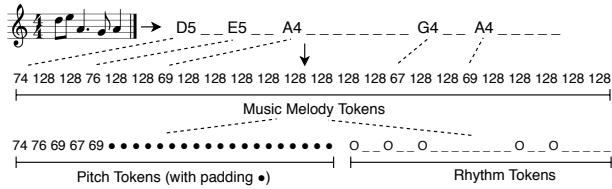
$$* P_\gamma(S^m_{pitch}|Z^p_{pitch}, Z^f_{pitch}) \qquad \text{(SketchInpainter)}$$

$$* P_\gamma(S^m_{rhythm}|Z^p_{rhythm}, Z^f_{rhythm}) \quad \text{(SketchInpainter)}$$

$$* Q_\theta(Z^p_{pitch}, Z^f_{pitch}|X^p_{pitch}, X^f_{pitch})$$

$$* Q_\tau(Z^p_{rhythm}, Z^f_{rhythm}|X^p_{rhythm}, X^f_{rhythm})$$

$$\text{(SketchVAE Encoders)}$$

X indicates the input/output music sequence, Z is the sequence for $\{z\}$ the latent variable , S is the SketchInpainter's predicted sequence, C is users' sketching input. The superscripts, p, m, f indicate the past, missing and future context. The subscripts, $pitch$ and $rhythm$ indicate the pitch and rhythm latent variables. Q_θ, Q_τ, P_ϕ are the SketchVAE pitch/rhythm encoders and decoder parameters, P_γ represents the SketchInpainter, and P_ε is the SketchConnector.


2.2 SketchVAE for Representation

MusicVAE [15] is one of the first works applying the variational auto-encoder [14] to music. MeasureVAE [13] further focuses on representing isolated measures and utilizes a hierarchical decoder to handle ticks and beats. EC^2-VAE [16] factorizes music measures with separate vectors representing pitch and rhythm by a single encoder and two decoders. Our proposed SketchVAE aims to factorize representations by introducing a factorized encoder that considers pitch and rhythm information separately in the encoder channels. Different from EC^2-VAE, it could allow users to enter parts of the information (rhythm and/or pitch) optionally.

SketchVAE aims to represent a single music measure as a latent variable z that encodes rhythm and pitch contour information in separate dimensions (z_{pitch}, z_{rhythm}). It contains (1) a pitch encoder $Q_\theta(z_{pitch}|x_{pitch})$, (2) a rhythm encoder $Q_\tau(z_{rhythm}|x_{rhythm})$, and (3) a hierarchical decoder $P_\phi(x|z_{pitch}, z_{rhythm})$ as shown in Figure 4.

2.2.1 Music Score Encoding

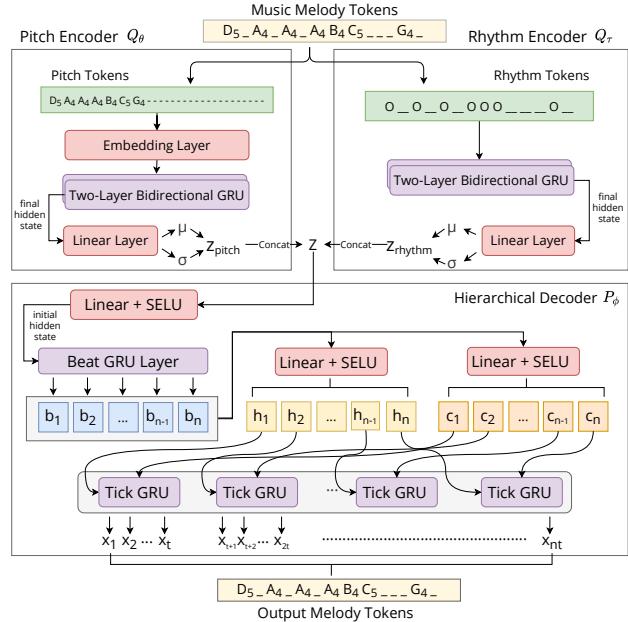
Similar to [15], we encode the monophonic midi melody by using [0, 127] for the note onsets, 128 for holding state, and 129 for the rest state. We cut each measure into 24 frames to correctly quantize eighth-note triplets like [13], and encode the midi as described in the previous sentence.

Figure 3. An example of the encoding of a monophonic melody.

As Figure 3 shows, we further process the encoded 24-frame sequence x into x_{pitch} and x_{rhythm}, the pitch and rhythm token sequences respectively. The pitch token sequence x_{pitch} is obtained by picking all note onsets in x with padding (shown by "•" in Figure 3) to fill 24 frames. The rhythm token sequence x_{rhythm} is obtained by replacing all pitch onsets with the same token (shown by "O" and "_" in Figure 3). A similar splitting strategy is also used in [17]. Our motivation is to provide users with two intuitive music dimensions to control, and to help enforce better factorization in the latent representation for later prediction and control.

2.2.2 The Pitch Encoder and Rhythm Encoder

After pre-processing x, x_{pitch} only contains the note value sequence, while x_{rhythm} only has the duration and onset information. x_{pitch} and x_{rhythm} are then fed into two different GRU [18] encoders for variational approximation. The outputs of each encoder are concatenated into $z = [z_{pitch}, z_{rhythm}]$.

2.2.3 The Hierarchical Decoder


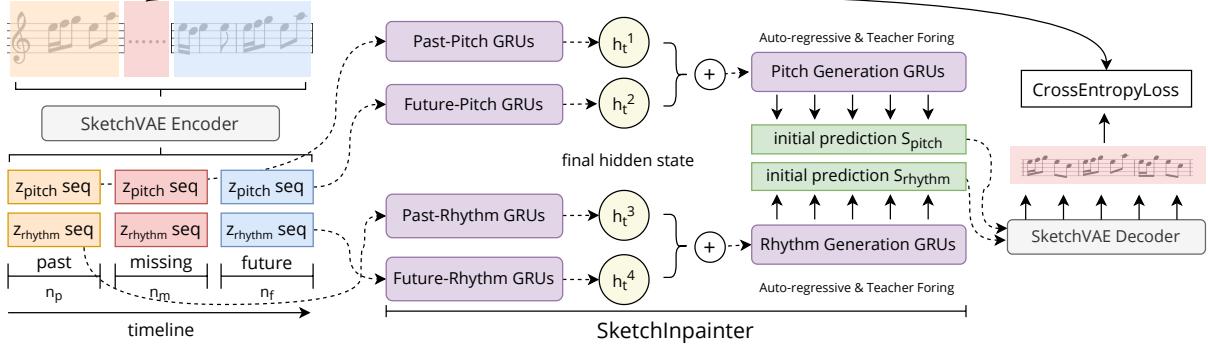
After we obtain the latent variable z, we feed it into the hierarchical decoder. This decoder is similar to the decoder used in MeasureVAE [13]. As shown in the bottom part in Figure 4, it contains an upper "beat" GRU layer and a lower "tick" GRU layer. This division's motivation is to decode z into n beats first and then decode each beat into t ticks. As a result, the note information in each measure will be decoded in a musically intuitive way. For the tick GRU, we use the teacher forcing [19, 20] and auto-regressive techniques to train the network efficiently. The output is conditioned frame-by-frame not only on the beat token but also on the last tick token.

2.2.4 Encoding the Past, Missing and Future Musical Context

The latent variable sequences Z^p, Z^m, and Z^f are then obtained by processing the music input in measure sequences X^p, X^m, and X^f. Both X^m and Z^m are masked during training. This encoding part is shown in the left block of Figure 5.

2.3 SketchInpainter for Initial Prediction

Next, we describe the model component that performs the music inpainting to predict latent representations for the missing measures. The SketchInpainter accepts Z_{pitch} and Z_{rhythm} as two independent inputs from SketchVAE.

Figure 4. SketchVAE structure: pitch encoder, rhythm encoder and hierarchical decoder. Rhythm tokens: the upper dashes denote the onsets of note, and the bottom dashes denote the hold/duration state. We use pitch symbols to represent the tokens numbers for better illustration.


Then only the past and future Z_{pitch} and Z_{rhythm} are fed into the pitch/rhythm GRU groups respectively. The output from each GRU group is the hidden state h, as shown in the middle of Figure 5.

Then we combine the past/future hidden states h from both the pitch and rhythm GRU groups and use them as the initial states for the pitch/rhythm generation GRUs. The generation GRUs then predict the missing latent variables by $S^m = (S_{pitch}, S_{rhythm})$, as shown in the green box in Figure 5. Each generation GRU is trained with the teach forcing and auto-regressive techniques.

Each output vector s^m from S^m has the same dimension as the latent variable z from Z. We first build a model with only SketchVAE and SketchInpainter that directly predicts the missing music material, X^m. As the right block of Figure 5 shows, S^m is sent into the SketchVAE decoder and we compute the cross entropy loss between the predicted music output and the ground truth. This is the stage I training in our model, detailed in Section 3.3.

2.4 SketchConnector for Finalization

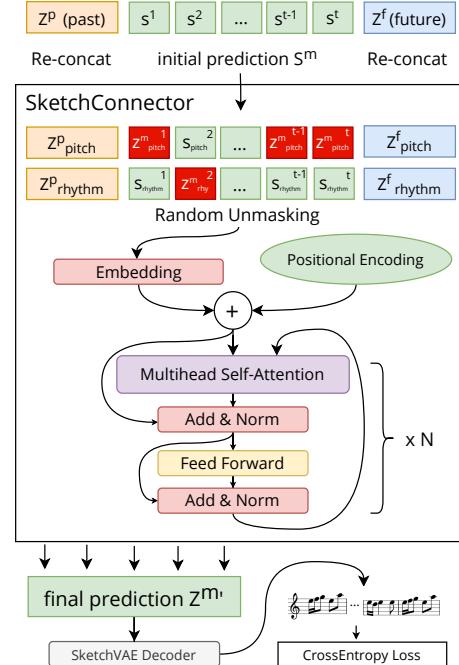
The predicted S^m from SketchInpainter can already serve as a good latent representation for the missing part X^m. We continue by devising the SketchConnector, $P_\varepsilon(Z^m|S^m, C)$, to modify the prediction with user control. To make up for the lack of correlation between pitch and rhythm in current predictions, we introduce the SketchConnector as a way to intervene/control the generative process, that also leads to a wider musical expressivity of the proposed system.

Figure 5. SketchInpainter structure. We feed the music tokens into the SketchVAE and obtain the latent variable sequences. And we feed the sequences into the pitch GRU and the rhythm GRU groups to generate the initial prediction S.

2.4.1 Random Unmasking

With S^m obtained from SketchInpainter, we concatenate it with Z^p and Z^f again. However, before we feed it back into the network, we randomly unmask some of the missing parts to be the ground-truth (simulating user providing partial musical context). The masked S^m are shown by the red boxes in Figure 6. We replace some s from S^m to be the real answer in Z^m, denoted as C. We observe that this optimization is very similar to BERT [21] training. The difference is that BERT randomly masks the ground truth labels to be unknown, but SketchConnector randomly unmasks the predictions to be truths. The unmasking rate is set to 0.3.

Intuitively, this allows the model to learn a more close relation among current rhythm, pitch tokens, and the nearest neighbour tokens. In the sketch inference scenario, the randomly unmasked measures will be replaced by the user sketching information, which allows a natural transition between the training and testing process.

2.4.2 Transformer-based Connector


Then with S^m and the random unmasking data C, we feed them into a transformer encoder with absolute positional encoding. In contrast to [5], we do not use relative positional encoding because our inputs are vectors representing individual measures, whose length is far shorter than midi-event sequences.

The output of the SketchConnector, Z^m, will be the final prediction for the missing part. We feed it into the SketchVAE decoder, and compute the cross entropy loss of the output with the ground-truth.

3. EXPERIMENT

3.1 Dataset and Baseline

To evaluate the SketchVAE independently, we compare our model with two related systems: MeasureVAE [13] and EC^2-VAE [16]. For SketchNet, we compare our generation results with Music InpaintNet [13], which has shown better results than the earlier baseline [12]. Similar to [13], we use the Irish and Scottish monophonic music

Figure 6. The SketchConnector: the output of SketchInpainter is randomly unmasked and fed into a transformer encoder to get the final output.

Dataset [22] and select the melodies with a 4/4 time signature. About 16000 melodies are used for training and 2000 melodies for testing.

3.2 SketchVAE Measurements

3.2.1 Reconstruction

For SketchVAE, MeasureVAE and EC^2-VAE, the dimension of latent variable $|z|$ is set to 256, half for the pitch contour, and the other half for the rhythm. We set the learning rate to 1e-4 and use Adam Optimization with $\beta_1 = 0.9$ and $\beta_2 = 0.998$. Three models achieve the accuracy (the reconstruction rate of melodies) 98.8%, 98.7%, 99.0% respectively. We can clearly conclude that all VAE models are capable of converting melodies to latent variables by achieving the accuracy around 99%. SketchVAE is capable of encoding/decoding musical materials in SketchNet.

Model	Irish-Test			Irish-Test-R			Irish-Test-NR		
	loss ↓	pAcc ↑	rAcc ↑	loss ↓	pAcc ↑	rAcc ↑	loss ↓	pAcc ↑	rAcc ↑
Music InpaintNet	0.662	0.511	0.972	0.312	0.636	0.975	0.997	0.354	0.959
SketchVAE + InpaintRNN	0.714	0.510	0.975	0.473	0.619	0.981	1.075	0.374	0.964
SketchVAE + SketchInpainter	0.693	0.552	0.985	0.295	0.692	0.991	1.002	0.389	0.977
SketchNet	**0.516**	**0.651**	**0.985**	**0.206**	**0.799**	**0.991**	**0.783**	**0.461**	**0.977**

InpaintNet	2.98	3.01	3.09
SketchNet	3.04	3.29	3.26

Table 2. Results of the subjective listening test.

3.2.2 Comparison with EC^2-VAE

EC^2-VAE [16] is also capable of decoupling the latent variable into rhythm and pitch contour dimensions. However, SketchVAE's encoders can accept pitch contour/rhythm inputs separately. Rhythm and pitch controls can be manipulated independently in the sketching scenario where the user might not specify an entire musical measure (e.g., just a rhythm pattern). By contrast, EC^2-VAE requires a completed measure before encoding. If users want to specify either rhythm or pitch controls, the model must first fill in the other half part before inputting it, which prohibits the possibility of the separate control.

3.3 Generation Performance

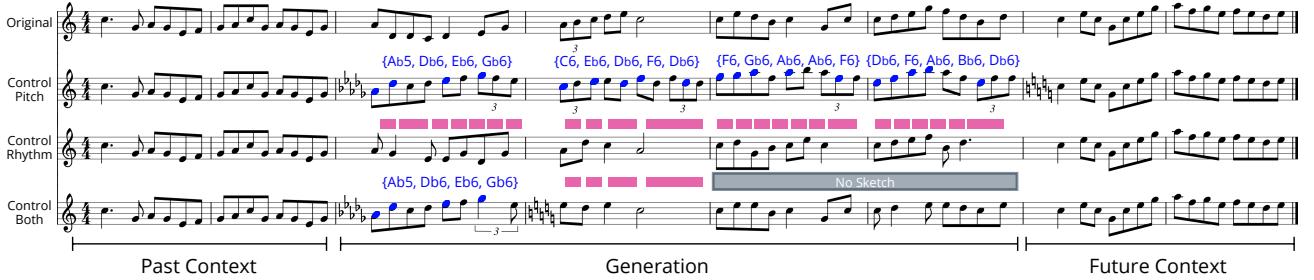
3.3.1 Training Results

The SketchNet's training is separated into stage I and II. In stage I, after training the SketchVAE, we freeze its parameters and train the SketchInpainter as shown in the right block of Figure 5. In stage II, with the trained SketchVAE and SketchInpainter, we freeze both, concatenate S^m with the past/future latent variables, and feed them to the SketchConnector for training.

We compare four models by using 6 measures of past and future contexts to predict 4 measures in the middle (i.e. $n_p = n_f = 6$, and $n_m = 4$). Music InpaintNet [13] is used as the baseline, along with several variations. Early stopping is used for all systems.

We compute three metrics: loss, pitch accuracy, and rhythm accuracy to evaluate the model's performance. The pitch accuracy is calculated by comparing only the pitch tokens between each generation and the ground truth (whether the model generates the correct pitch in the correct position). And the rhythm accuracy is calculated by comparing the duration and onset (regardless of what pitches it generates). The overall accuracy and loss are

negatively correlated.

For this part of the experiment, we also use two special test subsets. We compute the similarities between the past and future contexts of each song in the Irish test set, pick the top 10% similar pairs (past and future contexts are almost the same) and bottom 10% pairs (almost different), and create the Irish-Test-R (repetition) and Irish-Test-NR (non-repetition) subsets.


From Table 1, we can see that SketchNet beats all other models for all test sets. The performance improved more for pitch then for rhythm. The accuracy is almost the same between the 1st and 2nd model. Accuracy is slightly better if we use SketchInpainter to treat rhythm and pitch independently during generation. Lastly, with the power of transformer encoder and random unmasking process done in SketchConnector, we can achieve the best performance by using SketchNet (bottom row in Table 1). We further follow [23] to use the Bootstrap significance test to verify the difference between each pair's overall accuracy for models in the whole Irish-Test set (Four models, i.e. six pairs in total). The sample time is set to 10000. After calculation, all p-values except the fist and second model pair (p-value = 0.402) are less than 0.05, which proves that SketchNet is different from the left three models.

In the repetition test subsets, the loss of Music Inpaint-Net is 0.312, which is lower enough to capture repetitions in the musical context and fill in the missing part by copying. In most cases, copying is the correct behaviour because the original melody has repetitive pattern structures. The loss is a measurement to evaluate if the model can learn the repetitive pattern and copy mechanism from the data. the SketchNet slightly outperforms InpaintNet.

3.3.2 Subjective Listening Test

However, the more interesting result is the generation with non-repetition subset. In this case, models cannot merely copy because original melodies do not repeat its content. We see higher losses in all models in this subset compared to the repetition subset. Intuitively, it means that repetitive patterns are essential to the reconstruction task, not necessarily the expressivity of the generated output would be less.

To further evaluate the proposed SketchNet, we conduct an online subjective listening test to let subjects judge the generated melodies from the non-repetition subset. Each subject will listen to three 32-second piano-rendered

Figure 7. An example of sketch generation. From top to bottom: original, pitch/rhythm/mixture control. The blue pitch texts denote pitch controls, and the pink segments denote rhythm controls.

Control Info.	Rhythm	Pitch
Pitch Acc.	0.189	**0.881**

Table 3. The accuracy of the virtual control experiment.

melodies: the original, the Music InpaintNet's generation, and the SketchNet's generation. Songs are randomly picked from the Irish-Test-NR set. The beginning and ending (past & future) are the same for the three melodies. Since the subjective feeling of music is complicated to quantify, we chose three criteria: the number of notes (**complexity**), the repetitiveness between musical structures (**structure**), and the degree of harmony of the music (**overall musicality**). In this way, subjects with different levels of music skills can all give reasonable answers.

Before rating the songs, subjects will see three criteria descriptions as we introduced below. The rating is ranged from 1.0 to 5.0 with a 0.5 step. We collected 318 surveyed results from 106 subjects (each subject listens to three groups, nine melodies in total). The average rating of each criteria for all models are shown in Table 2. The subjective evaluations of all three criteria in SketchNet are better for those of Music InpaintNet. Similar to section 3.3.1, we also conduct a pairwise significance test via Bootstrap in three criteria. All p-values except the <complexity: InpaintNet, SketchNet> (p-value = 0.364) are less than 0.05. It proves that three models (including original songs) are significantly different in structure and overall musicality (subjective feeling to a person). As for the complexity, we believe that the results generated by the two models are similar in terms of the richness of notes, and our model does not significantly increase the number of notes generated.

3.4 Sketch Scenario Usage

The contribution of Music SketchNet is not only shown in the performance of the generation in section 3.3, but can also be shown in the interactive scenario where users can control the generated output by specifying the rhythm or pitch contour in each measure.

Figure 7 shows an example of a non-repetition subset melody, where the first and last two measures are given, and the middle parts is generated. The first track is the

original melody, the second track is generated with the pitch contour control, the third track is generated with the rhythm control, and the fourth track is controlled with both pitch and rhythm. We can see that each generated melody follows the control from users and develops music phrases accordingly in the missing part. Moreover, each measure is in line with the past and future measures even in the case of scale shift.

We also provide a "virtual control experiment" to statistically show that users' control did influence the model's generation process. We randomly collect 3000 sample pairs (A, B) from the Irish-Test set. And we use the pitch/rhythm of Sample B to be the sketch information in the same missing position of Sample A. Then we let the model make the generation. We then compute the pitch/rhythm accuracy [2] in the missing position between the generation and Song B. From 3 we can see if we sketch song B's rhythm into the model, the generation will follow the rhythm with 97.3% accuracy but has different (18.9%) pitches. However, when we sketch pitches, the pitches in the generation will be highly (88.1%) in line with the sketching. This proves that the user's control has a relatively high guiding effect on the result of the model generated at the specified position.

4. CONCLUSION & FUTURE WORK

In this paper, we propose a new framework to explore decoupling latent variables in music generation. We further convert this decoupling into controllable parameters that can be specified by the user. The proposed Music SketchNet achieves the best results in the objective and subjective evaluations. Practically, we show the framework's application for the music sketching scenario where users can control the pitch contour and/or rhythm of the generated results. There are several possible extensions for this work. Music elements other than pitch and rhythm can be applied into the music sketching scenario by the latent variable decoupling. Also, how to represent a polyphonic music piece in the latent space is another pressing issue. Both are future works that can generalize this model to more applied scenarios.

---

[2] The metric to calculate the pitch accuracy is different from section 3.3.1, because the generated pitches in the new song might have different onset positions. We leverage the Longest Common Sequence to calculate the accuracy. The implementation is presented in the code archive.

ABSTRACT

Music is hierarchically structured, in which the global attributes (e.g., the determined tonal structure, musical form) dominate the distribution of local elements (e.g., pitch, playing technique arrangement). Existing methods for instrumental playing technique detection mostly focus on the local features extracted from audio. However, we argue that structural information is critical for both global and local tasks, particularly considering the characteristics of guqin music. Incorporating mode and playing technique analysis, this study demonstrates that the structural relationship between notes is crucial for detecting mode, and such information also provides extra guidance for the playing technique detection in local-level. In this study, a new dataset is compiled for guqin performance analysis. The mode detection is achieved by pattern matching, and the predicted results are conjoined with audio features to be inputted into a neural network for playing technique detection. Advanced techniques are developed to optimize the extracted pitch contour from the audio. It is manifest in the results that the global and local features are inter-connected in guqin music. Our analysis identifies key components affecting the recognition of mode and playing technique, and challenging cases resulting from unique properties of guqin audio signal are discussed for further research.

1. INTRODUCTION

The guqin (古琴) is a plucked seven-string Chinese musical instrument existing for over 3,000 years, and has been selected as UNESCO World Cultural Heritage.[1] In guqin performance, it is an intrinsic convention for musicians to implement diverse playing techniques, in order to communicate their interpretations of the performed music. In the theory of guqin performance, such configuration of playing technique in local-level is considered to be connected and reflect the higher-level, hierarchical tonal structure in

---

[1] https://ich.unesco.org/en/RL/guqin-and-its-music-00061

pentatonic modes [1]. However, existing research does not appear to provide sufficient empirical evidence to support the theory. In particular, in the research area of Music Information Retrieval (MIR), key/mode detection has been regarded as the recognition of the overall, global construction of music piece, whereas playing technique detection is usually taken as a classification task relying on local features extracted from the audio. This study aims to solve this discontinuity, and argue that the global tonal structure and the local configuration of playing technique are interconnected in guqin performance. This work takes MIR and machine learning frameworks as the means for empirical music analysis, and contribute to several aspects including:

1) to design and compile a new dataset, GQ39, featured by representative historical guqin recordings and note-by-note annotations;
2) to demonstrate the importance of tonal structural information, and to identify the crucial components contributing to both the mode detection and playing technique detection;
3) to bridge the knowledge gap between the theory and empirical observations, as well as to highlight the connection between the high-level structure and local elements in music.

In the subsequent section, related research regarding the tonal structure investigation, playing technique classification, and guqin performance theories will be reviewed. The theoretical basis and the procedure to construct the GQ39 dataset will be described in Section 3. The mode detection is performed on the dataset, and the results are analyzed in Section 4. The playing technique is further investigated using a neural network, and decisive components playing important roles in the task are discussed in Section 5, followed by the concluding remarks in Section 6.

2. RELATED WORK

For the high-level tonal structure in music, key detection has been one of the core issues to be explored in Western tonal music. Methods based on chord progression rules are applied to detect key modulation in audio [2]. Neural networks are utilized for key classification, and it has been found that the global harmonic structure in the whole piece plays an important role to identify local keys of short segments [3]. In addition to the connection between the local and global tonal structures, it has also been proven that

different music styles are more easily to be classified by informing the global key and key-related pitch classes [4]. In Indian art music, the usage of raga achieves the structural coherence in music, and different types of raga can be identified according to their pitch distribution [5]. The implicit patterns of melodic and timing features in raga has also been explored [6]. In Arab-Andalusian music, its centonization is analyzed using a high-order n-gram model [7], and different music patterns, nawba, can be classified using template matching [8]. In Georgian music, its unique tuning system has been examined through melodic and harmonic aspects, and the structural relationship between pitch intervals has been found [9].

In previous studies of playing technique classification, diverse features are extracted from audio according to the traits of individual instruments. In particular, strings appear to be high-profile instruments in this research area. For electric guitar, note-level timbral and pitch features are considered to be major components for identifying different types of playing techniques [10], whereas for guitar, each playing technique possesses distinguishable cepstral and phase features [11]. In a study to classify plucking styles of electric bass guitar, intra-note attributes corresponding to the attack and decay parts of the notes are further examined using spectral and statistical descriptors [12]. In violin performance, note-level features including dynamics, vibrato rate and vibrato extent are proven to be connected with score-informed expressive schemes [13], and idiosyncratic performing styles of individual violinists can be characterized by their articulation, energy, and vibrato attributes [14].

In guqin performance, the fingering and playing techniques for strings pressing in the left hand have been regarded as a primary component to affect the expression and aesthetic perception of performance, especially since the late Ming dynasty (around the late 17th century) [15–17]. Furthermore, the left-hand techniques are not merely local ornaments attached to single musical events, and should be contemplated within the global context of complete music composition. As stated in conventional guqin performance theory, the hierarchical tonal structure in the mode can vastly affect the selection of playing technique in the practice of guqin performance [1, 18, 19]. The connection between the global tonal structure and local technique elements is manifest in guqin music theories, and such association between the mode and playing technique is also a prevailing, shared character in many Asian music cultures [20,21]. However, only few efforts have been devoted to explore empirical evidence regarding how the global and local aspects conjoin with one another in the actual performance practice [22, 23]. This study therefore aims to bridge the knowledge gap between the guqin music theories and the empirical observation, and explore the connection between the mode structure and the playing technique implement using statistics and machine learning.

3. GQ39 DATASET

Guqin music is constructed from diverse modes of pentatonic scale, and the performance carries distinctive ex-

Rank	Mode 1	Mode 2	Mode 3	Mode 5	Mode 6
1st	1	2	3	5	6
2nd	5	6	-	2	3
3rd	2	3	-	6	-

Table 1. The hierarchical structure in pentatonic scale (the top row): the 3 importance level for note degrees (the bottom row) in 5 modes (the middle row).

pressions in playing techniques. We therefore design and compile a new dataset for music performance analysis according to such properties.

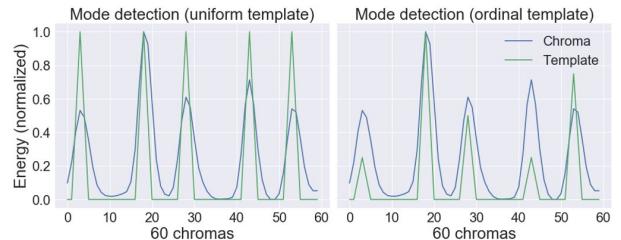
3.1 The guqin performance and pentatonic scale

Guqin performers pluck strings by their right hands and press strings using left hands for performing. Guqin performance is characterized by its flexibility, which render plenty of freedom for musicians to choose a wide selection of playing techniques to perform the same piece of music. In particular, the usage of vibrato and portamento is central among all playing techniques to carry the representative traits of individual music pieces and musicians.

The pentatonic scale (see the top row of Table 1 as an example) forms the main construction of guqin music. While other altered chromatic tones and microtones can be included, the pentatonic scale retain the central position in guqin compositions. The pentatonic scale can be transformed into 5 different modes, each of which has a different order of notes according to its initial degree: mode 1 (mode Gong (宫); degree 1, 2, 3, 5, 6), mode 2 (mode Shang (商); degree 2, 3, 5, 6, 1), mode 3 (mode Jue (角); degree 3, 5, 6, 1, 2), mode 5 (mode Zhi (徵); degree 5, 6, 1, 2, 3), and mode 6 (mode Yu (羽); degree 6, 1, 2, 3, 5). Each mode has its own hierarchical structure, which is achieved by assigning different importance levels to note degrees based on the Circle of Fifths. In each mode, at most 3 notes can be considered as prominent component (equivalent concept to the Tonic, Dominant, and Subdominant in Western major and minor scales, see the lower two rows in Table 1) [1, 19]. It should be noted that the pentatonic scale only denotes the relative intervals between notes, but not the absolute pitches, which means that the degree 1 in the scale can be assigned to any pitch in 12 semitones.

3.2 Data collection and labelling

The GQ39 dataset consists of 39 audio recordings of prevalent guqin solo compositions and corresponding event-by-event annotations. The audio data are extracted from a massive collection of guqin historical recording, with the recording years ranging from 1960 to 1990 [24]. 39 excerpts played by five different guqin performers are se-

lected according to a professional guqin musician's opinion (with the performing experience of 18 years). The 39 selected audio excerpts cover representative composing and performing styles and contain diverse playing techniques. The GQ39 dataset only includes guqin music in mode 1, 2, and 5, on account of the facts that: 1) the 2 modes with less than 3 important notes (mode 3 and mode 6) are considered as having less stable structure; 2) mode 3 is only occasionally applied to guqin composition; 3) guqin music composed by mode 6 is relatively complicated, which is not applicable for this exploratory study. The collected audio recordings are roughly 2,000 seconds long in total.


Considering the typical feature of guqin playing, we define an event as a plucking movement in the right hand, which may correspond to either one single note, or a series of note pitch variations and sliding movements in the left hand (ranging up to 5 semitones). Each event is then annotated with 13 types of label by professional guqin musicians, including 2 music-level features (tuning, mode), and 11 event-level features regarding the event context (note degree, pitch range), playing techniques in the right hand for plucking (plucked string, plucking finger, plucking technique type), playing techniques in the left hand for string pressing (pressed position, pressing finger, technique type for pitch variation, technique type for timbre variation), and performing matters (event onset, event duration). As the result, the GQ39 dataset comprises 2,303 annotated events in total (mean # of event = 59.1, SD = 29 per excerpt). The annotations are available on the website, together with details regarding the annotation procedure and dataset descriptions. [2]

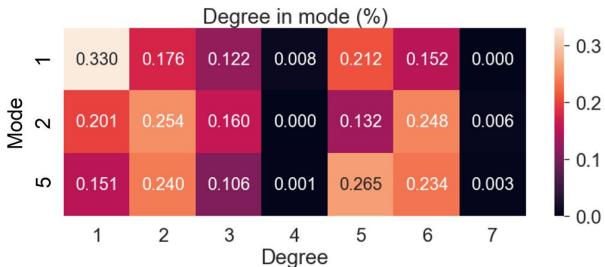
4. MODE DETECTION AND ANALYSIS

In this section, we examine mode, the global tonal structure in guqin performance. Chromas are derived from audio recordings. Two types of template representing the tonal structure are designed for pattern matching. The statistical analysis reveals that the inherent characters of mode construction are reflected in the performance. And the results of mode detection indicate that the hierarchical configuration is a crucial element to identify different modes.

4.1 Data representation and mode matching

In mode detection, three types of data are obtained from audio data: the chroma representation of constant-Q transform (CQT), pitch salience function, and pitch contour. For the first type of data, the chromagrams of audio recordings are derived using CQT [25]. For the second and the third types of data, the pitch estimation network, Crepe, is applied to estimate the pitch salience function and the pitch contour [26]. For all types of data, we obtain 60 chromas instead of 12 chromas per octave for higher pitch resolution, considering the facts that: 1) the tuning in guqin is not equal temperament, and 2) the dataset contains large amounts of protamento and transitions between semitones.

Figure 1. The mode detection with 2 template types: the uniform template (left) and the ordinal template (right). This instance shows the mode 5 template, with degree 5 being shifted to the position of 18 in x-axis.

For each recording, the energy of each chroma is accumulated and is normalized to the range between 0 and 1.


We design two types of mode template, i.e., the uniform template and the ordinal template (see Figure 1 as examples), to be matched up with the chroma representation from audio. For each mode, the *uniform mode template* is constructed by denoting the positions of note degrees as 1 and otherwise 0 in 12 semitones (e.g., mode 1 = (1,0,1,0,1,0,0,1,0,1,0,0)). In addition to the degree positions, the *ordinal mode template* includes the information regarding the importance level of degrees. The degree positions are represented as 4, 3, 2 individually following the order of importance ranking in Table 1, and the two trivial degrees are marked as 1, otherwise 0 in 12 semitones (e.g., mode 1 = (4,0,2,0,1,0,0,3,0,1,0,0)). The two 12-D templates are extended to 60-D for the subsequent matching with 60-chroma representation (each chroma unit represents 20 cents). Complying the treatment procedure for audio chroma representation, all mode templates are normalized to the range between 0 and 1.

The chroma representation of each music excerpt is then matched with mode templates. The built mode templates are shifted to the position of 60 chromas in turn, and are then compared with the audio chroma representation using Pearson correlation. This procedure results in 360 matching pairs for per music excerpt (2 template types (uniform/ordinal) x 3 modes (mode1/2/5) x 60 chroma shifts). The mode is determined by the matching with the highest Pearson correlation coefficient.

4.2 Results and discussion

The statistics of the annotated note degrees reveal the structural configuration of modes, and such observation provides insights regarding how the music theory is practiced in actual performances. As stated in conventional music theories, mode 1 holds the most solid construction among all modes [18]. As can be observed in Figure 2, the note degrees with higher importance ranking usually occur more frequently in the composition (such as degree 1, 5, 2 in mode 1; degree 2, 6, 3 in mode 2; degree 5, 2, 6 in mode 5). Furthermore, in mode 1, the prominent roles of the three principal notes are settled by obvious differences of occurrence ratios, compared to two other trivial degrees. In the mode detection task, we can take a step

Figure 2. The statistics of the annotated degrees (x-axis) in different modes (y-axis) (in %).

Type	CQT		Salience		Contour	
Result	uni	ord	uni	ord	uni	ord
Correct #	14	**34**	19	29	17	30
Fifth #	4	**4**	5	8	6	8
Miss #	21	**1**	15	2	16	1
Accuracy	0.41	**0.92**	0.55	0.84	0.51	0.87

Table 2. The results of mode detection task (3 data types (CQT/ salience function/ pitch contour) x 2 template types (uniform/ ordinal)).

further to evaluate that how the structural configuration of mode affects the task outcome.

For the evaluation of mode detection, we follow the weighted accuracy used in the audio key detection campaign in MIREX.[3] The instance is marked as 1 point when the prediction is the same mode as the ground truth, whereas 0.5 points is marked when the predicted mode is in perfect fifth above the ground truth (i.e. mode 1 is predicted as mode 5). The results are shown in Table 2. It is evident that all the tasks with ordinal mode template outperform their counterparts applying uniform template. In fact, the *t*-test for the prediction accuracy using uniform/ ordinal template yields a two-tailed *p*-value of 0.0013, which indicates a significant difference between the tasks adopting/ without the structural configuration of mode. To incorporate the statistics of annotated notes with the results of mode detection, above analyses lead to the finding that the information regarding the hierarchical configuration in mode contributes vastly in the mode detection.

5. PLAYING TECHNIQUE DETECTION AND ANALYSIS

In this section, we investigate the classification of left-hand playing technique in guqin performance, and also examine the interaction between global and local features during the classification. Frame-level together with mid-level and high-level features are obtained from audio data and annotations. Dynamic programming is applied to optimize the extracted pitch contour. Six types of playing techniques are then classified using a neural network. The statistical analysis indicates that the hierarchical tonal configuration is embedded in the distribution of portamento types. The classification results suggest that mid-level and high-level features can facilitate the recognition of technique type in local-level. Major components to improve the classification are identified. Challenging cases are further discussed.

5.1 Data extraction

In playing technique detection, three types of data are derived from audio recordings. For the first and second types of data, we acquire the spectrogram using CQT, and obtain the pitch salience function using Crepe following the procedure stated in Section 4.1. For the third type of data, we further apply dynamic programming to eliminate the

---

[3] https://www.music-ir.org/mirex/wiki/2019:Audio_Key_Detection

spikes in the estimated pitch contour. Given the output of Crepe $X \in \mathbb{R}^{K \times N}$, the pitch salience function at time s_i is $X[:, s_i]$, K is the number of frequency bins, and N is the number of frames, the pitch contour $\mathcal{S} := \{s_i\}_{i=1}^N$ is extracted with the following objective function:

$$\mathcal{S}^* = \arg\max_{\mathcal{S}} \sum_{i=1}^N X[:, s_i] - \lambda \sum_{i=2}^N |s_{i+1} - s_i|. \quad (1)$$

Equation (1) can be solved with dynamic programming [27]. The seconds term of (1) is to enhance the smoothness of the extracted pitch contours. The parameter λ controls the smoothness of the pitch contour, and in this work we set $\lambda = 10^{-3}$. This facilitates the processing of those guqin historical recordings with relatively low audio quality.

Six types of playing techniques are labelled for the pitch variation movement in the left hand: *none* (such as 直按 and 散音), *vibrato* (such as 吟 and 猱), *upward portamento* (such as 綽 and 上), *downward protamento* (such as 注 and 下), *inverted-U protamento* (such as 進復 and 撞), and *U protamento* (such as 退復 and 豆). The three types of data mentioned above are then divided into event segments according to the onset and duration annotations, and each segment corresponds to one of the six technique types. Figure 3 illustrates the featured pitch contour and examples of event segments in 6 technique types. The segments are then treated with padding, resulting the the input segment size of cqt (156, 60), pitch salience function (361, 60), and pitch contour (361,).

In order to investigate that how the meta-, structural music features connect with technique implements in local-level, we further extract 62 high-level and mid-level features including 2 *music-level features* (mode, # of event in music), 12 *event-level features* (event duration, event index, note degree, importance ranking of degree, also 8 descriptive statistical indicators of pitch contour (the mean, maximum, minimum, range, standard deviation, skewness, kurtosis, the time difference between the maximum and minimum)). The first six features (the two features in music-level and the first four features in event-level) are obtained from the prediction of our mode detection model as described in section 4. The eight descriptive indicators are extracted from dynamic programming pitch contour. Since the critical traits of each technique type may appear in different parts of the overall pitch contour, we also extract *intra-event-level features* by computing the eight descriptive statistical indicators for six intra-event pitch con-

Figure 3. The CQT (middle) and pitch salience segments (right) corresponding to the six technique types of guqin.

Data type	CQT	Salience	Contour
Frame-level only	0.743	0.845	0.842
With mid-, high-level	0.840	0.839	0.842

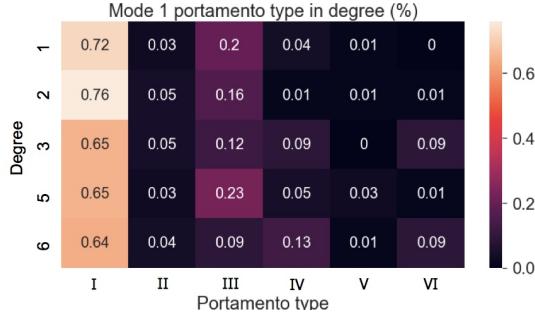
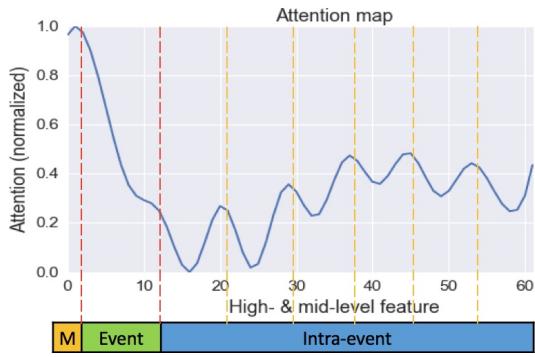
tour per event. To define the range of intra-event pitch contour, each segment is resampled to the mean length of all segments (0.7 seconds), and the resampled contour is divided by six hop windows (window size = 0.2 seconds, hop = 0.1 seconds), resulting 48 intra-event-level features for per musical event (8 indicators x 6 windows).

5.2 Playing technique classification

The playing technique is classified by a 10-layer neural network, which is composed of 2 convolutional layers (kernel = 3 x 3, stride = 1, fmap = 32), 1 self-attention layer (kernel = 1 x 1), and then followed by 3 convolutional layers (kernel = 3 x 3, stride = 1, fmap = 32), 3 fully-connected layers (neuron = 512), and a softmax output layer. The attention layer is constructed based on [28] to further investigate which high- and mid- level elements affect the results of technique classification in local level. The framework is implemented using Tensorflow. The training process is carried out by minimizing the cross-entropy between the model output and the one-hot label using Adam Optimizer with the learning rate of 10^{-5}. The dataset and the code to implement the model will be released afterward.

We design six experimental settings to examine the interaction between the global and local features. Three types of frame-level data: CQT, pitch salience function, and pitch contour with dynamic programming processing are inputted into the network respectively. They are then


associated with high-level and mid-level features derived from the prediction from the previous mode detection and labelled annotations, resulting six experimental settings in total (as shown in Table 3). For each setting, 10-fold cross-validation is performed (roughly 1800 seconds of audio recordings for training, and 200 seconds for testing).

5.3 Results and discussion


The statistical analysis shows that the distribution of portamento types reflects the high-level mode structure. As shown in Figure 4, except the type 1 technique without any pitch variation, type 3 portamento possesses highest occurrence ratio compared to other portamento types for important degrees in mode 1 (degree 1, 5, 2), and similar tendency can also be observed in other modes. This provides empirical evidence for the theoretical basis of guqin performing convention, where musicians frequently apply type 3 (upward) portamento to emphasize highlighted notes, and on the contrary, they tend to implement type 4 (downward) portamento to decorate trivial notes [16].

For the the results of technique classification, as can be seen in Table 3, the mid-level and high-level features contribute to the improvement of CQT data, but not for other two data types. This outcome may owing to the fact that the statistical descriptors of pitch contour are already contained in mid-level and high-level features, and such information of pitch contour may provide extra guidance for technique classification.

In order to further investigate that which are the decisive high-level and mid-level features to affect the technique classification, we follow the procedure in [28] and plot the self-attention with the feature map outputted from the neural network for 62 high- and mid- level features. All the values are normalized to the range between 0 and 1 for comparison. Figure 5 presents the attention map for the

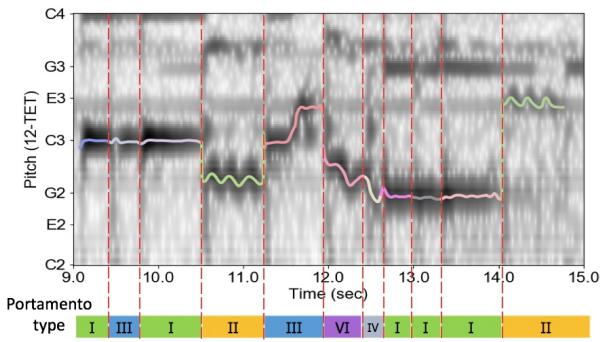

Figure 5. The attention map with feature map for 62 high- and mid- level features: music, event, and intra-event features. The red dotted lines indicate different feature types; the yellow dotted lines indicate features from 6 windows.

Figure 6. The confusion matrix of playing technique detection with CQT (left) and with CQT and high-, mid-level features (right).

Figure 7. The example of CQT (the background figure) and pitch contour segments (color curves) for different portamento types (color blocks at the bottom).

CQT and mid-, high-level features combination. As can be observed in the graph, the music-level features receive the most attention in the classification model (mean value = 0.982), compared to the event-level features (mean value = 0.500) and intra-event-level features (mean value = 0.293). Moreover, in intra-event features, an obvious peak occurs in each window, which corresponds to a specific feature: the distance between the maximum and minimum value within the window. Above observations suggest that high-level features (music and event features) are more effective to facilitate technique classification. And in mid-level features (intra-event features), the distance between the maximum and minimum value is the most adequate element to represent the pitch contour constitution.

To analyze individual portamento types in depth, it is noted in the confusion matrix (Figure 6) that types II to IV (especially type II, vibrato) are easily confused with type 1 (no variation) portamento. It is an unexpected result contradicting the studies on other instruments [10, 29], where vibrato can be easily identified. The inter-type confusion is mainly caused by the data imbalance in guqin performance, in which type I occurs much more frequently than other types (see Figure 4). In addition, we further examine the spectrogram and pitch contours for different portamento types (Figure 7), and notice that the pitch contours of type 1 portamento are not straight lines as expected, but exhibit unstable and irregular pitch drift, which can be easily confused with weak type 2 portamento, partic-

ularly when only the spectral features are analyzed. Furthermore, the two type 3 portamento segments in this example display diverse manners. The divergent behaviour within one single portamento type can rise the difficulty for accurate classification. The insufficient quality of historical recordings may also blur the distinction between portamento types and add additional challenges for the task.

6. CONCLUDING REMARKS

In this paper, we design and compile a new dataset consulting the theoretical basis of guqin performance. Mode detection is performed on the collected dataset, and playing technique classification are conducted using neural network. The results indicate that the hierarchical construction is crucial for mode detection, and the high-level and mid-level features contribute to improving the playing technique classification task.

This work verifies the conventional theory by empirical observations, in which statistical analysis confirmed the solid connection between the mode structure and the arrangement of playing technique. This study highlights the joint-relationship between the global tonal structure and the local distribution of playing technique, as well as bridges the knowledge gap between the music theory and performance practice. The findings in this study contribute insights for constructing an auto-evaluation system for music performance, or an educational system for musicians and music listeners.

ABSTRACT

The lack of labeled data is a major obstacle in many music information retrieval tasks such as melody extraction, where labeling is extremely laborious or costly. Semi-supervised learning (SSL) provides a solution to alleviate the issue by leveraging a large amount of unlabeled data. In this paper, we propose an SSL method using teacher-student models for vocal melody extraction. The teacher model is pre-trained with labeled data and guides the student model to make identical predictions given unlabeled input in a self-training setting. We examine three setups of teacher-student models with different data augmentation schemes and loss functions. Also, considering the scarcity of labeled data in the test phase, we artificially generate large-scale testing data with pitch labels from unlabeled data using an analysis-synthesis method. The results show that the SSL method significantly increases the performance against supervised learning only and the improvement depends on the teacher-student models, the size of unlabeled data, the number of self-training iterations, and other training details. We also find that it is essential to ensure that the unlabeled audio has vocal parts. Finally, we show that the proposed SSL method enables a baseline convolutional recurrent neural network model to achieve performance comparable to state-of-the-arts.

1. INTRODUCTION

One of the key elements in the success of deep learning is a large amount of labeled data. However, when the labeled data is scarce in a given task, it can be a bottleneck in leveraging the power of deep neural networks. The issue has been found in many music information retrieval (MIR) tasks as well. Among others, melody extraction research has suffered from it as pitch labeling requires experienced annotators to handle the annotation tool and the process is extremely labor-intensive [1].

The lack of labeled data in melody extraction research has been tackled in several different ways. A popular

method to alleviate the issue is data augmentation which increases labeled data by transforming the input audio, for example, using pitch-shifting [2–4]. Data augmentation, however, has the limitation in covering the diversity in the input space. Another approach is using multi-track audio data [5–7]. This allows to use monophonic pitch tracking algorithms for the melodic source and therefore it expedites laborious the pitch labeling. However, multi-track recording datasets often maintain individual tracks as stem files where multiple similar sound sources can be mixed (e.g., main vocal and backing vocal). Therefore, obtaining clean pitch labels from multi-track audio can be not straightforward [8, 9]. Recently, melody MIDI files, which are more easily accessible, have been utilized to guide melody extraction from audio with transfer learning techniques from the symbolic to audio domain [3, 10]. MIDI data exhibit greater flexibility than audio on data augmentation, but still face limitations on representing natural pitch contours of singing voice, which usually contain subtle variations such as vibrato and portamento.

Semi-supervised learning (SSL) is another but more general strategy to address the lack of labeled data. SSL uses a large amount of unlabeled data, which is usually easy to collect, jointly with labeled data. A popular class of SSL methods is based on self-training in the teacher-student framework. Recent works have combined random data augmentation with the SSL methods to encourage the model to produce robust output even when input is perturbed. This approach has achieved state-of-the-art performance on image classification [11–13], speech recognition [14], and audio classification [15]. There are a few MIR researches that used the teacher-student framework to address the lack of labeled data, for example, in automatic drum transcription [16] and singing voice detection [17, 18]. However, to the best of our knowledge, recent advances in SSL methods that leverage the power of deep neural networks and random data augmentation in the teacher-student framework have been not studied yet in the music domain.

In this paper, we apply the SSL methods to vocal melody extraction with the following contributions. First, we present the SSL methods for vocal melody extraction leveraging large-scale unlabeled music datasets. This prevents the model from overfitting to small labeled data and improve the performance. Second, we compare three setups of teacher-student models along with various audio

data augmentation techniques. We show the model with the consistency regularization is most effective. Third, we investigate effective SSL strategies by exploring joint training, the size of unlabeled data, and the number of self-training iterations. Fourth, we show that the proposed teacher-student training method enables a baseline convolutional recurrent neural network model to achieve performance comparable to state-of-the-arts. Finally, apart from the SSL method, we propose large-scale testing data artificially generated from unlabeled data using an analysis-synthesis framework, considering the lack of labeled data even at the testing stage. Evaluation on the diverse and sizable test set will reinforce the effectiveness of the proposed method. For reproducibility, the source code and pre-trained model used in this paper are available online [1].

2. RELATED WORK

The teacher-student framework has been previously studied in several MIR tasks to address the lack of labeled data. Wu and Lerch applied the approach to automatic drum transcription [16]. They used multiple teacher models based on non-negative matrix factorization (NMF) trained with different datasets and a student model based on deep neural network trained with labels from the teachers. They showed that the student model outperforms the teacher models. However, it was not a self-training setting where the teacher model is repeatedly replaced with an improved student model. Schlüter explored the self-training for singing voice detection [17]. They first trained a convolutional neural network (CNN) on the original labels with low-granularity, then a second network on pseudo-labels with high-granularity from the first network, and a third network on the summarized saliency maps from the second network. They showed this self-improvement worked up to the third network. However, they conducted the self-training on weakly-labeled data in the context of multiple-instance learning and did not used any unlabeled data. Recently, Meseguer-Brocal et al. used the teacher-student paradigm for singing voice detection to create a large-scale time-aligned vocal melody and lyrics dataset [18]. They consistently improved the teacher model by increasing the correlation between the prediction of the model and the time-aligned lyrics annotation.

3. METHODS

3.1 Model Architecture

Recent melody extraction algorithms have used CNN [9, 19, 20] and its variants [4, 21, 22] as a standard architecture. Since we focus on the effectiveness of SSL in this paper, we employ a previously proposed convolutional recurrent neural network (CRNN) which was a baseline architecture in [4]. The CRNN architecture consists of 4 ResNet blocks and a bi-directional long short-term memory layer. We first merge the audio waveforms into a mono channel and downsample them to 8 kHz. We then calculate the logarithmic-magnitude spectrogram using short-time

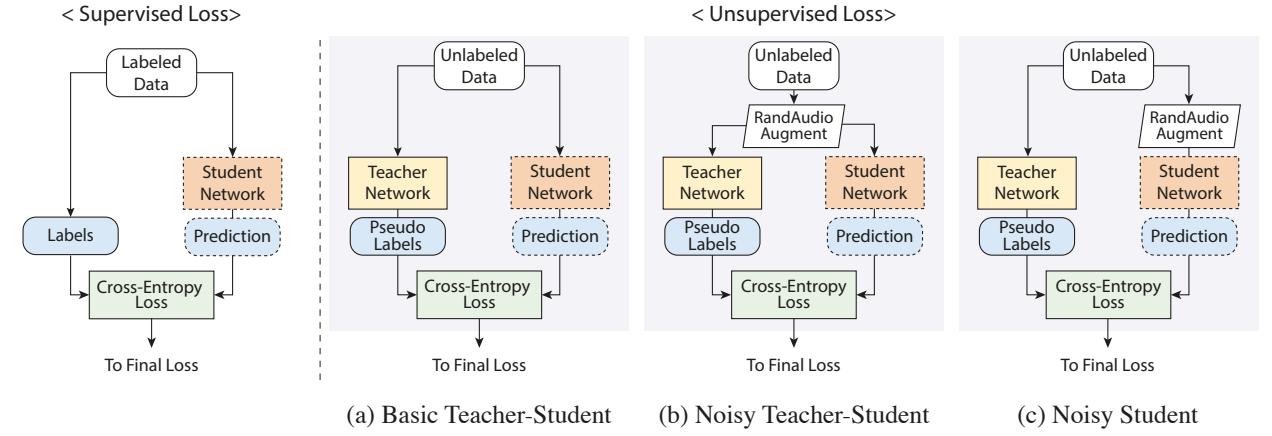
end

Fourier transform with a 1024-point Hann window and an 80-point hop size. The CRNN architecture takes 31 consecutive frames of the spectrogram as input and predicts a pitch label quantized with a resolution of 1/8 semitone and ranged from E2 (82.4 Hz) to B6 (1975.7 Hz). The size of the output layer is 442, including a non-vocal label.

3.2 SSL in the Teacher-Student Framework

Our SSL method is based on self-training in the teacher-student framework where the teacher model is first trained with labeled data and then the student model is trained with artificial labels generated from the teacher model using unlabeled data. The artificial labels can be the prediction distribution vector [11, 12] or one-hot vector determined by the class with a highest confidence [13, 23]. We formally describe the overall procedure in Algorithm 1. We first train the initial teacher model T_1 using only labeled data $\mathcal{D}$ where x_d are labeled examples and y_d are one-hot reference labels. For unlabeled data $\mathcal{U}$ where x_u are unlabeled examples, we use random data augmentation to generate noisy input data $\tilde{\mathcal{U}}$ where $\tilde{x}_u$ are noisy unlabeled examples. RandAudioAugment (RAA) is an audio version of random data augmentation method which is described in Section 3.4. While it is more effective to use random data augmentation on the student model only in image classification [12], we also try applying it for both teacher and student models for ablation study. Once we train the student model jointly with the labeled data and unlabeled data (with pseudo labels), we replace the teacher model with the student model. We repeat the same pseudo labeling and the training with a new student model.


3.3 Proposed Teacher-Student Models

Our proposed Teacher-Student models are illustrated in Figure 1. The supervised loss $\mathcal{L}_D$ is computed with labeled data and defined as:

$$\mathcal{L}_D = \frac{1}{N} \sum_{d=1}^{N} H(y_d, p(y|x_d; \theta_s)) \qquad (1)$$

where $H(\cdot)$ denotes the cross-entropy between the pitch label y_d and pitch prediction $p(y|x)$, and θ_s denotes a set of parameters of the student model. The supervised loss is a common loss term of the three investigated

(a) Basic Teacher-Student   (b) Noisy Teacher-Student   (c) Noisy Student

Figure 1. Diagram of the three Teacher-Student models.

teacher-student models. Each of them are explained below.

Basic Teacher-Student is a fundamental teacher-student framework that uses the unlabeled data $\mathcal{U}$ but trains the student network with the pseudo labels generated from the teacher network. The final loss of Basic Teacher-Student $\mathcal{L}_B$ is defined as

$$\mathcal{L}_B = \mathcal{L}_D + \frac{1}{M} \sum_{u=1}^{M} H(y_u, p(y|x_u; \theta_s)) \qquad (2)$$

where y_u is the pseudo labels on $\mathcal{U}$ generated by the teacher network, i.e. $y_u = p(y|x_u; \theta_t)$ where θ_t to denote the parameters of teacher network. The basic teacher-student model is illustrated in Figure 1(a).

Noisy Teacher-Student takes noisy unlabeled data $\tilde{\mathcal{U}}$ for both of the teacher and student networks using RAA and the rest is the same as the basic teacher-student model. The final loss of Noisy Teacher-Student $\mathcal{L}_N$ is defined as

$$\mathcal{L}_N = \mathcal{L}_D + \frac{1}{M} \sum_{u=1}^{M} H(\tilde{y}_u, p(y|\tilde{x}_u; \theta_s)) \qquad (3)$$

where $\tilde{y}_u$ is a prediction on $\tilde{\mathcal{U}}$ generated by the teacher network, i.e. $\tilde{y}_u = p(y|\tilde{x}_u; \theta_t)$. The noisy teacher-student model is illustrated in Figure 1(b).

Noisy Student takes noisy unlabeled data $\tilde{\mathcal{U}}$ only for the student network while the teacher network takes unnoised input $\mathcal{U}$ to generate the pseudo labels. The idea is that the student should produce consistent outputs that minimize the difference from the teacher even though the input is perturbed [12]. This notion is also similar to consistency regularization [24, 25]. The final loss of Noisy Student $\mathcal{L}_C$ is defined as

$$\mathcal{L}_C = \mathcal{L}_D + \frac{1}{M} \sum_{u=1}^{M} H(y_u, p(y|\tilde{x}_u; \theta_s)) \qquad (4)$$

The noisy student model is illustrated in Figure 1(c).

3.4 Data Augmentation

We conducted pitch-shift by $\pm$ 1,2 semitone on the labeled data $\mathcal{D}$ (audio and corresponding labels). In the melody extraction task, it has shown that pitch-shifting can improve the generality and performance of the model by increasing the amount of audio and label pairs for different f_0 [2, 26]. For data augmentation of unlabeled data $\mathcal{U}$, we propose RandAudioAugment (RAA) inspired by RandAugment [27], which is a method of randomly applying different kinds of transformations to increase image data. RAA converts audio by randomly selecting multiple audio effects as follows: audio equalizer (low-shelf, high-shelf), filters (low-pass, high-pass), overdrive, phaser, and reverb. Here, we use *pysndfx* that is a Python library designed for applying effects to audio files [2]. We sampled a random magnitude of each transformation from a predefined range. The implementation details for RAA are also described in the source code.

3.5 Data Selection

The SSL algorithm using large-scale unlabeled data may suffer from labeling noise. Unlabeled data are highly likely to have audio without vocals. Filtering only high-confidence examples or the top-K examples in image classification has demonstrated to be an effective method to handle the labeling noise [12, 28]. Likewise, we performed data selection so that only the tracks with vocal ratios exceeding a threshold were used for training. To estimate the ratio of vocals included in the track, we used our singing voice detector [3] based on CNN based on [29]. Considering the distribution of vocal ratio in the FMA, we set the threshold to 0.3.

4. DATASETS

Table 1 shows the simple statistics of the labeled and unlabeled training datasets and test datasets.

	AST218	218	14h 53m

Table 1. Description of datasets. In FMA, The two numbers indicate tracks with vocal (the vocal ratio above 0.3) and all tracks respectively.

4.1 Labeled Data

We used the three labeled datasets (RWC [30], MedleyDB [6], and iKala [7]) and split them into a train and validation set following [9]. We augmented the training data by pitch-shifting with $\pm$ 1,2 semitone. The total length of the labeled training data amounts to about 55 hours after the data augmentation.

4.2 Unlabeled Data

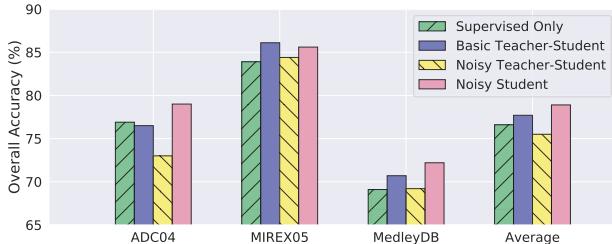
As to unlabeled data, we used an in-house dataset crawled from YouTube and the Free Music Archive (FMA) [31]. The in-house dataset is pop songs with vocals recorded in a variety of environments. It includes both public-released and user-uploaded tracks. FMA is a large-scale open dataset containing up to 106,574 tracks and covers 161 genres of music. We used FMA for performance comparison on data scalability. The FMA has three different subsets depending on the number of the track and genre included: FMA_small (FMA_S), FMA_medium (FMA_M), and FMA_large (FMA_L). We selected vocal tracks from them as described in Section 3.5 and denote the selected versions as FMA_{Sv}, FMA_{Mv}, and FMA_{Lv}, respectively. We augmented the unlabeled datasets via RAA during training as described in Section 3.4.

4.3 Test Data

4.3.1 Public Test Sets

We used three public test sets (ADC04 [4], MIREX05 [4], and MedleyDB) to evaluate the performance of vocal melody extraction. In this study, we excluded non-vocal tracks from ADC04 and MIREX05, and used songs not included in training data for MedleyDB. To obtain the ground truth for singing voice in MedleyDB, we adopted its 'MELODY2' annotations. These three datasets have been commonly used to compare the performance of melody extraction. However, the number of tracks and the total length are very limited as shown in Table 1.

4.3.2 Proposed Large-Scale Test Set

To make up the scarcity of testing data for evaluating singing voice extraction algorithms, we propose a new test set composed of DSD100 [32] and MusDB18 [33]. The two multitrack datasets were originally designed for source separation. Each track has four isolated stems: vocals, drums, bass, and others. Following the analysis/synthesis framework [8], the singing melodies for 218 selected tracks [5] were synthesized with automatically generated f_0 contours. In detail, for each song, we extracted the melody of the vocals with five different pitch trackers, and each f_0 information along with the vocal audio was fed into the WORLD [34] (D4C edition [35]) vocoder to reproduce five monophonic variations of the vocal stem. The original vocal audio was parameterized into harmonic and aperiodic spectral envelopes, and then resynthesized with provided pitch contours. Then a mask was applied to filter intervals without f_0 information. For remixing, the amplitude of the synthesized vocal was weighted to that of the original vocal stem, and the rest stems were directly summed up as accompaniments, then mixed with the weighted synthesized vocal that perfectly matched the f_0 annotation. These 1,090 polyphonic mixtures with accurate and automatic annotations constitute the proposed analysis/synthesis test set, AST218 [6].


Each track in AST218 has five variations whose vocal melody was annotated separately with five different pitch estimators: CREPE [36] (with confidence threshold of 0.5 and 0.7), pYIN [37], and Lu&Su [3] (with time step of 10 and 20ms), as they have different merits. Since there is no exact way to pinpoint a common optimal confidence threshold across the entire dataset, we chose two different threshold values for CREPE: one is 0.5, suffering from high false positive (FP) but preserving details; the other threshold is 0.7, acceptable FP though sacrificing some recall. pYIN was chosen for it has even lower FP while producing stable and continuous melodic lines when the vocal stem is monophonic. However, it is not stable in the pholyphonic scenario, which is universal in DSD100 and MusDB18. In need of other polyphonic-based melody estimators to balance the f_0 quality, we chose two time step setups of the Lu&Su model: 20ms, at which this model is optimized; and 10ms, which provides more continuous predictions and offers alternative pitch contours when encountering multiple melodic vocal lines.

The analysis/synthesis framework has been practiced successfully in evaluating monotonic pitch trackers [36]. As a sanity check, we evaluated several patchCNN [19] setups on the original and resynthesized ADC04, MIREX05, and MedleyDB. The differences of OA are within $\pm$ 2–5%, which is acceptable, meaning this framework is also applicable for polyphonic test set generation.

When evaluating vocal extraction algorithms on AST218, we averaged the scores from the five variations. Our pilot study shows that these five pitch contours reach

---

[4] http://labrosa.ee.columbia.edu/projects/melody/

[5] Songs that appear in MedleyDB were excluded for they were part of the training data, but songs in MusDB18 having counterparts in DSD100 were not removed for they are not exactly identical. Additionally, 12 songs that do not have discernible vocal melodies were also excluded.

Figure 2. Comparison with supervised-learning model and three student models on three test sets.

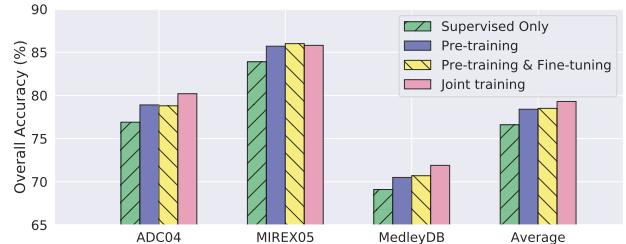
Figure 3. Comparison with pre-training, fine-tuning, and joint training methods on three test sets.

consensus over a majority of frames, while the estimations differ for tricky frames. Rather than manually check on the estimated f_0, we used AST218 in an ensemble manner, fully leveraging the spirit of automatic pitch annotation.

5. EXPERIMENTS

5.1 Experimental Setup

5.1.1 Training Details

We used the CRNN architecture with residual connections and bi-directional long short-term memory in all experiments. The implementation of the model was consistent with that of the main network of [4]. We trained our models using Adam optimizer for 70 epochs on 2 GPUs. The initial learning rate was set to 0.003 in all the experiments. We used a learning rate schedule that reduces the learning rate by 0.7 times if validation accuracy did not increase within three epochs. The model and the training procedures were implemented using Keras [7] [38].


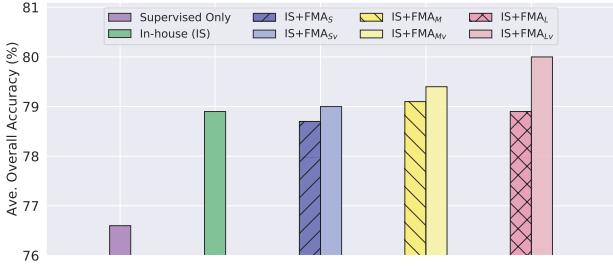
5.1.2 Evaluation

To evaluate the performance of melody extraction, we mainly used overall accuracy (OA) which combines the accuracy of pitch estimation with voice detection. We also used three metrics raw pitch accuracy (RPA) for pitch estimation, and voicing recall (VR) and voicing false alarm (VFA) for voice detection [39]. These metric are computed by *mir_eval* [40] library designed.

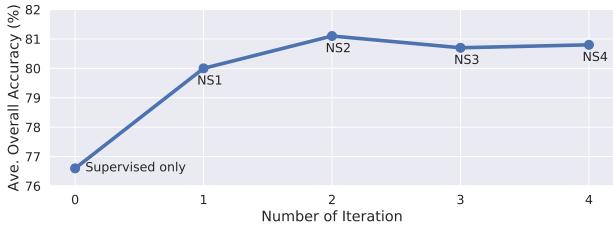
5.2 Experiment 1: Teacher-Student Models

Our first experiment is to demonstrate the efficacy of the proposed Teacher-Student models for SSL. In this experiment, we trained three Teacher-Student models described in Section 3.3 using an in-house dataset as unlabeled data. We evaluated the performance of each model on ADC04, MIERX05, and MedleyDB, which have been used as standard test sets for evaluation. As shown in Figure 2, the basic teacher-student model can achieve 1.1% higher average OA than the supervised-only model which has 77.7% average OA. This confirms the possibility of using unlabeled data to improve the performance of melody extraction. Our experiment also shows that the noisy student model outperforms all the others, having 78.9% average OA.

The noisy student model increases OA by 3.1% with respect to the supervised-only model in MedleyDB, which is

especially a challenging dataset because it contains tracks that are difficult to distinguish between vocals and background music, or tracks with excessive audio effects. The results indicate that the student network can be trained reliably using the noisy student model, even if the initial teacher network is not robust to diverse noise. Meanwhile, the performance of the noisy teacher-student has deteriorated, being worse than the supervised-only model. This degradation is probably because the noised teacher model is not generating reliable pseudo labels.


5.3 Experiment 2: Joint Training vs. Fine-Tuning

The training methods of the teacher-student framework can be divided into three approaches depending on how $\mathcal{D}$ and $\mathcal{U}$ are used for training: pre-training on only $\mathcal{U}$ and then fine-tuning on $\mathcal{D}$; joint-training on both $\mathcal{U}$ and $\mathcal{D}$ simultaneously. Figure 3 compares the results among pre-training, fine-tuning, and joint training for the noisy student model. The jointly trained model achieves 0.8% higher average OA than the fine-tuned model, with the highest results on MedleyDB. This indicates that joint training on unlabeled data and labeled data would help the networks produce a decision boundary that better reflects real music [41]. Interestingly, the average OA of the pre-trained model only on unlabeled data is higher than that of the supervised learning model. This suggests that the distribution of unlabeled data is similar to that of labeled data. Considering that the in-house dataset consists of pop songs with vocals, the in-house dataset can be seen as having a similar tendency to the labeled data. It provides insight into the data selection in the next experiment.


5.4 Experiment 3: Size of Training Data

We investigated the importance of the size and validity of unlabeled data. To explore the effect of the size of unlabeled data, we started with the in-house dataset as training data for the noisy student model and progressively included larger subsets of FMA. The results can be seen in Figure 4. Although the FMA data set contains more numerous tracks than the in-house dataset, the average OA of FMA_S and FMA_L is lower than that of the model trained only with the in-house dataset. Note that the proposed model focuses only on vocal melodies. As a result, teacher models may suffer from labeling noise generated by numerous instrument tracks included in the FMA. In addition, all labels on the instrumental track are classified as non-vocal pitch, resulting in data imbalance.

---

[7] We used Keras 2.3.0, Accessed: 15 May 2020

Figure 4. Comparison with Noisy Students on varied sizes of unlabeled datasets. The subscript 'v' denotes a selected subset of FMA whose vocal ratio exceeds a threshold. We use the average of OA for three public test sets.

Figure 5. Effect of iteration training for Noisy Students.

To confirm the validity of the dataset, we performed data selection for each FMA subset as mentioned in Section 3.5 and used them to train each student model. Interestingly, as the size of the $\mathcal{U}$ increases, the performance of each model tends to be significantly improved. For example, FMA_{Lv} achieves an average OA of 80.2%, which is 3.6% higher than the supervised-only model. This indicates that effective SSL requires a large amount of $\mathcal{U}$ with a similar distribution for $\mathcal{D}$.

5.5 Experiment 4: Iterative Training

We iterated the self-training 4 times for the noisy student model using the in-house dataset and FMA_{Lv}. The results are illustrated in Figure 5. We observe that the performance continuously increases up to 2 iterations achieving the highest average OA of 81.1%. Generally, self-training tends to amplify the error caused by labelling noise during training. However, the noisy student model trained on large-scale unlabeled data can help overcome this difficulty. Nevertheless, increasing the number of training iterations three or more times does not improve performance, and rather slightly lower the accuracy.

5.6 Comparison with State-of-the-Arts

We compared the supervised-only model (as a baseline) and proposed the noisy student model (NS) with four recent melody extraction algorithms based on deep neural networks: the patch-based CNN (patchCNN) [19], the deep salience map (DSM) [9], the streamlined encoder/decoder network (segNet) [21], and the joint detection and classification model (JDC) [4], which have open-sourced codes with vocal mode. Each method was run with its default parameters, and then evaluated on the three conventional test sets and the newly introduced AST218.

Methods	ADC04	MIREX05	MedleyDB	AST218
PatchCNN [19]	76.9 / 72.9	69.7 / 73.8	44.0 / 59.3	42.3 / 59.7
DSM [9]	89.2 / 72.2	87.7 / 80.1	80.6 / 75.4	38.9 / 68.3
SegNet [21]	88.7 / 83.3	82.6 / 80.0	70.6 / 75.5	41.5 / 68.1
JDC [4]	**90.6 / 83.5**	**91.4 / 87.4**	72.7 / 78.1	55.8 / **75.4**
Baseline	78.7 / 76.8	79.9 / 81.5	57.2 / 70.7	**56.3** / 69.7
Proposed (NS)	90.4 / 82.2	90.4 / 85.9	**76.3 / 79.2**	54.2 / 74.2

Table 2. Vocal melody extraction results in terms of (RPA / OA) of the proposed and other methods on various test sets. The proposed model is iterated the self-training two times using the in-house dataset and FMA_{Lv}.

Methods	ADC04	MIREX05	MedleyDB	AST218
PatchCNN	91.8 / 46.1	80.3 / **11.6**	60.1 / 22.4	61.6 / 26.0
DSM	95.7 / 61.1	93.9 / 29.4	**85.4** / 26.6	44.6 / 7.7
SegNet	95.2 / 38.5	92.2 / 24.0	78.8 / 21.7	51.7 / 10.0
JDC	96.7 / 40.2	**97.5** / 18.5	80.5 / 18.3	64.7 / **8.6**
Baseline	92.6 / **33.8**	89.1 / 15.2	71.0 / **16.7**	**72.0** / 19.2
Proposed (NS)	**97.4** / 42.1	97.3 / 20.4	83.3 / 19.1	61.6 / 9.4

Table 3. Voicing detection results in terms of (VR / VFA) of the proposed and other methods on various test sets.

Besides, we report the frame-level scores instead of song-level ones to settle uneven song lengths.

Table 2 and Table 3 list the results of each method on the four test sets. In general, performances of the proposed NS model are comparable to other supervised-learning-based methods and even outperforms others in MedleyDB, and it effectively improves the OA of the baseline by 4.5–8.5%. The overall rankings of VR and VFA vary across the test sets, but the behavior converges in terms of OA. One can also observe that the AST218 is the most challenging in the majority of cases. In such a dataset, the performance of the NS model shows that the proposed method is robust to large-scale evaluation. However, the NS model improves the baseline except for VR and RPA in AST218. This result might be because the simple rule-based remixing of vocal and accompaniment tracks in AST218 is different from the artistic practice of mixing engineers, which can affect voicing detection and, in turn, RPA.

6. CONCLUSION

This study provides a framework of semi-supervised learning using the teacher-student model for vocal melody extraction. We compared three setups of teacher-student models and revealed that the NS model is the most effective and robust to real-world music where various noises can be present. We showed that large-scale unlabeled data is effective when they are properly selected. We found that iterative training for the teacher-student model helps improve performance. We also confirmed the effectiveness of the proposed method by evaluating it on artificial large-scale test data generated from automatically annotated multitrack data. Although these findings are based only on vocal melody extraction, we believe our method can be extended to other MIR tasks that suffer from the lack of labeled data such as automatic music transcription and chord recognition.

ABSTRACT

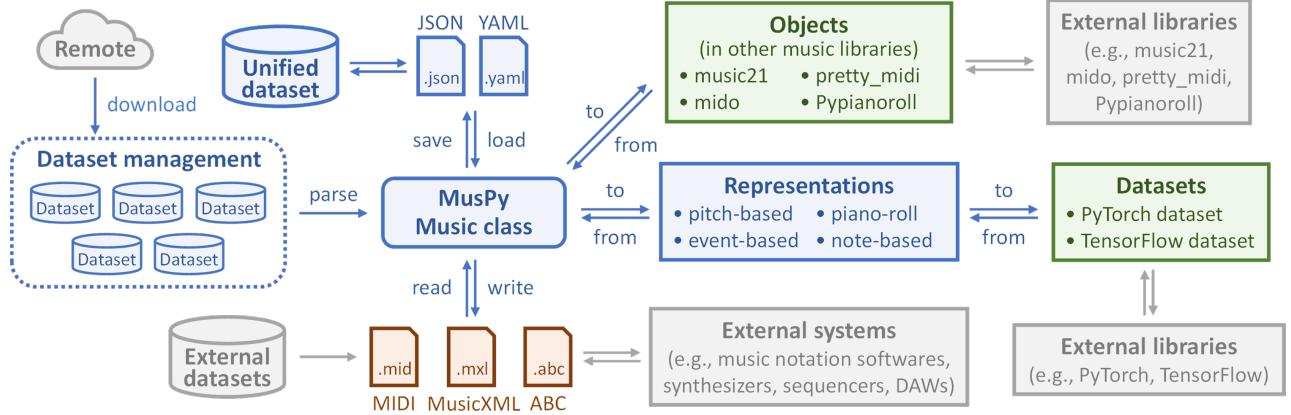
In this paper, we present MusPy, an open source Python library for symbolic music generation. MusPy provides easy-to-use tools for essential components in a music generation system, including dataset management, data I/O, data preprocessing and model evaluation. In order to showcase its potential, we present statistical analysis of the eleven datasets currently supported by MusPy. Moreover, we conduct a cross-dataset generalizability experiment by training an autoregressive model on each dataset and measuring held-out likelihood on the others—a process which is made easier by MusPy's dataset management system. The results provide a map of domain overlap between various commonly used datasets and show that some datasets contain more representative cross-genre samples than others. Along with the dataset analysis, these results might serve as a guide for choosing datasets in future research. Source code and documentation are available at `https://github.com/salu133445/muspy`.

1. INTRODUCTION

Recent years have seen progress on music generation, thanks largely to advances in machine learning [1]. A music generation pipeline usually consists of several steps—data collection, data preprocessing, model creation, model training and model evaluation, as illustrated in Figure 1. While some components need to be customized for each model, others can be shared across systems. For symbolic music generation in particular, a number of datasets, representations and metrics have been proposed in the literature [1]. As a result, an easy-to-use toolkit that implements standard versions of such routines could save a great deal of time and effort and might lead to increased reproducibility. However, such tools are challenging to develop for a variety of reasons.

First, though there are a number of publicly-available symbolic music datasets, the diverse organization of these collections and the various formats used to store them presents a challenge. These formats are usually designed for different purposes. Some focus on playback capability

Figure 1. An example of a learning-based music generation system. MusPy provides basic routines specific to music as well as interfaces to machine learning frameworks.

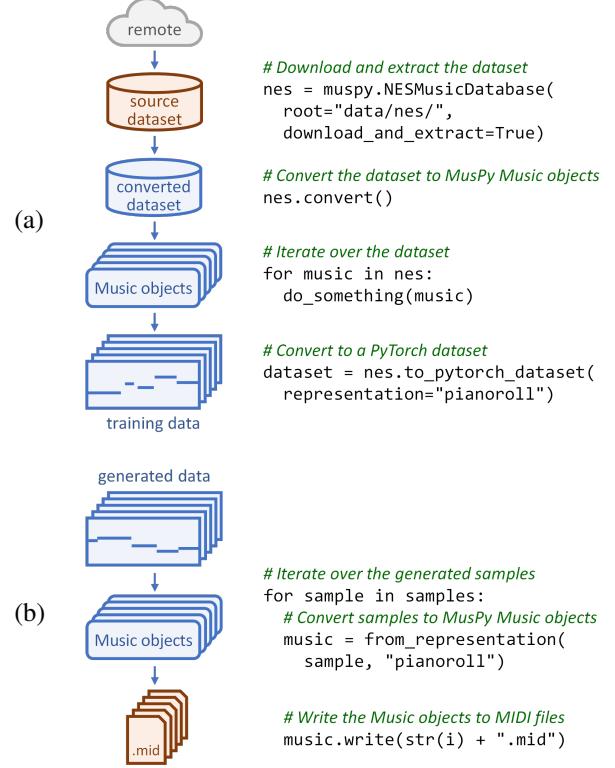
(e.g., MIDI), some are developed for music notation softwares (e.g., MusicXML [2] and LilyPond [3]), some are designed for organizing musical documents (e.g., Music Encoding Initiative (MEI) [4]), and others are research-oriented formats that aim for simplicity and readability (e.g., MuseData [5] and Humdrum [6]. Oftentimes researchers have to implement their own preprocessing code for each different format. Moreover, while researchers can implement their own procedures to access and process the data, issues of reproducibility due to the inconsistency of source data have been raised in [7] for audio datasets.


Second, music has hierarchy and structure, and thus different levels of abstraction can lead to different representations [8]. Moreover, a number of music representations designed specially for generative modeling of music have also been proposed in prior art, for example, as a sequence of pitches [9–12], events [13–16], notes [17] or a time-pitch matrix (i.e., a piano roll) [18, 19].

Finally, efforts have been made toward more robust objective evaluation metrics for music generation systems [20] as these metrics provide not only an objective way for comparing different models but also indicators for monitoring training progress in machine learning-based systems. Given the success of mir_eval [21] in evaluating common MIR tasks, a library providing implementations of commonly used evaluation metrics for music generation systems could help improve reproducibility.

To manage the above challenges, we find a toolkit dedicated for music generation a timely contribution to the MIR community. Hence, we present in this paper a new Python library, MusPy, for symbolic music generation. It provides essential tools for developing a music generation system, including dataset management, data I/O, data preprocessing and model evaluation.

With MusPy, we provide a statistical analysis on the eleven datasets currently supported by MusPy, with an eye

Figure 2. System diagram of MusPy. The MusPy Music object at the center is the core element of MusPy.


to unveiling statistical differences between them. Moreover, we conduct three experiments to analyze their relative diversities and cross-dataset domain compatibility of the various datasets. These results, along with the statistical analysis, together provide a guide for choosing proper datasets for future research. Finally, we also show that combining multiple heterogeneous datasets could help improve generalizability of a music generation system.

2. RELATED WORK

Few attempts, to the best of our knowledge, have been made to develop a dedicated library for music generation. The Magenta project [22] represents the most notable example. While MusPy aims to provide fundamental routines in data collection, preprocessing and analysis, Magenta comes with a number of model instances, but is tightly bound with TensorFlow [23]. In MusPy, we leave the model creation and training to dedicated machine learning libraries, and design MusPy to be flexible in working with different machine learning frameworks.

There are several libraries for working with symbolic music. music21 [24] is one of the most representative toolkits and targets studies in computational musicology. While music21 comes with its own corpus, MusPy does not host any dataset. Instead, MusPy provides functions to download datasets from the web, along with tools for managing different collections, which makes it easy to extend support for new datasets in the future. jSymbolic [25] focuses on extracting statistical information from symbolic music data. While jSymbolic can serve as a powerful feature extractor for training supervised classification models, MusPy focuses on generative modeling of music and supports different commonly used representations in music generation. In addition, MusPy provides several objective metrics for evaluating music generation systems.

Related cross-dataset generalizability experiments [15] show that pretraining on a cross-domain data can improve music generation results both qualitatively and quantitatively. MusPy's dataset management system makes it easier for us to thoroughly verify this hypothesis by examining pairwise generalizabilities between various datasets.

Figure 3. Examples of (a) training data preparation and (b) result writing pipelines using MusPy.

3. MUSPY

MusPy is an open source Python library dedicated for symbolic music generation. Figure 2 presents the system diagram of MusPy. It provides a core class, MusPy Music class, as a universal container for symbolic music. Dataset management system, I/O interfaces and model evaluation tools are then built upon this core container. We provide in Figure 3 examples of data preparation and result writing pipelines using MusPy.

3.1 MusPy Music class and I/O interfaces

We aim at finding a middle ground among existing formats for symbolic music and design a unified format dedicated

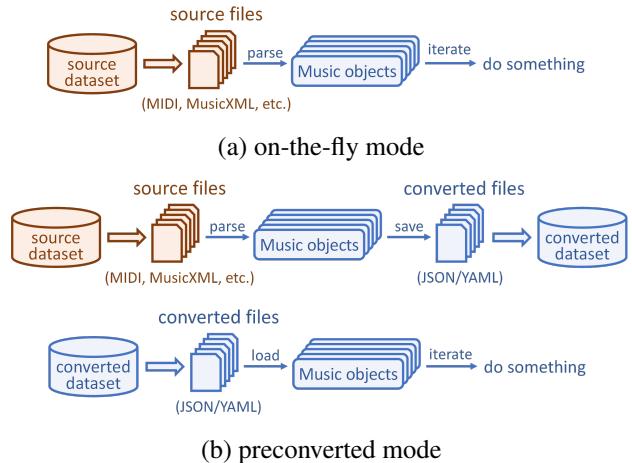
Dataset	Format	Hours	Songs	Genre	Melody	Chords	Multitrack
Lakh MIDI Dataset (LMD) [26]	MIDI	>9000	174,533	misc	△	△	△
MAESTRO Dataset [27]	MIDI	201.21	1,282	classical			
Wikifonia Lead Sheet Dataset [28]	MusicXML	198.40	6,405	misc	✓	✓	
Essen Folk Song Database [29]	ABC	56.62	9,034	folk	✓	✓	
NES Music Database [30]	MIDI	46.11	5,278	game	✓		✓
Hymnal Tune Dataset [31]	MIDI	18.74	1,756	hymn	✓		
Hymnal Dataset [31]	MIDI	17.50	1,723	hymn			
music21 Corpus [24]	misc	16.86	613	misc	△		△
Nottingham Database (NMD) [32]	ABC	10.54	1,036	folk	✓	✓	
music21 JSBach Corpus [24]	MusicXML	3.46	410	classical			✓
JSBach Chorale Dataset [11]	MIDI	3.21	382	classical			✓


Table 1. Comparisons of datasets currently supported by MusPy. Triangle marks indicate partial support. Note that, in this version, only MusicXML and MIDI files are included for the music21 Corpus.

	MIDI	MusicXML	MusPy
Sequential timing	✓		✓
Playback velocities	✓	△	✓
Program information	✓	△	✓
Layout information		✓	
Note beams and slurs		✓	
Song/source meta data	△	✓	✓
Track/part information	△	✓	✓
Dynamic/tempo markings		✓	✓
Concept of notes		✓	✓
Measure boundaries		✓	✓
Human readability		△	✓

Table 2. Comparisons of MIDI, MusicXML and the proposed MusPy formats. Triangle marks indicate optional or limited support.

(a) on-the-fly mode

(b) preconverted mode

Figure 4. Two internal processing modes for iterating over a MusPy Dataset object.

for music generation. MIDI, as a communication protocol between musical devices, uses velocities to indicate dynamics, beats per minute (bpm) for tempo markings, and control messages for articulation, but it lacks the concepts of notes, measures and symbolic musical markings. In contrast, MusicXML, as a sheet music exchanging format, has the concepts of notes, measures and symbolic musical markings and contains visual layout information, but it falls short on playback-related data. For a music generation system, however, both symbolic and playback-specific data are important. Hence, we follow MIDI's standard for playback-related data and MusicXML's standard for symbolic musical markings.

In fact, the MusPy Music class naturally defines a universal format for symbolic music, which we will refer to as the MusPy format, and can be serialized into a human-readable JSON/YAML file. Table 2 summarizes the key differences among MIDI, MusicXML and the proposed MusPy formats. Using the proposed MusPy Music class as the internal representation for music data, we then provide I/O interfaces for common formats (e.g., MIDI, MusicXML and ABC) and interfaces to other symbolic music libraries (e.g., music21 [24], mido [33], pretty_midi [34]

and Pypianoroll [35]). Figure 3(b) provides an example of result writing pipeline using MusPy.

3.2 Dataset management

MusPy provides an easy-to-use dataset management system similar to torchvision datasets [36] and TensorFlow Dataset [37]. Table 1 presents the list of datasets currently supported by MusPy and their comparisons. Each supported dataset comes with a class inherited from the base MusPy Dataset class. The modularized and flexible design of the dataset management system makes it easy to handle local data collections or extend support for new datasets in the future. Figure 4 illustrates the two internal processing modes when iterating over a MusPy Dataset object. In addition, MusPy provides interfaces to PyTorch [38] and TensorFlow [23] for creating input pipelines for machine learning (see Figure 3(a) for an example).

3.3 Representations

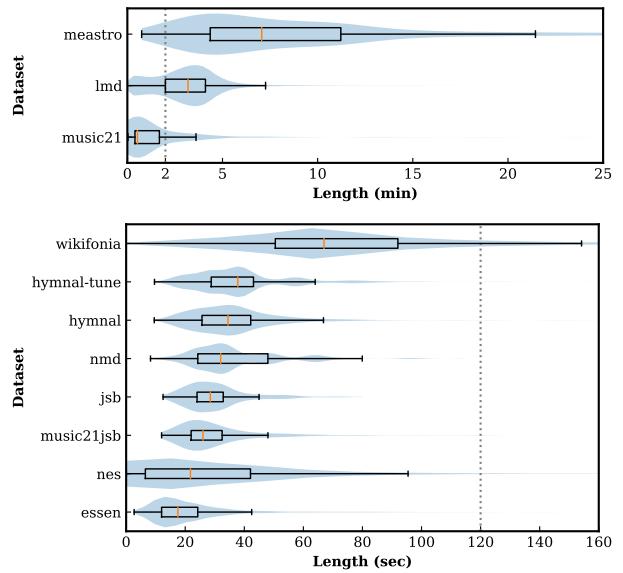
Music has multiple levels of abstraction, and thus can be expressed in various representations. For music generation in particular, several representations designed for

Representation	Shape	Values	Default configurations
Pitch-based	$T \times 1$	$\{0, 1, \ldots, 129\}$	128 note-ons, 1 hold, 1 rest (*support only monophonic music*)
Event-based	$T \times 1$	$\{0, 1, \ldots, 387\}$	128 note-ons, 128 note-offs, 100 time shifts, 32 velocities
Piano-roll	$T \times 128$	$\{0, 1\}$ or $\mathbb{R}^+$	$\{0, 1\}$ for binary piano rolls; $\mathbb{R}^+$ for piano rolls with velocities
Note-based	$N \times 4$	$\mathbb{N}$ or $\mathbb{R}^+$	List of $(time, pitch, duration, velocity)$ tuples

Table 3. Comparisons of representations supported by MusPy. T and N denote the numbers of time steps and notes, respectively. Note that the configurations can be modified to meet specific requirements and use cases.

generative modeling of symbolic music have been proposed and used in the literature [1]. These representations can be broadly categorized into four types—the pitch-based [9–12], the event-based [13–16], the note-based [17] and the piano-roll [18,19] representations. Table 3 presents a comparison of them. We provide in MusPy implementations of these representations and integration to the dataset management system. Figure 3(a) provides an example of preparing training data in the piano-roll representation from the NES Music Database using MusPy.

3.4 Model evaluation tools

Model evaluation is another critical component in developing music generation systems. Hence, we also integrate into MusPy tools for audio rendering as well as score and piano-roll visualizations. These tools could also be useful for monitoring the training progress or demonstrating the final results. Moreover, MusPy provides implementations of several objective metrics proposed in the literature [17, 19, 39]. These objective metrics, as listed below, could be used to evaluate a music generation system by comparing the statistical difference between the training data and the generated samples, as discussed in [20].


- *Pitch-related metrics*—polyphony, polyphony rate, pitch-in-scale rate, scale consistency, pitch entropy and pitch class entropy.

- *Rhythm-related metrics*—empty-beat rate, drum-in-pattern rate, drum pattern consistency and groove consistency.

3.5 Summary

To summarize, MusPy features the following:

- Dataset management system for commonly used datasets with interfaces to PyTorch and TensorFlow.

- Data I/O for common symbolic music formats (e.g., MIDI, MusicXML and ABC) and interfaces to other symbolic music libraries (e.g., music21, mido, pretty_midi and Pypianoroll).

- Implementations of common music representations for music generation, including the pitch-based, the event-based, the piano-roll and the note-based representations.

- Model evaluation tools for music generation systems, including audio rendering, score and piano-roll visualizations and objective metrics.

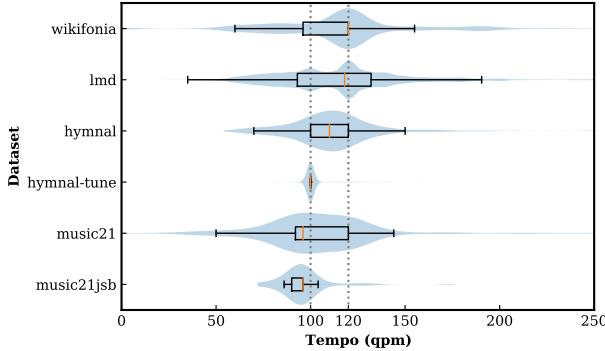

Figure 5. Length distributions for different datasets.

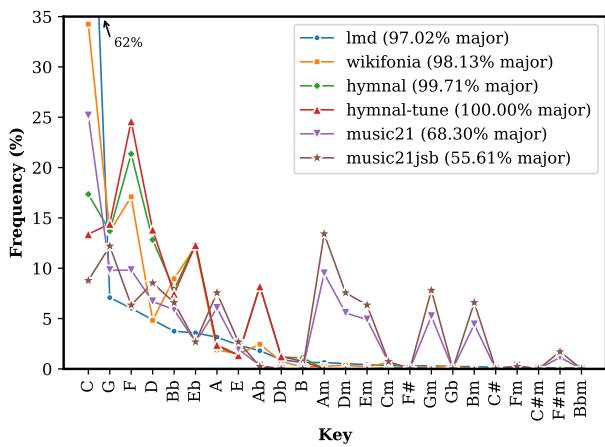
4. DATASET ANALYSIS


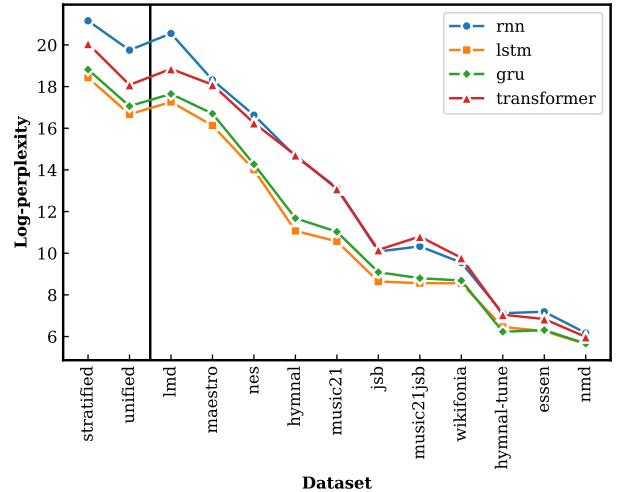
Analyzing datasets is critical in developing music generation systems. With MusPy's dataset management system, we can easily work with different music datasets. Below we compute the statistics of three key elements of a song—length, tempo and key using MusPy, with an eye to unveiling statistical differences among these datasets. First, Figure 5 shows the distributions of song lengths for different datasets. We can see that they differ greatly in their ranges, medians and variances.

Second, we present in Figure 6 the distributions of initial tempo for datasets that come with tempo information. We can see that all of them are generally bell-shaped but with different ranges and variances. We also note that there are two peaks, 100 and 120 quarter notes per minute (qpm), in Lakh MIDI Dataset (LMD), which is possibly because these two values are often set as the default tempo values in music notation programs and MIDI editors/sequencers. Moreover, in Hymnal Tune Dataset, only around ten percent of songs have an initial tempo other than 100 qpm.

Finally, Figure 7 shows the histograms of keys for different datasets. We can see that the key distributions are rather imbalanced. Moreover, only less than 3% of songs are in minor keys for most datasets except the music21 Corpus. In particular, LMD has the most imbalanced key distributions, which might be due to the fact that C major is

Figure 6. Initial-tempo distributions for different datasets (those without tempo information are not presented).

Figure 7. Key distributions for different datasets. The keys are sorted w.r.t. their frequencies in Lakh MIDI Dataset.

often set as the default key in music notation programs and MIDI editors/sequencers. [1] These statistics could provide a guide for choosing proper datasets in future research.


5. EXPERIMENTS AND RESULTS

In this section, we conduct three experiments to analyze the relative complexities and the cross-dataset generalizabilities of the eleven datasets currently supported by MusPy (see Table 1). We implement four autoregressive models—a recurrent neural network (RNN), a long short-term memory (LSTM) network [40], a gated recurrent unit (GRU) network [41] and a Transformer network [42].

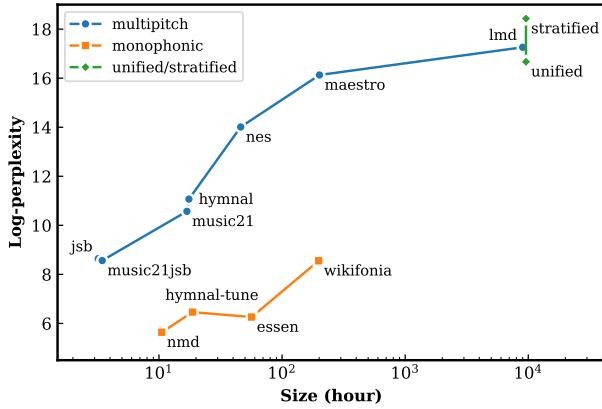
5.1 Experiment settings

For the data, we use the event representation as specified in Table 3 and discard velocity events as some datasets have no velocity information (e.g., datasets using ABC format). Moreover, we also include an end-of-sequence event, leading to in total 357 possible events. For simplicity, we downsample each song into four time steps per quarter note and fix the sequence length to 64, which is equivalent to

___

[1] Note that key information is considered as a meta message in a MIDI file. It does not affect the playback and thus can be unreliable sometimes.

Figure 8. Log-perplexities for different models on different datasets, sorted by the values for the LSTM model.

four measures in 4/4 time. In addition, we discard repeat information in MusicXML data and use only melodies in Wikifonia dataset. We split each dataset into train–test–validation sets with a ratio of 8 : 1 : 1. For the training, the models are trained to predict the next event given the previous events. We use the cross entropy loss and the Adam optimizer [43]. For evaluation, we randomly sample 1000 sequences of length 64 from the test split, and compute the perplexity of these sequences. We implement the models in Python using PyTorch. For reproducibility, source code and hyperparmeters are available at `https://github.com/salu133445/muspy-exp`.


5.2 Autoregressive models on different datasets

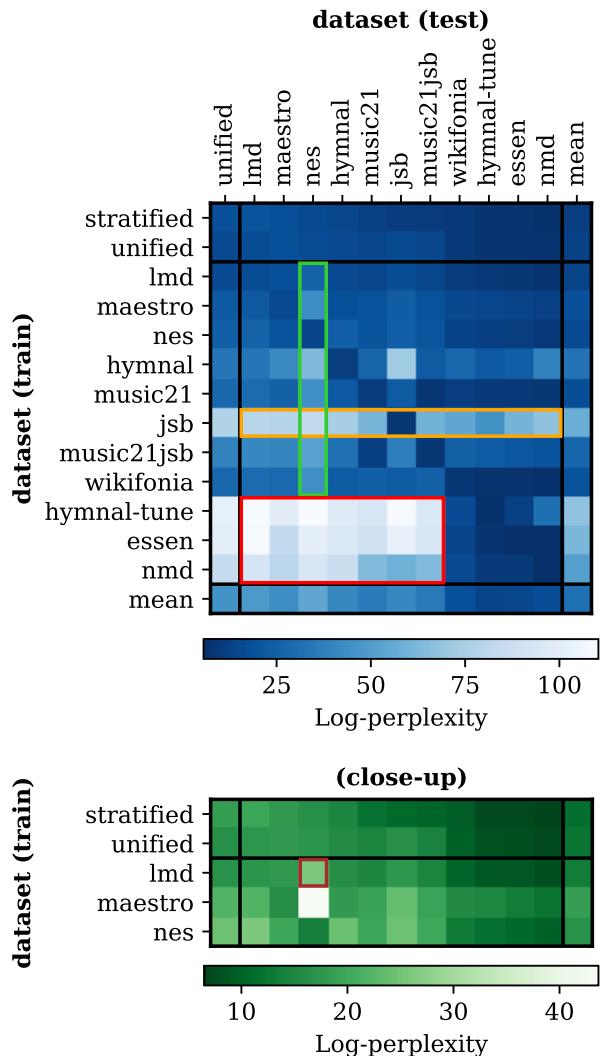
In this experiment, we train the model on some dataset $\mathcal{D}$ and test it on the same dataset $\mathcal{D}$. We present in Figure 8 the perplexities for different models on different datasets. We can see that all models have similar tendencies. In general, they achieve smaller perplexities for smaller, homogeneous datasets, but result in larger perplexities for larger, more diverse datasets. That is, the test perplexity could serve as an indicator for the diversity of a dataset. Moreover, Figure 9 shows perplexities versus dataset sizes (in hours). By categorizing datasets into multi-pitch (i.e., accepting any number of concurrent notes) and monophonic datasets, we can see that the perplexity is positively correlated to the dataset size within each group.

5.3 Cross-dataset generalizability

In this experiment, we train a model on some dataset $\mathcal{D}$, while in addition to testing it on the same dataset $\mathcal{D}$, we also test it on each other dataset $\mathcal{D}'$. We present in Figure 10 the perplexities for each train–test dataset pair. Here are some observations:

- Cross dataset generalizability is not symmetric in general. For example, a model trained on LMD generalizes well to all other datasets, while not all models trained on

Figure 9. Log-perplexities for the LSTM model versus dataset size in hours. Each point corresponds to a dataset.

other datasets generalize to LMD, which is possibly due to the fact that LMD is a large, cross-genre dataset.


- Models trained on multi-pitch datasets generalize well to monophonic datasets, while models trained on monophonic datasets do not generalize to multi-pitch datasets (see the red block in Figure 10).

- The model trained on JSBach Chorale Dataset does not generalize to any of the other datasets (see the orange block in Figure 10). This is possibly because its samples are downsampled to a resolution of quarter note, which leads to a distinct note duration distribution.

- Most datasets generalize worse to NES Music Database compared to other datasets (see the green block in Figure 10). This is possibly due to the fact that NES Music Database contains only game soundtracks.

5.4 Effects of combining heterogeneous datasets

From Figure 10 we can see that LMD has the best generalizability, possibly because it is large, diverse and cross-genre. However, a model trained on LMD does not generalize well to NES Music Database (see the brown block in the close-up of Figure 10). We are thus interested in whether combing multiple heterogeneous datasets could help improve generalizability.

We combine all eleven datasets listed in Table 1 into one large *unified* dataset. Since these datasets differ greatly in their sizes, simply concatenating the datasets might lead to severe imbalance problem and bias toward the largest dataset. Hence, we also consider a version that adopts stratified sampling during training. Specifically, to acquire a data sample in the *stratified* dataset, we uniformly choose one dataset out of the eleven datasets, and then randomly pick one sample from that dataset. Note that stratified sampling is disabled at test time.

We also include in Figures 8, 9 and 10 the results for these two datasets. We can see from Figure 10 that combining datasets from different sources improves the generalizability of the model. This is consistent with the finding in [15] that models trained on certain cross-domain

Figure 10. Cross-dataset generalizability results. The values and colors represent the log-perplexities of a LSTM model trained on a specific dataset (row) and tested on another dataset (column). The datasets are sorted by the diagonal values, i.e., trained and tested on the same dataset.

datasets generalize better to other unseen datasets. Moreover, stratified sampling alleviates the source imbalance problem by reducing perplexities in most datasets with a sacrifice of an increased perplexity on LMD.

6. CONCLUSION

We have presented MusPy, a new toolkit that provides essential tools for developing music generation systems. We discussed the designs and features of the library, along with data pipeline examples. With MusPy's dataset management system, we conducted a statistical analysis and experiments on the eleven currently supported datasets to analyze their relative diversities and cross-dataset generalizabilities. These results could help researchers choose appropriate datasets in future research. Finally, we showed that combining heterogeneous datasets could help improve generalizability of a machine learning model.

MUSIC FADERNETS: CONTROLLABLE MUSIC GENERATION BASED ON HIGH-LEVEL FEATURES VIA LOW-LEVEL FEATURE MODELLING

Hao Hao Tan[1]   **Dorien Herremans**[1]

ABSTRACT

High-level musical qualities (such as emotion) are often abstract, subjective, and hard to quantify. Given these difficulties, it is not easy to learn good feature representations with supervised learning techniques, either because of the insufficiency of labels, or the subjectiveness (and hence large variance) in human-annotated labels. In this paper, we present a framework that can learn high-level feature representations with a limited amount of data, by first modelling their corresponding quantifiable *low-level* attributes. We refer to our proposed framework as Music FaderNets, which is inspired by the fact that low-level attributes can be continuously manipulated by separate "sliding faders" through feature disentanglement and latent regularization techniques. High-level features are then inferred from the low-level representations through semi-supervised clustering using Gaussian Mixture Variational Autoencoders (GM-VAEs). Using arousal as an example of a high-level feature, we show that the "faders" of our model are disentangled and change linearly w.r.t. the modelled low-level attributes of the generated output music. Furthermore, we demonstrate that the model successfully learns the intrinsic relationship between arousal and its corresponding low-level attributes (rhythm and note density), with only 1% of the training set being labelled. Finally, using the learnt high-level feature representations, we explore the application of our framework in style transfer tasks across different arousal states. The effectiveness of this approach is verified through a subjective listening test.

1. INTRODUCTION

We consider *low-level* musical attributes as attributes that are relatively straightforward to quantify, extract and calculate from music, such as rhythm, pitch, harmony, etc. On the other hand, *high-level* musical attributes refer to semantic descriptors or qualities of music that are relatively abstract, such as emotion, style, genre, etc. Due to the nature of abstractness and subjectivity in these high-level musical qualities, obtaining labels for these qualities typically requires human annotation. However, training conditional models on top of these human-annotated labels using supervised learning might result in sub-par performance because firstly, obtaining such labels can be costly, hence the amount of labels collected might be insufficient to train a model that can generalize well [1]; Secondly, the annotated labels could have high variance among raters due to the subjectivity of these musical qualities [2, 3].

Instead of inferring high-level features directly from the music sample, we propose to use low-level features as a "bridge" between the music and the high level features. This is because the relationship between the sample and its low-level features can be learnt relatively easier, as the labels are easier to obtain. In addition, we learn the relationship between the low-level features and the high-level features in a data-driven manner. In this paper, we show that the latter works well even with a limited amount of labelled data. Our work relies heavily on the concept that each high-level feature is intrinsically related to a set of low-level attributes. By tweaking the levels of each low-level attribute in a constrained manner, we can achieve a desired change on the high-level feature. This idea is heavily exploited in rule-based systems [4–6], however rule-based systems are often not robust enough as their capabilities are constrained by the fixed set of predefined rules handcrafted by the authors. Hence, we propose an alternative path which is to *learn* these implicit relationships with semi-supervised learning techniques.

To achieve the goals stated above, we intend to build a framework which can fulfill these two objectives:

- Firstly, the model should be able to control multiple low-level attributes of the music sample in a continuous manner, as if it is controlled by sliding knobs on a console (or also known as *faders*). Each knob should be independent from the others, and only controls one single feature that it is assigned to.

- Secondly, the model should be able to learn the relationship between the levels of the sliding knobs controlling the low-level features, and the selected high-level feature. This is analogous to learning a *preset* of the sliding knobs on a console.

We named our model "Music FaderNets", with reference to musical "faders" and "presets" as described above. Achieving the first objective requires representation learning and feature disentanglement techniques. This motivates us to use *latent variable models* [7] as we can learn

separate latent spaces for each low-level feature to obtain disentangled controllability. Achieving the second objective requires the latent space to have a hierarchical structure, such that high-level information can be inferred from low-level representations. This is achieved by incorporating Gaussian Mixture VAEs [8] in our model.

2. RELATED WORK

2.1 Controllable Music Generation

The application of deep learning techniques for music generation has been rapidly advancing [9–13], however, embedding *control* and *interactivity* in these systems still remains a critical challenge [10]. Variants of conditional generative models (such as CGAN [14] and CVAE [15]) are used to allow control during generation, which have attained much success mainly in the image domain. Fader Networks [16] is one of the main inspirations of this work (hence the name Music FaderNets), in which users can modify different visual features of an image using "sliding faders". However, their approach is built upon a CVAE with an additional adversarial component, which is very different from our approach. Recently, controllable music generation has gained much research interest, both on modelling low-level [17–20] and high-level features [21, 22]. Specifically, [18] and [19] each proposed a novel latent regularization method to encode attributes along specific latent dimensions, which inspired the "sliding knob" application in this work.

2.2 Disentangled Representation Learning for Music

Disentangled representation learning has been widely used across both the visual [23–26] and speech domain [1, 27, 28] to learn disjoint subsets of attributes. Such techniques have also been applied to music in several recent works, both in the audio [29–31] and symbolic domain [32–34]. The discriminator component in our model draws inspiration from both the explicit conditioning component in the EC^2-VAE model [33], and the *extraction* component in the Ext-Res model [34]. We find that most of the work on disentanglement in symbolic music focuses on low-level features, and is done on monophonic music.

This research distinguishes itself from other related work through the following novel contributions:

- We combine latent regularization techniques with disentangled representation learning to build a framework that can control various continuous low-level musical attribute values using "faders", and apply the framework on *polyphonic* music modelling.

- We show that it is possible to infer high-level features from low-level latent feature representations, even under weakly supervised scenario. This opens up possibilities to learn good representations for abstract, high-level musical qualities even under data scarcity conditions. We further demonstrate that the learnt representations can be used for controllable generation based on high-level features.

3. PROPOSED FRAMEWORK

3.1 Gaussian Mixture Variational Autoencoders

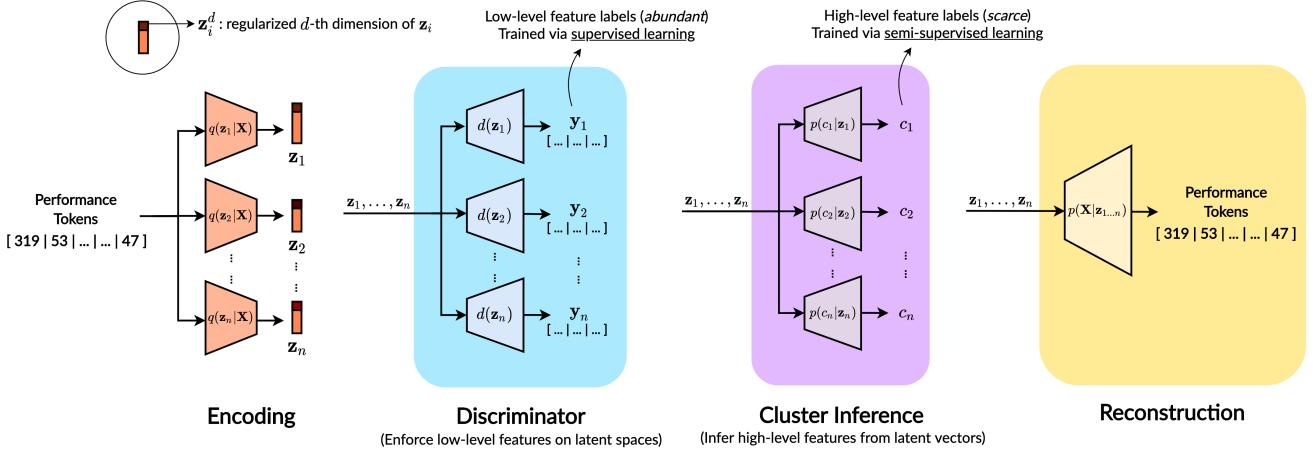
VAEs [35] combine the power of both latent variable models and deep generative models, hence they provide both representation learning and generation capabilities. Given observations $\mathbf{X}$ and latent variables $\mathbf{z}$, the VAE learns a graphical model $\mathbf{z} \to \mathbf{X}$ by maximizing the evidence lower bound (ELBO) of the marginal likelihood $p(\mathbf{X})$ as below:

$$\mathcal{L}(p, q; \mathbf{X}) = \mathbb{E}_{q(\mathbf{z}|\mathbf{X})}[\log p(\mathbf{X}|\mathbf{z})] - \mathcal{D}_{KL}(q(\mathbf{z}|\mathbf{X})||p(\mathbf{z}))$$

where $q(\mathbf{z}|\mathbf{X})$ and $p(\mathbf{z})$ represent the learnt posterior and prior distribution respectively. In vanilla VAEs, $p(\mathbf{z})$ is an isotropic, unimodal Gaussian. Gaussian Mixture VAEs (GM-VAE) [8] extend the prior to a mixture of K Gaussian components, which corresponds to learning a graphical model with an extra hierarchy of dependency $c \to \mathbf{z} \to \mathbf{X}$. The newly introduced categorical variable $c \in \mathcal{C}$, whereby $|\mathcal{C}| = K$, is a discrete representation of the observations. Hence, a new distribution $q(c|\mathbf{X})$ is introduced to infer the class of each observation, which enables semi-supervised and unsupervised clustering applications.

Following [8], the ELBO of a GM-VAE is derived as:

$$\mathcal{L}(p, q; \mathbf{X}) = \mathbb{E}_{q(\mathbf{z}|\mathbf{X})}[\log p(\mathbf{X}|\mathbf{z})]$$
$$- \sum_{k=1}^{K} q(c_k|\mathbf{X})\mathcal{D}_{KL}(q(\mathbf{z}|\mathbf{X})||p(\mathbf{z}|c_k))$$
$$- \mathcal{D}_{KL}(q(c|\mathbf{X})||p(c))$$

The original KL loss term from the vanilla VAE is modified into two new terms: (i) the KL divergence between the approximate posterior $q(\mathbf{z}|\mathbf{X})$ and the conditional prior $p(\mathbf{z}|c_k)$, marginalized over all Gaussian components; (ii) the KL divergence between the cluster inferring distribution $q(c|\mathbf{X})$, and the categorical prior $p(c)$.


3.2 Model Formulation

Figure 1 shows the model formulation of our proposed Music FaderNets. Input $\mathbf{X}$ is a sequence of performance tokens converted from MIDI following [12, 13]. Assume that we want to model a high-level feature with K discrete states, which is related to a set of N low-level features. We denote the latent variables learnt for each low-level feature as $\mathbf{z}_{1...N}$; the labels for each low-level feature as $\mathbf{y}_{1...N}$; and the class inferred from each latent variable as $c_{1...N}$.

The joint probability of $\mathbf{X}, \mathbf{z}_{1...N}, c_{1...N}$ is written as:

$$p(\mathbf{X}, \mathbf{z}_{1...N}, c_{1...N}) = p(\mathbf{X}|\mathbf{z}_{1...N}) \prod_{i=1}^{N} p(\mathbf{z}_i|c_i) \prod_{i=1}^{N} p(c_i)$$

We assume that each categorical prior $p(c_i)$, $i \in [1, N]$ is uniformly distributed, and the conditional distributions $p(\mathbf{z}_i|c_i) = \mathcal{N}(\mu_{c_i}, \text{diag}(\sigma_{c_i}))$ are diagonal-covariance Gaussians with learnable means and constant variances. For each low-level attribute, we learn an approximate posterior $q(\mathbf{z}_i|\mathbf{X})$, parameterized by an encoder neural network, that samples latent code $\mathbf{z}_i$ which represents the i-th low-level feature.

Figure 1. Music FaderNets model architecture.

The latent codes $\mathbf{z}_{1...N}$ are then passed through the remaining three components: (1) **Discriminator**: To ensure that $\mathbf{z}_i$ incorporates information of the assigned low-level feature, it is passed through a discriminator represented by a function $d(\mathbf{z}_i)$ to reconstruct the low-level feature label $\mathbf{y}_i$; (2) **Reconstruction**: All latent codes are fed into a global decoder network which parameterizes the conditional probability $p(\mathbf{X}|\mathbf{z}_{1...n})$ to reconstruct the input $\mathbf{X}$; (3) **Cluster Inference**: This component parameterizes the cluster inference probability $q(c|\mathbf{X})$, with c representing the selected high-level feature. It can be approximated by $q(c|\mathbf{X}) \approx \mathbb{E}_{q(\mathbf{z}|\mathbf{X})}p(c|\mathbf{z})$ [36], where the cluster state is predicted from each latent code $\mathbf{z}_i$ instead of $\mathbf{X}$.

To incorporate the "sliding knob" concept, we need to map the change of value of an arbitrary dimension on $\mathbf{z}_i$ (denoted as $\mathbf{z}_i^d$, shown on Figure 1 as the darkened dimension) linearly to the change of value of the low-level feature label $\mathbf{y}_i$. After comparing across previous methods on conditioning and regularization [15, 16, 18, 19], we choose to adopt [19] which applies a latent regularization loss term written as $\mathcal{L}_{\text{reg}}(\mathbf{z}_i^d, \mathbf{y}_i) = \text{MSE}(\tanh(\mathcal{D}_{\mathbf{z}_i^d}), \text{sign}(\mathcal{D}_{\mathbf{y}_i}))$, where $\mathcal{D}_{\mathbf{z}_i^d}$ and $\mathcal{D}_{\mathbf{y}_i}$ denotes the *distance matrix* of values $\mathbf{z}_i^d$ and $\mathbf{y}_i$ within a training batch respectively. We provide a detailed comparison study across each proposed method in Section 4.2. Hence, if we define:

$$\mathcal{L}_\phi^i(p, q; \mathbf{X}) = \begin{cases} \sum_{k=1}^{K} q(c_{i,k}|\mathbf{X})\mathcal{D}_{KL}(q(\mathbf{z}_i|\mathbf{X})||p(\mathbf{z}_i|c_{i,k})) \\ \quad + \mathcal{D}_{KL}(q(c_i|\mathbf{X})||p(c_i)), \text{if unsupervised} \\ \\ \mathcal{D}_{KL}(q(\mathbf{z}_i|\mathbf{X})||p(\mathbf{z}_i|c_i)), \text{if supervised} \end{cases}$$
(1)

then the entire training objective can be derived as:

$$\mathcal{L}(p, q; \mathbf{X}) = \mathbb{E}_{q(\mathbf{z}_1|\mathbf{X})...q(\mathbf{z}_N|\mathbf{X})}[\log p(\mathbf{X}|\mathbf{z}_1, \mathbf{z}_2, ..., \mathbf{z}_N)]$$
$$- \beta \cdot \sum_{i=1}^{N} \mathcal{L}_\phi^i(p, q; \mathbf{X}) + \sum_{i=1}^{N} \mathcal{L}_{\text{reg}}(\mathbf{z}_i^d, \mathbf{y}_i)$$
$$+ \mathbb{E}_{q(\mathbf{z}_1|\mathbf{X})...q(\mathbf{z}_n|\mathbf{X})}[\log p(\mathbf{y}_1|\mathbf{z}_1)...p(\mathbf{y}_N|\mathbf{z}_N)]$$
(2)

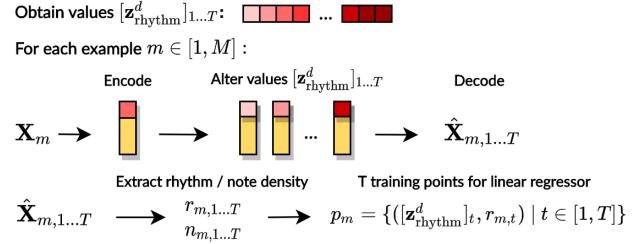
where β is the KL weight hyperparameter [24]. The first term in Eq. 2 represents the reconstruction loss. The second KL loss term (derived from the ELBO function of GM-VAE) correspond to the cluster inference component, which allows both *supervised* and *unsupervised* training setting, depending on the availability of label c. If we omit the cluster inference component, it could conform to a vanilla VAE by replacing this term with the KL loss term of VAE. The third term is the latent regularization loss applied during the encoding process. The last term is the reconstruction loss of the low-level feature labels, which corresponds to the discriminator component. All encoders and decoders are implemented with gated recurrent units (GRUs), and teacher-forcing is used to train all decoders.

4. EXPERIMENTAL SETUP

In this work, we chose *arousal* (which refers to the energy level conveyed by the song [37]) as the high-level feature to be modelled. In order to select relevant low-level features, we refer to musicology papers such as [6, 38, 39], which suggest that arousal is related to features including rhythm density, note density, key, dynamic, tempo, etc. Among these low-level features, we focus on modelling the score-level features in this work (i.e. rhythm, note and key).

4.1 Data Representation and Hyperparameters

We use two polyphonic piano music datasets for training: the **Yamaha Piano-e-Competition dataset** [12], and the **VGMIDI dataset** [3], which contains piano arrangements of 95 video game soundtracks in MIDI, annotated with valence and arousal values in the range of -1 to 1. The arousal labels are used to guide the cluster inference component in our GM-VAE model using semi-supervised learning. We extract every 4-beat segment from each music sample, with a beat resolution of 4 (quarter-note granularity). Each segment is encoded into event-based tokens following [12] with a maximum sequence length of 100. This results in a total of 103,934 and 1,013 sequences from the Piano e-Competition and VGMIDI dataset respectively, which are split into train/validation/test sets with a ratio of 80/10/10.

Inspired by [33], we represent each rhythm label, $\mathbf{y}_{\text{rhythm}}$, as a sequence of 16 one-hot vectors with 3 dimensions, denoting an onset for any pitch, a holding state, or a rest. The *rhythm density* value is calculated as the number of onsets in the sequence divided by the total sequence length. Each note label, $\mathbf{y}_{\text{note}}$, is represented by a sequence of 16 one-hot vectors with 16 dimensions, each dimension denoting the number of notes being played or held at that time step (we assume a minimum polyphony of 0 and a maximum of 15). The *note density* value is the average number of notes being played or held for per time step. For key, we use the key analysis tool from music21 [40] to extract the estimated global key of each 4-beat segment. The key is represented using a 24-dimension one-hot vector, accounting for major and minor modes. In this work, we directly concatenate the key vector as a conditioning signal with $\mathbf{z}_{\text{rhythm}}$ and $\mathbf{z}_{\text{note}}$ as an input to the global decoder for reconstruction. For representing arousal, we split the arousal ratings into two clusters ($K = 2$): *high* arousal cluster for positive labels, and *low* arousal cluster for negative labels. We remove labels annotated within the range [-0.1, 0.1] so as to reduce ambiguity in the annotations.


The hyperparameters are tuned according to the results on the validation set using grid search. The mean vectors of $p(c|\mathbf{z})$ are all randomly initialized with Xavier initialization, whereas the variance vectors are kept fixed with value e^{-2}. We observe that the following annealing strategy for β leads to the best balance between reconstruction and controllability: β is set to 0 in the first 1,000 training steps, and is slowly annealed up to 0.2 in the next 10,000 training steps. We set the batch size to 128, all hidden sizes to 512, and the encoded $\mathbf{z}$ dimensions to 128. The Adam optimizer is used with a learning rate of 10^{-3}.

4.2 Measuring the Controllability of Latent Features

The proposed Music FaderNets model should meet two requirements: (i) Each "fader" independently controls one low-level musical feature without affecting other features (disentanglement), and (ii) the "faders" should change linearly with the controlled attribute of the generated output (linearity). For disentanglement, we follow the definition proposed in [41] which decomposes the concept of disentanglement into *generator consistency* and *generator restrictiveness*. Using rhythm density as an example:

- *Consistency* on rhythm density means that for the same value of $\mathbf{z}_{\text{rhythm}}^{d}$, the value of the output's rhythm density should be consistent.

- *Restrictiveness* on rhythm density means that changing the value of $\mathbf{z}_{\text{rhythm}}^{d}$ does not affect the attributes other than rhythm density (in our case, note density).

- *Linearity* on rhythm density means that the value of rhythm density is directly proportional to the value of $\mathbf{z}_{\text{rhythm}}^{d}$, which is analogous to a sliding fader.

We will be evaluating all three of these points in our experiment. For evaluating linearity, [19] proposed a slightly modified version of the interpretability metric by [42],

Figure 2. Workflow of obtaining evaluation metrics for "faders" controlling rhythm density.

which includes the following steps: (1) encode each sample in the test set, obtain the rhythm latent code and the dimension $\mathbf{z}^{d}$ which has the maximum mutual information with regards to the attribute; (2) learn a linear regressor to predict the input attribute values based on $\mathbf{z}^{d}$. The linearity score is hence the coefficient of determination (R^2) score of the linear regressor. However, this method evaluates only the encoder and not the decoder. As we want the sliding knobs to directly impact the output, we argue that the relationship between $\mathbf{z}^{d}$ and the output attributes should be more important. Hence, we propose to "slide" the values of the regularized dimension $\mathbf{z}^{d}$ within a given range and decode them into reconstructed outputs. Then, instead of predicting the *input* attributes given the encoded $\mathbf{z}^{d}$, the linear regressor learns to predict the corresponding *output* attributes given the "slid" values of $\mathbf{z}^{d}$.

We demonstrate a single workflow to calculate the consistency, restrictiveness and linearity scores of a given model based on the low-level features (we use rhythm density as an example low-level feature for the discussion below), as depicted in Figure 2. After obtaining the rhythm density latent code for all samples in the training set and finding the minimum and maximum value of $\mathbf{z}_{\text{rhythm}}^{d}$, we "slide" for $T = 8$ steps by calculating $\min(\mathbf{z}_{\text{rhythm}}^{d}) + \frac{t}{T}(\max(\mathbf{z}_{\text{rhythm}}^{d}) - \min(\mathbf{z}_{\text{rhythm}}^{d}))$, with $t \in [1, T]$. This results in a list of values denoted as $[\mathbf{z}_{\text{rhythm}}^{d}]_{1...T}$. Then, we conduct the following steps:

1. Randomly select $M = 100$ samples from the test set, and encode each sample into $\mathbf{z}_{\text{rhythm}}$ and $\mathbf{z}_{\text{note}}$;
2. Alter the d-th element in $\mathbf{z}_{\text{rhythm}}$ using the values in the range $[\mathbf{z}_{\text{rhythm}}^{d}]_{1...T}$, to obtain $[\hat{\mathbf{z}}_{\text{rhythm}}]_{m,1...T}$ for each sample m;
3. Decode each new rhythm density latent code together with the unchanged note density latent code $\mathbf{z}_{\text{note}}$ to get $\hat{\mathbf{X}}_{m,1...T}$;
4. Calculate rhythm density $r_{m,1...T}$ and note density $n_{m,1...T}$ for each reconstructed output;
5. Pair up the new rhythm density latent code with the resulting rhythm density of the output as T training data points $p_m = \{([\mathbf{z}_{\text{rhythm}}^{d}]_t, r_{m,t}) \mid t \in [1, T]\}$ for a linear regressor.

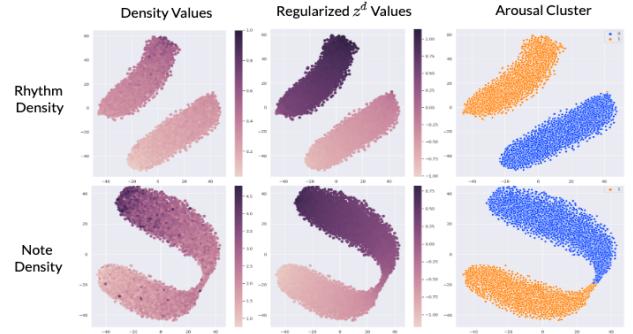
The final evaluation scores are then calculated as follows:

$$\text{Consistency score} = 1 - \frac{1}{T}\sum_{t=1}^{T}\sigma_t(r_{1...M,t}) \qquad (3)$$

	Consistency		Restrictiveness		Linearity	
	Rhythm Density	Note Density	Rhythm Density	Note Density	Rhythm Density	Note Density
Proposed (Vanilla VAE)	0.4367 ± 0.0258	0.3490 ± 0.0360	0.6645 ± 0.0169	0.6481 ± 0.0154	$\mathbf{0.7805 \pm 0.0142}$	$\mathbf{0.8255 \pm 0.0107}$
Proposed (GM-VAE)	$\mathbf{0.5096 \pm 0.0248}$	0.4207 ± 0.0309	0.6603 ± 0.0164	0.6457 ± 0.0132	0.7580 ± 0.0124	0.7792 ± 0.0177
Pati et al. [19]	0.4625 ± 0.0264	$\mathbf{0.5100 \pm 0.0150}$	0.6417 ± 0.0171	0.5497 ± 0.0206	0.7613 ± 0.0171	0.8220 ± 0.0143
CVAE [15]	0.2613 ± 0.0376	0.4997 ± 0.0355	$\mathbf{0.6863 \pm 0.0221}$	0.7140 ± 0.0130	0.4969 ± 0.0166	0.3997 ± 0.0411
Fader Networks [16]	0.2730 ± 0.0366	0.4983 ± 0.0425	0.6861 ± 0.0163	$\mathbf{0.7379 \pm 0.0149}$	0.5482 ± 0.0283	0.4647 ± 0.0292
GLSR [18]	0.1891 ± 0.0346	0.1969 ± 0.0831	0.6365 ± 0.0276	0.7136 ± 0.0185	0.2465 ± 0.0197	0.1799 ± 0.0209

Table 1. Experimental results (conducted on the Yamaha dataset test split) on the controllability of low-level features (rhythm density and note density) using disentangled latent variables. Bold marks the best performing model.

$$\text{Restrictiveness score} = 1 - \frac{1}{M} \sum_{m=1}^{M} \sigma_{m}(n_{m,1..T}) \quad (4)$$

$$\text{Linearity score} = R^2(\mathcal{M}(p_{1...M})) \quad (5)$$


where $\sigma(\cdot)$ denotes the standard deviation, and $\mathcal{M}$ denotes the linear regressor model. In other words, consistency calculates the average standard deviation across all output rhythm density values given the same $\mathbf{z}^d_{\text{rhythm}}$, whereas restrictiveness calculates the average standard deviation across all output note density values given the changing $\mathbf{z}^d_{\text{rhythm}}$. In a perfectly disentangled and linear model, the consistency, restrictiveness and linearity scores should be equal to 1, and higher scores indicate better performance.

5. EXPERIMENTS AND RESULTS

We compare the evaluation scores of our proposed model, using both a vanilla VAE (omitting the cluster inference component) and GM-VAE, with several models proposed in related work on controllable synthesis: CVAE [15], Fader Networks [16], GLSR [18] and Pati et al. [19]. We repeat the above steps for 10 runs for each model and report the mean and standard deviation of each score. Table 1 shows the evaluation results. Overall, our proposed models achieve a good all-rounded performance on every metric as compared to other models, especially in terms of linearity, models that use [19]'s regularization method largely outperform other models. Our model shares similar results with [19], however as compared to their work, we encode a multi-dimensional, regularized latent space instead of a single dimension value for each low-level feature, thus allowing more flexibility. Our model can also be used for "generation via analogy" as mentioned in EC^2-VAE [33], by mix-matching $\mathbf{z}_{\text{rhythm}}$ from one sample with $\mathbf{z}_{\text{note}}$ from another. Moreover, the feature latent vectors can be used to infer interpretable and semantically meaningful clusters.

5.1 Inferring High-Level Features from Latent Low-Level Representations

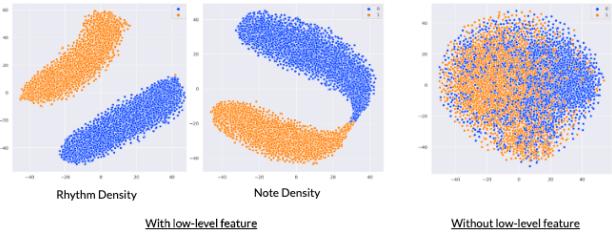
Figure 3 visualizes the rhythm and note density latent space learnt by GM-VAE using t-SNE dimensionality reduction. We observe that both spaces successfully learn a Gaussian-mixture space with two well-separated components, which correspond to high and low arousal clusters, even though it was trained with only around 1% of labelled data. We also find that the regularized $\mathbf{z}^d$ values capture


Figure 3. Visualization of rhythm (top) and note (bottom) density latent space in the GM-VAE. Each column is colored in terms of: (left) original density values, (middle) regularized $\mathbf{z}^d$ values, (right) arousal cluster labels (0 refers to low arousal and 1 refers to high arousal).
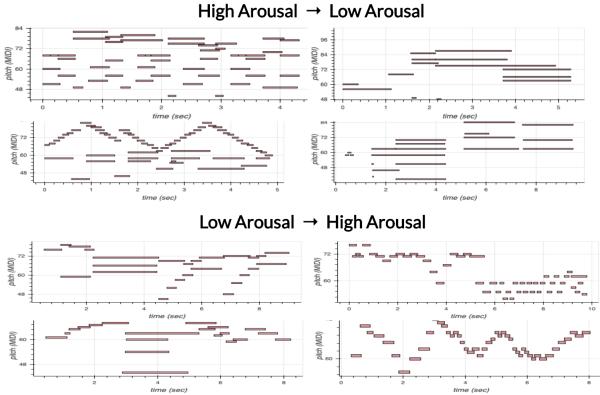


the overall trend of the actual rhythm and note density values. Interestingly, the model learns the implicit relationship between high/low arousal and the corresponding levels of rhythm/note density. From Figure 3, we observe that the high arousal cluster corresponds to higher rhythm density and lower note density, whereas the low arousal cluster corresponds to lower rhythm density and higher note density. This is reasonable as music segments with high arousal often consist of fast running notes and arpeggios, being played one note at a time, whereas music segments with low arousal often exhibit a chordal texture with more sustaining notes and relatively less melodic activity.

To further inspect the importance of using low-level features, we train a separate GM-VAE model with only one encoder (without discriminator component), which encodes only a single latent vector for each segment. The model is trained to infer the arousal label with the single latent vector similarly in a semi-supervised manner, and the hyperparameters are kept the same. From Figure 4, we can observe that the latent space learnt without using low-level features is not well-segregated into two separate components, suggesting that the right choice of low-level features helps the learning of a more discriminative and disentangled feature latent space.

The major advantage demonstrated from the results above is that by carefully choosing low-level features supported by domain knowledge, semi-supervised (or weakly supervised) training can be leveraged to learn interpretable representations that can capture implicit relationships between high-level and low-level features, overcoming the

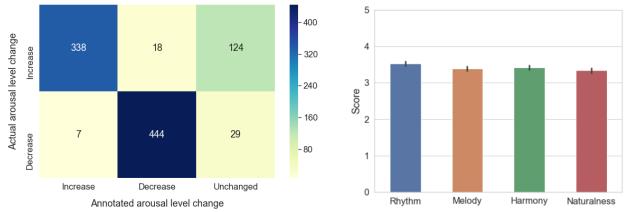
Figure 4. Arousal cluster visualization of GM-VAE with (left), and without (right) using low-level features.


Figure 5. Examples of arousal transfer on music samples.

difficulties mentioned in the introduction section. This is an important insight for learning representations of abstract musical qualities under label scarcity conditions in future.

5.2 Style Transfer on High Level Features

Utilizing the learnt high-level feature representations enables the application of feature style transfer. Following [29], given the means of each Gaussian component, $\mu_{\text{arousal}=0}$ and $\mu_{\text{arousal}=1}$, the "shifting vector" from high arousal to low arousal is $s_{\text{low\_shift}} = \mu_{\text{arousal}=0} - \mu_{\text{arousal}=1}$, and vice versa. To shift a music segment from high to low arousal, we modify the latent codes by $\mathbf{z}'_{\text{rhythm}} = \mathbf{z}_{\text{rhythm}} + s_{\text{low\_shift}}$, $\mathbf{z}'_{\text{note}} = \mathbf{z}_{\text{note}} + s_{\text{low\_shift}}$. Both new latent codes $\mathbf{z}'_{\text{rhythm}}$ and $\mathbf{z}'_{\text{note}}$ are fed into the global decoder for reconstruction. For cases where $c_{\text{rhythm}} \neq c_{\text{note}}$, we choose to perform shifting only on the latent codes which are not lying within the target arousal cluster. Figure 5 shows several examples of arousal shift performed on given music segments. We can observe that the shift is clearly accompanied with the desired changes in rhythm density and note density, as mentioned in Section 5.1. More examples are available online. [1] We also conducted a subjective listening test to evaluate the quality of arousal shift performed by Music FaderNets. We randomly chose 20 music segments from our dataset, and performed a low-to-high arousal shift on 10 segments and a high-to-low arousal shift on the other 10. Each subject listened to the original sample and then the transformed sample, and was asked whether (1) the arousal level changes after the transformation, and; (2) how well the transformed sample sounds in terms of rhythm, melody, harmony and naturalness, on a

Figure 6. Subjective listening test results. Left: Heat map of annotated arousal level change against actual arousal level change. Right: Bar plot of opinion scores for each musical quality, with 95% confidence interval.

Likert scale of 1 to 5 each.

A total of 48 subjects participated in the survey. We found that 81.45% of the responses agreed with the actual direction of level change in arousal, shifted by the model. This showed that our model is capable of shifting the arousal level of a piece to a desired state. From the heat map shown in Figure 6, we observe that shifting from high to low arousal has a higher rate of agreement (92.5%) than shifting from low to high arousal (70.41%). Meanwhile, the mean opinion score of rhythm, melody, harmony and naturalness were reported at 3.53, 3.39, 3.41 and 3.33 respectively, showing that the quality of the generated samples are generally above moderate level.

6. CONCLUSION AND FUTURE WORK

We propose a novel framework called Music FaderNets [2], which can generate new variations of music samples by controlling levels ("sliding knobs") of low-level attributes, trained with latent regularization and feature disentanglement techniques. We also show that the framework is capable of inferring high-level feature representations ("presets", e.g. arousal) on top of latent low-level representations by utilizing the GM-VAE framework. Finally, we demonstrate the application of using learnt high-level feature representations to perform arousal transfer, which was confirmed in a user experiment. The key advantage of this framework is that it can learn interpretable mixture components that reveal the intrinsic relationship between low-level and high-level features using semi-supervised learning, so that abstract musical qualities can be quantified in a more concrete manner with limited amount of labels.

While the strength of arousal transfer is gradually increased, we find that the identity of the original piece is also gradually shifted. A recent work on text generation using VAEs [43] observed this similar trait and attributed its cause to the "latent vacancy" problem by topological analysis. A possible solution is to adopt the Constrained-Posterior VAE [43], in which we aim to explore in future work. Future work will also focus on applying the framework on other sets of abstract musical qualities (such as valence [37], tension [44], etc.), and extending the framework to model multi-track music with longer duration to produce more complete music.

ABSTRACT

Data-driven approaches to automatic drum transcription (ADT) are often limited to a predefined, small vocabulary of percussion instrument classes. Such models cannot recognize out-of-vocabulary classes nor are they able to adapt to finer-grained vocabularies. In this work, we address open vocabulary ADT by introducing few-shot learning to the task. We train a Prototypical Network on a synthetic dataset and evaluate the model on multiple real-world ADT datasets with polyphonic accompaniment. We show that, given just a handful of selected examples at inference time, we can match and in some cases outperform a state-of-the-art supervised ADT approach under a fixed vocabulary setting. At the same time, we show that our model can successfully generalize to finer-grained or extended vocabularies unseen during training, a scenario where supervised approaches cannot operate at all. We provide a detailed analysis of our experimental results, including a breakdown of performance by sound class and by polyphony.

1. INTRODUCTION

Automatic Drum Transcription (ADT) aims at deriving a symbolic annotation of percussion instrument events from a music audio recording. It is a subtask of Automatic Music Transcription, where the aim is to transcribe all events within a musical piece. An accurate ADT system enables diverse applications in music education, music production, music search and recommendation, and computational musicology.

Early studies on ADT often combined multiple signal processing, information retrieval, and machine learning techniques such as support vector machines (SVM) and hidden Markov models (HMM) [1–3]. While these methods work well when applied to solo drum recordings, they often generalize poorly when applied to polyphonic music [4]. Recent approaches utilizing non-negative matrix factorization (NMF) [5, 6] and deep neural networks [7, 8] have shown promising performance in the presence of polyphonic music. However, such systems are often

Figure 1. Few-shot drum transcription. We input a music recording and one or more target example sounds into our trained model, output the likelihood of the selected event over time, and then post-process to generate onset times per percussion instrument.

limited to transcribing a very small subset of percussive sound classes, such as the bass drum (BD), snare drum (SD), and hi-hat (HH). For deep learning methods, in particular, this is mainly due to the limited number and size of ADT datasets, and the small class vocabulary size of the annotations in these datasets [9–12]. Recently, studies have utilized synthetic data and deep learning to expand ADT systems to support transcribing larger vocabularies of 10 or more instruments [11, 13]. However, 10–20 classes are still far from the wide gamut of percussive instruments used in recorded music. For example, rare or non-western percussion sounds are usually considered out-of-vocabulary. Moreover, when transcribing different datasets, we often need to manually map the percussion instruments in a dataset to the limited output vocabulary of an existing ADT system with reduced granularity. It can also be challenging for ADT systems that utilize fully-supervised learning to generalize to different musical genres or diverse drum sounds [11].

Recently, few-shot learning has been proposed for recognizing and detecting novel sound events [14–17], which is of great relevance to ADT. Under this paradigm, a model is trained to learn to recognize novel classes, unseen during training, given only very few examples from each class at inference time. Expanding on this, a few-shot sound event detection system for open vocabularies was recently proposed [14], yielding a search-by-example paradigm where a human first selects a handful of target example sounds that are passed to a trained model that automatically locates similar sounding events within the same audio track. This work, however, was developed for speech data, while other studies have focused on environmental sound. The main challenges in applying few-shot learning to music audio are the limited size of available datasets and the polyphonic

nature of music audio. While few-shot learning methods are designed to work with few labeled examples at inference time, they still require large amounts of labeled data at train time. Standard few-shot models are designed to solve multi-class problems where only one class is active at a time, while polyphonic music is inherently multi-label since multiple instruments can be active at once.

In this work, we propose a new paradigm for drum transcription in polyphonic music by introducing few-shot learning. Instead of trying to train a standard supervised model with more data for better generalizability, we propose to incorporate minimal human input with a few-shot model. Our proposed few-shot drum transcription system is shown in Figure 1, which can easily adapt to detecting a novel percussion instrument given a handful (e.g., five) of labeled target examples. By doing so, we can support open-vocabulary drum transcription, while minimizing the human labeling effort in order to make the transcription process as close to automatic as possible. To address the aforementioned challenges to applying few-shot learning to polyphonic music audio, we propose (1) utilizing a large synthetic dataset for training and (2) transcribing one percussion instrument at a time as a binary classification problem during inference. We evaluate our proposed model on multiple real music ADT datasets, compare it to a state-of-the-art supervised learning benchmark, and provide a detailed analysis of our model's performance including breakdowns by instrument class and polyphony. We show that our approach not only matches or outperforms past methods, but enables open vocabulary drum transcription, which is highly-advantageous for real-world applications.

2. METHODS

2.1 Prototypical Networks with Episodic Training

In our work, we focus on metric learning-based few-shot methods and, in particular, prototypical networks [18–21]. Prototypical networks have been found to perform well on several audio-related tasks [14, 15, 17, 22], rely on a simple training framework, and support efficient feed-forward inference [20], all of which are advantageous for our problem domain. They are designed to project an input audio example into a discriminative embedding space such that similar sounding events are clustered around a single prototype (average class embedding) via a neural network. Classification is then performed for an embedded query point by simply finding the nearest class prototype via the squared Euclidean distance.

Few-shot learning models, and prototypical networks specifically, are typically trained to solve a *C-way K-shot* multi-class classification task. In this setup, the method is tasked with labeling a query recording with one of C novel class labels, given K labeled examples per class at inference time, where K is typically a small number in the range of one to five. The availability of only very few examples of the new classes limits our ability to fine-tune a pre-trained model. To address this, *episodic training* has been proposed to train a prototypical network, which mim-

ics the few-shot inference problem during training, improving model generalizability [19]. In each training iteration, a training *episode* is formed by randomly selecting C classes from the training set. For each selected class, K samples are first selected to build a support set $\mathcal{S}$ of size of $C \times K$, while a disjoint set of q samples are selected to form a query set $\mathcal{Q}$ of size $C \times q$. Prototypes $\mathcal{M} = \{\mu_1, ..., \mu_C\}$ are the mean vectors of the embedded support samples belonging to each class:

$$\mu_c = \frac{1}{K} \sum_{(x,y) \in \mathcal{S}_c} f_\theta(x), \qquad (1)$$

where $\mathcal{S}_c$ denotes a set of examples labeled with class c and f_θ is parametrized by a neural network. Given a sample $\mathbf{x}_q$ in $\mathcal{Q}$, we take a softmax over distances to the prototypes in the embedding space to obtain per-class likelihoods:

$$p_\theta(y = c \mid \mathbf{x}_q) = \frac{\exp(-d(f_\theta(\mathbf{x}_q), \mu_c))}{\sum_{c'} \exp(-d(f_\theta(\mathbf{x}_q), \mu_{c'}))}, \quad (2)$$

where d is the squared Euclidean distance function. The training objective is to minimize the negative log-likelihood of the true class c:

$$\mathcal{L}(\theta) = -\log p_\theta(y = c \mid \mathbf{x}_q). \qquad (3)$$

Therefore, in each training episode, the model is learning to solve a *C-way K-shot* classification task. By training with a large collection of episodes, each consisting of a different set of C classes, the model learns *how to learn* from limited labeled data and obtains a class-agnostic discriminative ability. In this work, we train a prototypical network on a *10-way 5-shot* classification task [14] as the few-shot model in our proposed system.

2.2 Few-shot Drum Transcription

While the training task is a specific *C-way K-shot* classification, the trained few-shot model provides an embedding function that projects the input data into a discriminative space in which sound events are classified by finding the nearest class prototype, where each prototype is derived from a few examples. We propose to use this embedding space for percussion sound event detection by providing a support set containing examples for both the positive (target) and negative (non-target) classes, and classify a given query by measuring its distance to the positive and negative class prototypes. Here, the trained few-shot model is essentially performing a binary, 2-way, classification at inference time for each target class, ultimately resulting in a multi-label prediction.

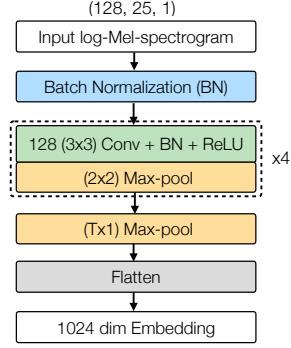
Given a target instrument and an audio track, we first slice the track into a series of query frames. To construct a support set of labeled examples for the few-shot model, we randomly sample target examples from the track as positive examples, simulating the human input in Figure 1, and take all frames within the track as negative examples to model the non-target class. Note that, while the full track will also contain the target class, previous work has shown that since the target class is relatively sparse compared to

the full track, this strategy works well [14]. Given the support set, the trained few-shot model outputs the likelihood of each query frame containing the target class. Finally, we perform peak-picking on these probabilities to get a list of onset locations as is commonly done for ADT [11, 13].

3. EXPERIMENTAL DESIGN

To evaluate the proposed few-shot drum transcription paradigm, we first train a prototypical network as our few-shot model on a large synthetic dataset. Then, we apply the trained model to three real-music ADT datasets to get transcription performance. We focus on one target instrument at a time and use randomly selected target examples to simulate human input at inference time.

3.1 Dataset for Episodic Training: Slakh2100

We use the Slakh2100 dataset to train our few-shot model [23]. Slakh2100 is synthesized from the Lakh MIDI Dataset [24] using professional-grade sample-based virtual instruments. It contains 2100 automatically mixed tracks and accompanying MIDI files, totaling 145 hours of mixtures. Slakh2100 is synthesized using eight different drum patches, where each patch can be viewed as a unique drummer playing a unique drum kit. In each patch, there are around 25 to 45 different percussion classes, each consisting of a combination of a percussion instrument with a playing technique. For episodic training, we alternatively define a class as a specific percussion class (e.g. snare drum side stick) played by a specific patch, resulting in a total of 282 classes. Each drum patch has its own MIDI note-instrument mapping, which does not follow the general MIDI convention. We manually check the mapping to group duplicates and remove empty ones. Each patch is used to synthesize approximately 250 songs. We partition the dataset into patch-conditional train, validation and test splits using 5, 1, 2 patches per split, respectively.


3.2 Evaluation Datasets

3.2.1 ENST-Drums

ENST-Drums is a dataset of recordings from three drummers each playing a different drum kit [9]. It contains drum onset annotations for 20 classes of percussion sounds. While the dataset also contains many solo drum recordings, we only use the subset of 64 recordings with accompaniment for evaluation. The accompaniments are mixed with corresponding drum tracks using a scaling factor of 1/3 and 2/3 to get natural-sounding mixtures and to be consistent with prior studies [6, 11, 25].

3.2.2 MDB-Drums

MDB-Drums is a set of 23 fully-produced music tracks from the MedleyDB dataset [10, 26]. It contains two levels of drum onset annotations — we use the finer level which divides the classes by instrument and playing technique, resulting in 21 classes.

Figure 2. Our backbone prototypical network embedding model architecture.

3.2.3 RBMA13

RBMA13 consists of 30 fully-produced music tracks in the genres of electronic dance music, singer-songwriter, and fusion-jazz [11]. The drum sounds of this set are more diverse compared to the previous sets, and it is considered a particularly difficult dataset [11]. It contains annotations for 23 percussive classes.

3.3 Training

For each percussion instrument onset in Slakh2100, we center a 250 ms context window around the onset as the input to the model. We compute a log-scaled Mel-spectrogram from the context window with `librosa` [27] using a window size of 46 ms (2048 samples for a sample rate of 44.1 kHz) and a hop size of 10 ms. In preliminary experiments, we studied a range of short (160 ms) to long (500 ms) context windows and found that a 250 ms window yields consistent, well-performing results across different datasets. We conjecture that a 250 ms window is wide enough to capture most percussive onsets, while also capturing some context around the onset.

To construct a *10-way 5-shot* training episode, we randomly sample a drum patch from the training set, sample 10 percussion instrument classes from the drum patch, and sample 5 instances per class as the support set. Note that, while each instance is guaranteed to contain the target class, it may also contain other sound classes if they overlap in time with the target class. The query set is comprised of 16 separate instances per each of the 10 classes [28].

We use a backbone convolutional neural network (CNN) to embed the input as shown in Figure 2. It consists of four convolution blocks, each of which has a convolutional layer with a 3×3 kernel, a batch normalization layer, a ReLU activation layer, and a 2×2 max-pooling layer. To allow our model to handle varying-duration input, we apply max-pooling along the time dimension to the output of the convolution blocks (rather than a fully connected layer). Finally, we flatten the feature map to get an embedding with a dimensionality of 1024. We train our model using the `Adam` optimizer [29] in `PyTorch` [30] with a learning rate of 0.001 for 100,000 episodes with early stopping. We choose the best model based on the

few-shot classification loss on the validation set.

3.4 Evaluation

To evaluate our proposed few-shot drum transcription paradigm, we apply the prototypical network trained on Slakh2100 to perform drum transcription on three real music datasets. For each dataset, we first evaluate transcription under the fixed vocabulary scenario by mapping percussion instruments to a predefined 18-class vocabulary used in a state-of-the-art ADT system [11] for comparison. Then, we transcribe all classes that exist in the test set, including those classes that do not exist in our training data, mimicking the open vocabulary scenario.

Given a target class and an audio track, we first pre-process the track into a series of overlapping query frames with a 250 ms window size, matching the context window used during training, and 10 ms hop size. To simulate human selections at inference time, we randomly sample 5 target examples from the track as positive examples. Then, we take all frames within the track as negative examples and predict each query frame as described in Section 2.2. We run 10 iterations of this prediction process to account for randomness and concatenate all predictions to compute performance metrics. We estimate target onset locations from the model output using the peak picking method described in [31]. A frame n is selected as an onset if the corresponding output probability $p(n)$ meets the following criteria:

1. $p(n) = max(p(n - w_1) : p(n + w_2))$,

2. $p(n) \geq mean(p(n - w_3) : p(n + w_4)) + \delta$,

3. $n - n_{last\ onset} > w_5$,

where δ is a threshold parameter, w_1 to w_4 are sample offset values defining the windows for the max and $mean$ functions, and w_5 is the minimum allowed number of samples between onsets.

We divide each dataset used for evaluation into three splits for 3-fold cross-validation. For each fold, we tune the peak-picking parameters on the validation split using a randomized search with 1000 iterations, and perform drum

transcription on the test split. Finally, we report the model performance averaged over the three test splits. For ENST-Drums, each split contains a different drummer. For MDB-Drums and RBMA13, we use the same splits as [11].

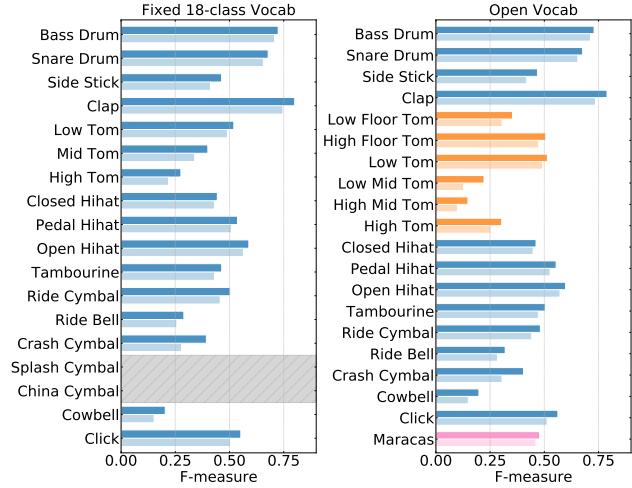
3.5 Metrics

We compute performance metrics by first using the `onset_evaluation` function in madmom [32] to find matching onset locations with a 20 ms tolerance window. We then compute F-measure as the primary performance metric, using both *micro* and *macro* aggregation. For *micro* F-measure, we aggregate all true positives (TP), false positives (FP), and false negatives (FN) over all classes and tracks in the entire dataset. For *macro* F-measure, we first compute a track-level F-measure for each track by averaging all class-level F-measures in the track, and we then average over all track-level F-measures in the dataset to compute the final metric.

When computing *macro* F-measure, if an instrument does not exist in a track and the ADT model under evaluation does not predict any corresponding positive labels, previous work defined its class-level F-measure to be 1 [11]. This convention is informative for a standard supervised approach since the model may produce false positives for non-existing classes. However, a few-shot model would never predict non-existing classes since there are no positive examples to begin with, which is one of the advantages of the few-shot drum transcription paradigm. Therefore, when evaluating our few-shot model, it makes more sense to exclude non-existing classes in a track from the evaluation to avoid artificially inflating the *macro* F-measure. For completeness and comparison to previous work, however, we report both variants, either excluding non-existing classes in a track (*macro* F-measure) or following the convention of setting the F-measure for such classes to 1 (*macro** F-measure).

Given that our model requires five user-labeled examples from the test data in each iteration of prediction, we can compute the aforementioned performance metrics either including or excluding the user-labeled examples. The former represents the joint human-computer performance of the proposed paradigm that a user would experience for

a track, while the latter represents our model's performance on strictly unlabeled data (i.e., the rest of the track). We report both variants for each metric described in the previous paragraph (labeled as Include/Exclude in the Tables).

4. RESULTS


4.1 Fixed Vocabulary

We first compare our few-shot drum transcription approach to a state-of-the-art CRNN model, which was trained on synthetic data and fine-tuned on real music data, under a fixed 18-class vocabulary [11]. Note that while NMF-based methods can be considered more closely related to our approach, they require iterative optimization at test time and the determination of the non-negative rank for the decomposition process can be difficult. Most previous NMF-based ADT systems were evaluated on solo drum tracks and a small subset of percussive sound classes [5, 12, 33]. Therefore, in this work, we choose the CRNN model as the baseline system and plan to compare our approach to NMF-based methods as part of future work.

In Table 1 we present model performance on three real music datasets. From these results, we find three distinct insights applicable to the fixed vocabulary ADT tasks. First, the results show that our approach, a prototypical network trained on synthetic data with only five examples provided at inference time, gives comparable and in some cases better performance compared to previous, fully supervised state-of-the-art results. Second, we see that our model performance is relatively stable across different datasets. Third, our proposed approach outperforms the supervised model on RBMA13 by a large margin, which is considered a difficult dataset with diverse drum sounds [11]. For instance, snare drum sounds on different tracks in RBMA13 are very diverse and can sound very different. Standard supervised approaches typically struggle to generalize well for classes with high intra-class variation. However, while a percussive sound class may exhibit large intra-class variation across different tracks (e.g. different tracks may have very different snare drum sounds), it's often the case that such sound classes display far less intra-class variation within the same track (e.g., the same snare drum is used throughout a track). Since our few-shot model detects a sound class based on target examples from the same track, it is considerably more robust when it comes to intra-class variation, as evidenced by the quantitative results. This highlights the strength of the few-shot drum transcription paradigm which instead of aiming at generalization, aims for quick adaptation with minimal human input.

4.2 Open Vocabulary

Next, we evaluate our few-shot model under an open-vocabulary scenario. Here, we evaluate the model against all the classes in each test set, including classes that were never seen by the model during training. Specifically, we evaluate on 20 classes for ENST-Drums, 19 classes for MDB-Drums, and 20 classes for RBMA13. Classes that do

Figure 3. F-measure for each percussion instrument in the RBMA13 dataset. (Left) Under 18-class vocabulary. (Right) Under all 20 classes. For each instrument, we show the metrics computed with target examples included (dark bar) and excluded (light bar).

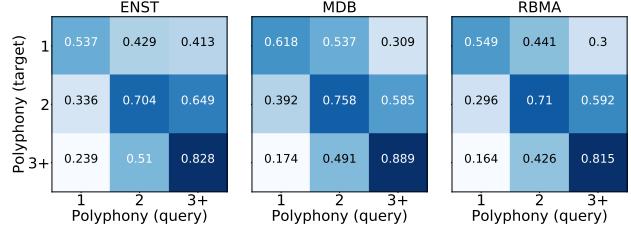
not appear more than five times in any track in the dataset are filtered out. Note that 6, 4, and 1 classes within the full vocabulary of ENST, MDB, and RBMA respectively do not exist in our training data. The results are presented in Table 2. Note that we do not compare our model to the fully supervised model in this scenario since, as noted earlier, such a model would fail (by design) to recognize classes that are outside of the training vocabulary. When we compare these results to those in Table 1 (fixed vocabulary), we note that there is no drop in performance when moving from a fixed known vocabulary to an open vocabulary with previously unseen sound classes. This is a direct result of adapting few-shot learning to ADT and highlights the benefit of our proposed approach.

Next, we break down the performance of the few-shot model by instrument class under both the fixed and open vocabulary scenarios on RBMA13, presented in Figure 3. Here, two out of 18 predefined classes, splash cymbal and china cymbal, do not exist in RBMA13 annotations and thus the results for these classes are absent from the figure. We see that in the open vocabulary scenario, we are able to transcribe fine-grained classes such as six different tom drums (orange bars in Figure 3) with comparable performance to predicting a coarser, fixed vocabulary. We can also transcribe Maracas (pink bar in Figure 3) which our model has not seen at training.

4.3 Transcribing Novel Classes

In the previous section, we saw that the model can detect a class that is out of the training vocabulary. To evaluate this more quantitatively, we re-train our few-shot model on the Slakh2100 dataset while completely excluding three classes from the training data: bass drum, tambourine, and clap, representing both common and rare classes. We then evaluate the model on predicting these three classes in the Slakh2100 test set and compare the results to those we ob-

Training data	Target examples	$\mathcal{H}$ in Slakh2100 test set		
		micro	macro	macro*
Slakh2100	Include	0.66	0.66	0.83
	Exclude	0.64	0.64	0.83
Slakh2100 - $\mathcal{H}$	Include	0.62	0.62	0.81
	Exclude	0.61	0.60	0.80

Table 3. F-measure evaluated on three classes: $\mathcal{H} = \{$bass drum, tambourine, clap$\}$ in the Slakh2100 test set when training with the entire Slakh2100 training set or with three classes held out from the training data.


tain when the three classes are included in the training data.

We present the results in Table 3. We see that the performance of the model is very stable, with only a minor decrease in F-measure when predicting classes that are completely excluded from the training set. This confirms that with the few-shot training paradigm, our model can detect entirely unseen classes given just a few examples at inference time.

4.4 Performance Breakdown by Polyphony

Next, we focus on the target example selection process at inference time. Due to the polyphonic nature of music audio, when a target example is selected, it can include non-target instrument sounds, played at the same time. We want to investigate how the polyphony of these selected examples affects transcription performance. To do so, we repeat our evaluation process three more times, each time varying the support set such that all positive target examples have the same degree of polyphony: 1, 2, and 3 or more (3+). To define the polyphony of each example, we look at a 20 ms window around its onset and count the number of percussion instruments that co-occur within the window. To assess how the performance is affected by the polyphony of the *query*, we break down the performance by the polyphony of the query frames.

We present the results in Figure 4, which show similar trends across the three evaluation datasets. First, we see high performance on the diagonal, where the polyphony between target and query examples match. Along the diagonal, performance also increases with increasing polyphony, for which a possible explanation is that the chance of having exactly matched instrument sources between target and query examples increases at high polyphony. That is, the number of different percussion instrument combinations decreases with increasing polyphony, due to the underlying pattern of drum playing. Another insight is that when there is a mismatch between target and query polyphony, having lower polyphony in target examples than in query examples gives better performance than the other way around (comparing the upper right triangle to the lower-left triangle in each figure). This matches the intuition that when the target examples have high polyphony, it is difficult for the few-shot model to latch onto the correct target instrument, result-

Figure 4. Break down F-measure by polyphony in both target and query examples.

ing in poor performance even on query examples with low polyphony. On the other hand, it is easier for the model to find the target class in common within examples with lower polyphony.

Overall, the results show that the performance of our few-shot drum transcription approach can significantly depend on the target examples selected for the support set. In future work, we plan to build on top of these results to investigate the best strategy of composing a support set, and how we can inform user to make effective selections.

5. LIMITATION AND FUTURE WORK

The main limitation of our proposed approach is that it requires the user to provide a few examples at inference time. If the vocabulary is known in advance and there is sufficient training data for each sound class, a fully supervised approach has the advantage of not requiring any user intervention. However, when the vocabulary is not known in advance, or when there isn't enough training data for every class, the few-shot paradigm is clearly advantageous. For future work, we plan to investigate the example selection process at inference time and the corresponding human element. This includes studying how we can compose sets of support examples to maximize performance, and how we can guide the user to those selections.

6. CONCLUSION

In this work, we address open vocabulary ADT by proposing a few-shot drum transcription paradigm, a combination of a few-shot model with minimal human input. We train a prototypical network on the Slakh2100 dataset as the few-shot model, and evaluate the proposed few-shot drum transcription system on multiple real-world ADT datasets with polyphonic accompaniment. We show that, given just a handful of target examples, we can match and, in some cases outperform, a state-of-the-art supervised ADT approach under a fixed vocabulary setting. At the same time, we show that our model can successfully generalize to finer-grained class labeling and extended vocabularies unseen during training. Lastly, we investigate the dependence of few-shot model performance on the polyphony of target examples. We show that matching polyphony in target and query examples gives better performance and when there is a mismatch, having lower polyphony in target examples than in query examples gives better results.

ABSTRACT

Representation learning focused on disentangling the underlying factors of variation in given data has become an important area of research in machine learning. However, most of the studies in this area have relied on datasets from the computer vision domain and thus, have not been readily extended to music. In this paper, we present a new symbolic music dataset that will help researchers working on disentanglement problems demonstrate the efficacy of their algorithms on diverse domains. This will also provide a means for evaluating algorithms specifically designed for music. To this end, we create a dataset comprising of 2-bar monophonic melodies where each melody is the result of a unique combination of nine latent factors that span ordinal, categorical, and binary types. The dataset is large enough (≈ 1.3 million data points) to train and test deep networks for disentanglement learning. In addition, we present benchmarking experiments using popular unsupervised disentanglement algorithms on this dataset and compare the results with those obtained on an image-based dataset.

1. INTRODUCTION

Representation learning deals with extracting the underlying factors of variation in a given observation [1]. Learning compact and *disentangled* representations (see Figure 1 for an illustration) from given data, where important factors of variation are clearly separated, is considered useful for generative modeling and for improving performance on downstream tasks (such as speech recognition, speech synthesis, vision and language generation [2–4]). Disentangled representations allow a greater degree of interpretability and controllability, especially for content generation, be it language, speech, or music. In the context of Music Information Retrieval (MIR) and generative music models, learning some form of disentangled representation has been the central idea for a wide variety of tasks such as genre transfer [5], rhythm transfer [6, 7], timbre synthesis [8], instrument rearrangement [9], manipulating musical attributes [10, 11], and learning music similarity [12].

Consequently, there exists a large body of research in

Figure 1: Disentanglement example where a high dimensional observed data is disentangled into a low dimensional representation comprising of semantically meaningful factors of variation.

the machine learning community focused on developing algorithms for learning disentangled representations. These span unsupervised [13–16], semi-supervised [17–19] and supervised [10, 20–22] methods. However, a vast majority of these algorithms are designed, developed, tested, and evaluated using data from the image or computer vision domain. The availability of standard image-based datasets such as dSprites [23], 3D-Shapes [24], and 3D-Chairs [25] among others has fostered disentanglement studies in vision. Additionally, having well-defined factors of variation (for instance, size and orientation in dSprites [23], pitch and elevation in Cars3D [26]) has allowed systematic studies and easy comparison of different algorithms. However, this restricted focus on a single domain raises concerns about the generalization of these methods [27] and prevents easy adoption into other domains such as music.

Research on disentanglement learning in music has often been application-oriented with researchers using their own problem-specific datasets. The factors of variation have also been chosen accordingly. To the best of our knowledge, there is no standard dataset for disentanglement learning in music. This has prevented systematic research on understanding disentanglement in the context of music.

In this paper, we introduce *dMelodies*, a new dataset of monophonic melodies, specifically intended for disentanglement studies. The dataset is created algorithmically and is based on a simple and yet diverse set of independent latent factors spanning ordinal, categorical and binary attributes. The full dataset contains ≈ 1.3 million data points which matches the scale of image datasets and should be sufficient to train deep networks. We consider this dataset as the primary contribution of this paper. In addition, we also conduct benchmarking experiments using three popular unsupervised methods for disentanglement learning and present a comparison of the results with the dSprites dataset [23]. Our experiments show that disentanglement

learning methods do not directly translate between the image and music domains and having a music-focused dataset will be extremely useful to ascertain the generalizability of such methods. The dataset is available online [1] along with the code to reproduce our benchmarking experiments. [2]

2. MOTIVATION

In representation learning, given an observation $\mathbf{x}$, the task is to learn a representation $r(\mathbf{x})$ which "makes it easier to extract useful information when building classifiers or other predictors" [1]. The fundamental assumption is that any high-dimensional observation $\mathbf{x} \in \mathcal{X}$ (where $\mathcal{X}$ is the dataspace) can be decomposed into a semantically meaningful low dimensional latent variable $\mathbf{z} \in \mathcal{Z}$ (where $\mathcal{Z}$ is referred to as the latent space). Given a large number of observations in $\mathcal{X}$, the task of disentanglement learning is to estimate this low dimensional latent space $\mathcal{Z}$ by separating out the distinct factors of variation [1]. An ideal disentanglement method ensures that changes to a single underlying factor of variation in the data changes only a single factor in its representation [27]. From a generative modeling perspective, it is also important to learn the mapping from $\mathcal{Z}$ to $\mathcal{X}$ to enable better control over the generative process.

2.1 Lack of diversity in disentanglement learning

Most state-of-the-art methods for unsupervised disentanglement learning are based on the Variational Auto-Encoder (VAE) [28] framework. The key idea behind these methods is that factorizing the latent representation to have an aggregated posterior should lead to better disentanglement [27]. This is achieved using different means, e.g., imposing constraints on the information capacity of the latent space [13, 29, 30], maximizing the mutual information between a subset of the latent code and the observations [31], and maximizing the independence between the latent variables [14, 15]. However, unsupervised methods for disentanglement learning are sensitive to inductive biases (such network architectures, hyperparameters, and random seeds) and consequently there is a need to properly evaluate such methods by using datasets from diverse domains [27].

Apart from unsupervised methods for disentanglement learning, there has also been some research on semi-supervised [18, 19] and supervised [20, 21, 32, 33] learning techniques to manipulate specific attributes in the context of generative models. In these paradigms, a labeled loss is used in addition to the unsupervised loss. Available labels can be utilized in various ways. They can help with disentangling known factors (e.g., digit class in MNIST) from latent factors (e.g., handwriting style) [34], or supervising specific latent dimensions to map to specific attributes [10]. However, most of these approaches are evaluated using image domain datasets.

Tremendous interest from the machine learning community has led to the creation of benchmarking datasets (albeit image-based) specifically targeted towards disentanglement learning such as dSprites [23], 3D-Shapes [24], 3D-chairs [25], MPI3D [35], most of which are artificially generated and have simple factors of variation. While one can argue that artificial datasets do not reflect real-world scenarios, the relative simplicity of these datasets is often desirable since they enable rapid prototyping.

2.2 Lack of consistency in music-based studies

Representation learning has also been explored in the field of MIR. Much like images, learning better representations has been shown to work well for MIR tasks such as composer classification [36, 37], music tagging [38], and audio-to-score alignment [39]. The idea of disentanglement has been particularly gaining traction in the context of interactive music generation models [5, 6, 11, 33]. Disentangling semantically meaningful factors can significantly improve the usefulness of music generation tools. Many researchers have independently tried to tackle the problem of disentanglement in the context of symbolic music by using different musically meaningful attributes such as genre [5], note density [10], rhythm [6], and timbre [8]. However, these methods and techniques have all been evaluated using different datasets which makes a direct comparison impossible. Part of the reason behind this lack of consistency is the difference in the problems that these methods were looking to address. However, the availability of a common dataset allowing researchers to easily compare algorithms and test their hypotheses will surely aid systematic research.

3. dMELODIES DATASET

The primary objective of this work is to create a simple dataset for music disentanglement that can alleviate some of the shortcomings mentioned in Section 2: first, researchers interested in disentanglement will have access to more diverse data to evaluate their methods, and second, research on music disentanglement will have the means for conducting systematic, comparable evaluation. This section describes the design choices and the methodology used for creating the proposed *dMelodies* dataset.

While core MIR tasks such as music transcription, or tagging focus more on analysis of audio signals, research on generative models for music has focused more on the symbolic domain. Considering most of the interest in disentanglement learning stems from research on generative models, we decided to create this dataset using symbolic music representations.

3.1 Design Principles

To enable objective evaluation of disentanglement algorithms, one needs to either know the ground-truth values of the underlying factors of variation for each data point, or be able to synthesize the data points based on the attribute values. The dSprites dataset [23], for instance, consists of single images of different 2-dimensional shapes with simple attributes specifying the position, scale and orientation of these shapes against a black background. The design of our

---

dataset is loosely based on the dSprites dataset. The following principles were used to finalize other design choices:

(a) The dataset should have a simple construction with homogenous data points and intuitive factors of variation. It should allow for easy differentiation between data points and have clearly distinguishable latent factors.

(b) The factors of variation should be independent, i.e., changing any one factor should not cause changes to other factors. While this is not always true for real-world data, it enables consistent objective evaluation.

(c) There should be a clear one-to-one mapping between the latent factors and the individual data points. In other words, each unique combination of the factors should result in a unique data point.

(d) The factors of variation should be diverse. In addition, it would be ideal to have the factors span different types such as discrete, ordinal, categorical and binary.

(e) Finally, the different combinations of factors should result in a dataset large enough to train deep neural networks. Based on size of the different image-based datasets [23,40], we would require a dataset of the order of at least a few hundred thousand data points.

3.2 Dataset Construction

Considering the design principles outlined above, we decided to focus on monophonic pitch sequences. While there are other options such as polyphonic or multi-instrumental music, the choice of monophonic melodies was to ensure simplicity. Monophonic melodies are a simple form of music uniquely defined by the pitch and duration of their note sequences. The pitches are typically based on the key or scale in which the melody is being played and the rhythm is defined by the onset positions of the notes.

Since the set of all possible monophonic melodies is very large and heterogeneous, the following additional constraints were imposed on the melody in order to enforce homogeneity and satisfy the other design principles:

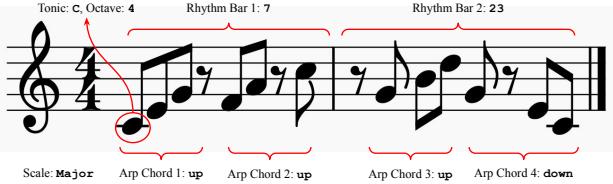
(a) Each melody is based on a scale selected from a finite set of allowed scales. This choice of scale also serves as one of the factors of variation. The melody will also be uniquely defined by the pitch class of the tonic (root pitch) and the octave number.

(b) In order to constrain the space of all possible pitch patterns within a scale, we restrict each melody to be an arpeggio over the standard I-IV-V-I cadence chord pattern. Consequently, each melody consists of 12 notes (3 notes for each of the 4 chords).

(c) In order to vary the pitch patterns, the direction of arpeggiation of each chord, i.e. up or down, is used as a latent factor. This choice adds a few binary factors of variation to the dataset.

(d) The melodies are fixed to 2-bar sequences with 8th note as the minimum note duration. This makes the dataset uniform in terms of sequence lengths of the data points and also helps reduce the complexity of the sequences. 2-bar sequences have been used in other music generation studies as well [10, 41]. We use a tokenized data representation such that each melody is

Factor	# Options	Notes
Tonic	12	C, C#, D, through B
Octave	3	Octave 4, 5 and 6
Scale	3	major, harmonic minor, and blues
Rhythm Bar 1	28	$\binom{8}{6}$, based on onset locations of 6 notes
Rhythm Bar 2	28	$\binom{8}{6}$, based on onset locations of 6 notes
Arp Chord 1	2	up/down, for Chord 1
Arp Chord 2	2	up/down, for Chord 2
Arp Chord 3	2	up/down, for Chord 3
Arp Chord 4	2	up/down, for Chord 4

Table 1: Table showing the different factors of variation for the dMelodies dataset. Since all factors of variation are independent, the total dataset contains 1,354,752 unique melodies.


a sequence of length 16.

(e) If we consider the space of all possible unique rhythms, the number of options will explode to $\binom{16}{12}$ which will be significantly larger than other factors of variation. Hence, we choose to break the latent factor for rhythm into 2 independent factors: rhythm for bar 1 and bar 2.

(f) The rhythm of a melody is based on the metrical onset position of the notes [42]. Consequently, rhythm is dependent on the number of notes. In order to keep rhythm independent from other factors, we constrain each bar to have 6 notes (play 2 chords) thereby obtaining $\binom{8}{6}$ options for each bar.

Based on the above design choices, the dMelodies dataset consists of 2-bar monophonic melodies with 9 factors of variations listed in Table 1. The factors of variation were chosen to satisfy the design principles listed in Section 3.1. For instance, while melodic transformations such as repetition, inversion, retrograde would have made more musical sense, they did not allow creation of a large-enough dataset with independent factors of variation. The resulting dataset thus contains simple melodies which do not adequately reflect real-world musical data. A side-effect of this choice of factors is that some of them (such as arpeggiation direction and rhythm) affect only a specific part of the data. Since each unique combination of these factors results in a unique data point we get 1,354,752 unique melodies. Figure 2 shows one such melody from the dataset and its corresponding latent factors. The dataset is generated using the *music21* [43] python package.

4. BENCHMARKING EXPERIMENTS

In this section, we present benchmarking experiments to demonstrate the performance of some of the existing unsupervised disentanglement algorithms on the proposed dMelodies dataset and contrast the results with those obtained on the image-based dSprites dataset.

Figure 2: Example of a sample melody from the dMelodies dataset. Also shown are the values of the different latent factors. For rhythm latent factors, the shown value corresponds to the index from the rhythm dictionary.

4.1 Experimental Setup

We consider 3 different disentanglement learning methods: β-VAE [13], Annealed-VAE [29], and FactorVAE [15]. All these methods are based on different regularization terms applied to the VAE loss function.

4.1.1 Data Representation

We use a tokenized data representation [44] with the 8th-note as the smallest note duration. Each 8th note position is encoded with a token corresponding to the note name which starts on that position. A special continuation symbol ('__') is used which denotes that the previous note is held. A special token is used for rest.

4.1.2 Model Architectures

Two different VAE architectures are chosen to conduct these experiments. The first architecture (dMelodies-CNN) is based on Convolutional Neural Networks (CNNs) and is similar to those used for several image-based VAEs, except that we use 1-D convolutions. The second architecture (dMelodies-RNN) is based on a hierarchical recurrent model [41, 45]. Details of the model architectures are provided in the supplementary material.

4.1.3 Hyperparameters

Each learning method has its own regularizing hyperparameter. For β-VAE, we use three different values of $\beta \in \{0.2, 1.0, 4.0\}$. This choice is loosely based on the notion of normalized-β [13]. In addition, we force the KL-regularization only when the KL-divergence exceeds a fixed threshold $\tau = 50$ [41, 46]. For Annealed-VAE, we fix $\gamma = 1.0$ and use three different values of capacity, $C \in \{25.0, 50.0, 75.0\}$. For FactorVAE, we use the Annealed-VAE loss function with a fixed capacity ($C = 50$), and choose three different values for $\gamma \in \{1, 10, 50\}$.

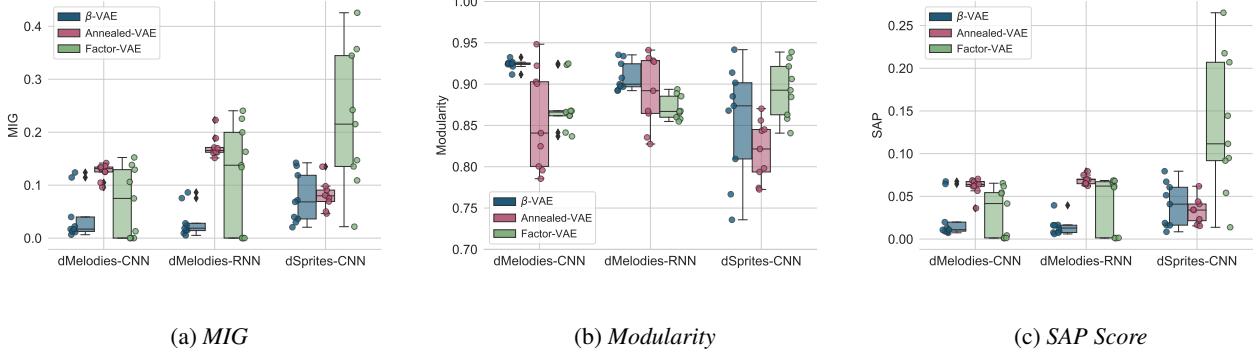
4.1.4 Training Specifications

For each of the above methods, model, and hyperparameter combination, we train 3 models with different random seeds. To ensure consistency across training, all models are trained with a batch-size of 512 for 100 epochs. The ADAM optimizer [47] is used with a fixed learning rate of $1e-4$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-8$. For β-VAE and Annealed-VAE, we use 10 warm-up epochs where $\beta = 0.0$. After warm-up, the regularization hyperparameter (β for

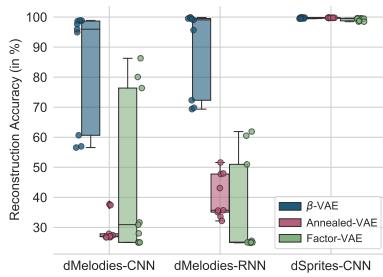
β-VAE and C for Annealed-VAE) is annealed exponentially from 0.0 to their target values over 100000 iterations. For FactorVAE, we stick to the original implementation and do not anneal any of the parameters in the loss function. The VAE optimizer is the same as mentioned earlier. The Factor-VAE discriminator is optimized using ADAM with a fixed learning rate of $1e-4$, $\beta_1 = 0.8$, $\beta_2 = 0.9$, and $\epsilon = 1e-8$. We found that utilizing the original hyperparameters [15] for this optimizer led to unstable training on dMelodies.

For comparison with dSprites, we present the results for all the three methods using a CNN-based VAE architecture. The set of hyperparameters and other training configurations were kept the same for the dSprites dataset, except for the FactorVAE where we use the originally proposed loss function and discriminator optimizer hyperparameters, as the model does not converge otherwise.

4.1.5 Disentanglement Metrics

The following objective metrics for measuring disentanglement are used: (a) *Mutual Information Gap (MIG)* [14], which measures the difference of mutual information between a given latent factor and the top two dimensions of the latent space which share maximum mutual information with the factor, (b) *Modularity* [48], which measures if each dimension of the latent space depends on only one latent factor, and (c) *Separated Attribute Predictability (SAP)* [16], which measures the difference in the prediction error of the two most predictive dimensions of the latent space for a given factor. For each metric, the mean across all latent factors is used for aggregation. For consistency, standard implementations of the different metrics are used [27].


4.2 Experimental Results

4.2.1 Disentanglement


In this experiment, we present the comparative disentanglement performance of the different methods on dMelodies. The result for each method is aggregated across the different hyperparameters and random seeds. Figure 3 shows the results for all three disentanglement metrics. We group the trained models based on the architecture. The results for the dSprites dataset are also shown for comparison.

First, we compare the performance of different methods on dMelodies. Annealed-VAE shows better performance for MIG and SAP. These metrics indicate the ability of a method to ensure that each factor of variation is mapped to a single latent dimension. The performance in terms of Modularity is similar across the different methods. High Modularity indicates that each dimension of the latent space maps to only a single factor of variation. For dSprites, FactorVAE seems to be best method overall across metrics. However, the high variance in the results shows that choice of random seeds and hyperparameters is probably more important than the disentanglement method itself. This is in line with observations in previous studies [27].

Second, we observe no significant impact of model architecture on the disentanglement performance. For both the CNN and the hierarchical RNN-based VAE, the performance of all the different methods on dMelodies is

(a) *MIG*   (b) *Modularity*   (c) *SAP Score*

Figure 3: Overall disentanglement performance (higher is better) of different methods on the dMelodies and dSprites datasets. Individual points denote results for different hyperparameter and random seed combinations. Please refer to supplementary material Sec.2.1 for the best hyperparameter settings.

Figure 4: Overall reconstruction accuracies (higher is better) of the different methods on the dMelodies and dSprites datasets. Individual points denote results for different hyperparameter and random seed combinations.

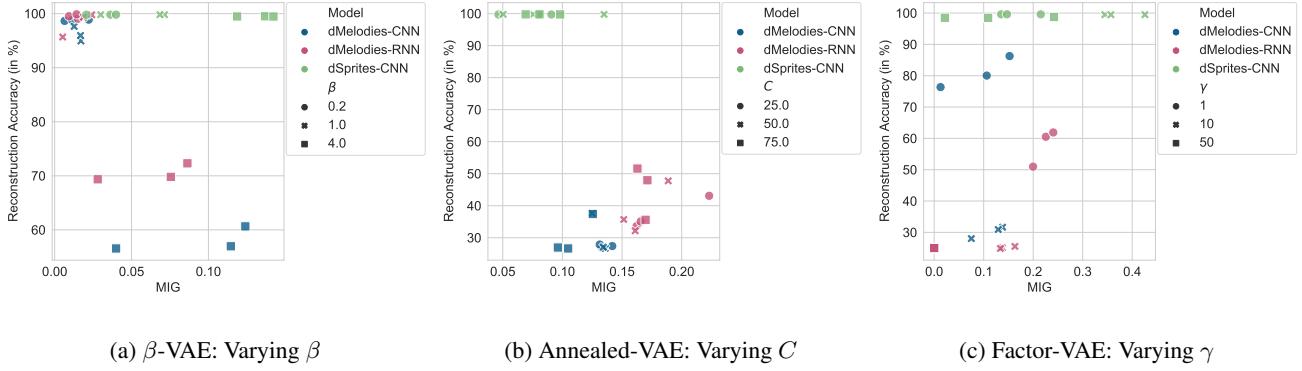
comparable. This might be due to the relatively short sequence lengths used in dMelodies which do not fully utilize the capabilities of the hierarchical-RNN architecture (which has been shown to work well in learning long-term dependencies [41]). On the positive side, this indicates that the dMelodies dataset might be agnostic to the VAE-architecture.

Finally, we compare differences in the performance between the two datasets. In terms of MIG and SAP, the performance for dSprites is slightly better (especially for Factor-VAE), while for Modularity, performance across both datasets is comparable. However, once again, the differences are not significant. Looking at the disentanglement metrics alone, one might be tempted to conclude that the different methods are domain invariant. However, as the next experiments will show, there are significant differences.

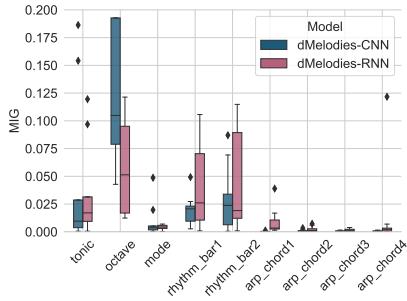
4.2.2 Reconstruction Fidelity

From a generative modeling standpoint, it is important that along with better disentanglement performance we also retain good reconstruction fidelity. This is measured using the reconstruction accuracy shown in Figure 4. It is clear that all three methods fail to achieve a consistently good reconstruction accuracy on dMelodies. β-VAE gets an accuracy $\geq 90\%$ for some hyperparameter values (more on this in

Section 4.2.3). However, both Annealed-VAE and Factor-VAE struggle to cross a median-accuracy of 40% (which would be unusable from a generative modeling perspective). The performance of the hierarchical RNN-based VAE is slightly better than the CNN-based architecture. In comparison, for dSprites, all three methods are able to consistently achieve better reconstruction accuracies.

4.2.3 Sensitivity to Hyperparameters


The previous experiments presented aggregated results over the different hyperparameter values for each method. Next, we take a closer look at the individual impact of those hyperparameters, i.e., the effect of changing the hyperparameters on the disentanglement performance (MIG) and the reconstruction accuracy. Figure 5 shows this in the form of scatter plots. The ideal models should lie on the top right corner of the plots (with high values of both reconstruction accuracy and MIG).

Models trained on dMelodies are very sensitive to hyperparameter adjustments. This is especially true for reconstruction accuracy. For instance, increasing β for the β-VAE model improves MIG but severely reduces reconstruction performance. For Annealed-VAE and Factor-VAE there is a wider spread in the scatter plots. For Annealed-VAE, having a high capacity C seems to marginally improve reconstruction (especially for the recurrent VAE). For FactorVAE, increasing γ leads to a drop in both disentanglement and reconstruction.


Contrast this with the scatter plots for dSprites. For all three methods, the hyperparameters seem to only significantly affect the disentanglement performance. For instance, increasing β and γ (for β-VAE and FactorVAE, respectively) result in clear improvement in MIG. More importantly, however, there is no adverse impact on the reconstruction accuracy.

4.2.4 Factor-wise Disentanglement

We also looked at how the individual factors of variation are disentangled. We consider the β-VAE model for this since it has the highest reconstruction accuracy. Figure 6

(a) β-VAE: Varying β

(b) Annealed-VAE: Varying C

(c) Factor-VAE: Varying γ

Figure 5: Effect of the hyperparameters on the different disentanglement methods. Overall, for improving disentanglement on dMelodies results in severe drop in reconstruction accuracy. The dSprites dataset does not suffer from this drawback.

Figure 6: Factor-wise MIG for the β-VAE method.

shows the factor-wise *MIG* for both the CNN and RNN-based models. Factors corresponding to octave and rhythm are disentangled better. This is consistent with some recent research on disentangling rhythm [6, 7]. In contrast, the factors corresponding to the arpeggiation direction perform the worst. This might be due to their binary type. Similar analysis for the dSprites dataset reveals better disentanglement for the scale and position based factors. Additional results are provided in the supplementary material.

5. DISCUSSION

As mentioned in Section 2, disentanglement techniques have been shown to be sensitive to the choice of hyper-parameters and random seeds [27]. The results obtained in our benchmarking experiments in the previous section using dMelodies seem to ascertain this even further. We find that methods which work well for image-based datasets do not extend directly to the music domain. When moving between domains, not only do we have to tune hyperparameters separately, but the model behavior may vary significantly when hyperparameters are changed. For instance, reconstruction fidelity is hardly effected by hyperparameter choice in the case of dSprites while for dMelodies it varies significantly. While sensitivity to hyperparameters is expected in neural networks, this is also one of the main reasons for evaluating methods on more than one dataset, preferably from multiple domains.

Some aspects of the dataset design, especially the na-

ture of the factors of variation, might have affected our experimental results. While the factors of variation in dSprites are continuous (except the shape attribute), those for dMelodies span different data-types (categorical, ordinal and binary). This might make other types of models (such as VQ-VAEs [49]) more suitable. Another consideration is that some factors of variation (such as the arpeggiation direction and rhythm) effect only a part of the data. However, the effect of this on the disentanglement performance needs further investigation since we get good performance for rhythm but poor performance for arpeggiation direction.

Unsupervised methods for disentanglement learning have their own limitations and some degree of supervision might actually be essential [27]. It is still unclear if it is possible to develop general domain-invariant disentanglement methods. Consequently, supervised and semi-supervised methods have been garnering more attention [10, 11, 19, 34]. The dMelodies dataset can also be used to explore such methods for music-based tasks. There has been some work recently in disentangling musical attributes such as rhythm and melodic contours which are considered important from an interactive music generation perspective [6,11,50]. Apart from the designed latent factors of variation, other low-level musical attributes such as rhythmic complexity and contours can also be computationally extracted using this dataset to meet task-specific requirements.

6. CONCLUSION

This paper addresses the need for more diverse modes of data for studying disentangled representation learning by introducing a new music dataset for the task. The *dMelodies* dataset comprises of more than 1 million data points of 2-bar melodies. The dataset is constructed based on fixed rules that maintain independence between different factors of variation, thus enabling researchers to use it for studying disentanglement learning. Benchmarking experiments conducted using popular disentanglement learning methods show that existing methods do not achieve performance comparable to those obtained on an analogous image-based dataset. This showcases the need for further research on domain-invariant algorithms for disentanglement learning.

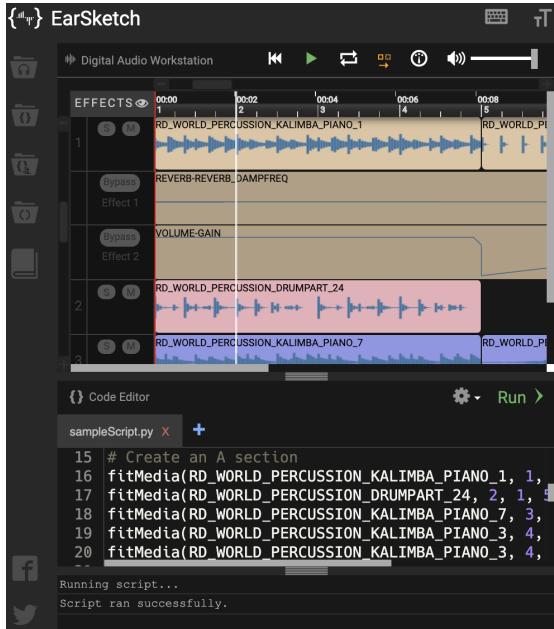
ABSTRACT

EarSketch is an online environment for learning introductory computing concepts through code-driven, sample-based music production. This paper details the design and implementation of a module to perform code and music analyses on projects on the EarSketch platform. This analysis module combines inputs in the form of symbolic metadata, audio feature analysis, and user code to produce comprehensive models of user projects. The module performs a detailed analysis of the abstract syntax tree of a user's code to model use of computational concepts. It uses music information retrieval (MIR) and symbolic metadata to analyze users' musical design choices. These analyses produce a model containing users' coding and musical decisions, as well as qualities of the algorithmic music created by those decisions. The models produced by this module will support future development of CAI, a Co-creative Artificial Intelligence. CAI is designed to collaborate with learners and promote increased competency and engagement with topics in the EarSketch curriculum. Our module combines code analysis and MIR to further the educational goals of CAI and EarSketch and to explore the application of multimodal analysis tools to education.

1. INTRODUCTION

Digital music creation environments often use a combination of raw audio data, symbolic information, code, and metadata to represent user-generated music. For example, a digital audio workstation might represent a song through a combination of audio files, genre and artist labels, MIDI events, and a data source indicating the placement of audio and MIDI segments on a multi-track timeline, along with device and mixer settings and automation.

In the context of music information retrieval (MIR), access to these multiple types of music representation can vastly simplify common retrieval tasks that are too complex to perform on audio alone. Examples of this include music preference modeling using a combined model of audio and metadata [1] and genre recognition using feature analysis alongside symbolic representation of the same audio through statistical descriptors of melody, harmony, and rhythm [2, 3]. A multimodal analytical approach can therefore help develop powerful MIR-driven applications within these digital music creation environments, such as creativity-support tools that generate ideas and feedback for users as they create music with the software.

Digital environments that include algorithmic composition elements offer yet another mode of analysis: the code that generates the music. A creativity support tool that incorporates code analysis in addition to these other modalities can potentially generate recommendations not only about the music users create but also about the code that they write and and the conceptual overlap thereof between the code and music.


This paper describes an analysis system we have created that uses audio features, audio metadata, symbolic multi-track music data, and code from user-created projects to understand the structure of algorithmic music and to model users' knowledge of coding and musical techniques. We have created the system in the context of EarSketch [4], an expressive and collaborative learning environment for high school students that is used by roughly 120,000 students per year. In EarSketch, users write Python or JavaScript code to algorithmically create multi-track compositions remixing a library of audio loops. Figure 1 depicts the EarSketch user interface. EarSketch aims to increase student engagement in computing across diverse student populations, promoting student perceptions of authenticity through its use of a professionally-produced audio loop library and design influences from industry-standard digital audio workstations [5].

The EarSketch curriculum contains musical concepts integral to algorithmic music and relevant to coding, including repetition, form, and effect usage. The EarSketch sound library contains over 3,500 sounds from professional

Figure 1. A Screenshot of the EarSketch web-based application, containing the Digital Audio Workstation (top), and Code Editor (bottom).

artists, split into folders and labeled with artist, genre, and instrument type. Users write code with Python and JavaScript APIs to manipulate sounds and create music.

EarSketch is designed for students without formal music training. It does not focus on traditional music theory concepts such as music notation, melody, and harmony. Instead, it uses audio loops, effects, automation, and step-sequenced rhythms to facilitate music production through code without prerequisite knowledge. In addition to modeling understanding of code, our module includes music analysis to compare a user project's traits to the information conveyed by the EarSketch curriculum.

Our analysis system was designed to support a new creativity-support tool within EarSketch called CAI (Co-creative Artificial Intelligence). CAI, which is still in the early stages of design, will assist EarSketch users in learning and practicing pedagogical concepts in both computing and music. CAI will use our multimodal analysis system in combination with user interaction to suggest additions and changes to student music and code, scaffolding student learning and producing co-creative musical output.

In the following sections, we position this work in the context of recent music information retrieval research, describe each component of the analytical system in turn, explain how we coalesce this data into a user model to inform CAI, and outline future areas of work in the design and implementation of the larger CAI system that will leverage this analysis tool.

The development of this analysis module for CAI marks a unique application of MIR and code analysis to educational systems. Further development of the CAI system will continue to illuminate the role of mixed-input models for the goal of supporting learners in expressive computing environments.

2. RELATED WORK

Multimodal music information retrieval relies on representations of information to perform analysis tasks beyond what is possible using raw audio signals [6]. Digital production environments and notation software use symbolic information to represent structural and artistic elements of user-generated music. Due to its prominent use in music software, symbolic music is a significant presence in the domain of music information retrieval, with well-known tools such as Music21 [7] performing operations on symbolic data. MIDI has also been used to train style transfer models [8] and detect meter in live performance [9].

MIDI note messages are direct symbolic representations of musical notes. Other combinations of symbolic and audio analysis performed by labeling audio with statistical descriptors have been used in applications of genre recommendation [2] and pattern-based style identification [3]. Another application [10] uses symbolic music representation to vectorize multiple aspects of music for the purpose of performing song recommendations. The LFM-1b dataset [11] contains recorded listening events tagged with metadata, and has been used in conjunction with audio feature analysis to model user music preference [1]. Our system differs from these applications by using audio and symbolic data to model a user's proficiency with the techniques required to produce musical output, using EarSketch curriculum topics as evaluation criteria.

Our system extends traditional music information retrieval applications in its use of source code analysis as an input. Code analysis tools often rely on the analysis of abstract syntax trees (ASTs) generated from student code to propose edits. Contemporary AST-based systems [12, 13] rely on step calculations between a student's current code-state and a previously seen code-state or family of code-states that fulfills a set of conditions. These systems use AST analysis to simplify a wide range of projects to their most basic structure and provide suggestions in almost all situations. This application has largely focused on moving students from an "incorrect" answer to a "correct" one. In comparison, the application of AST analysis to creative problems without a defined "solution" is relatively unexplored. Our code analysis module brings the advantages of AST analysis into the expressive domain, reorienting the process towards open-ended learning and development.

Examples of software analysis applied to music information retrieval include a tool that uses Source Code Analysis and Manipulation (SCAM) to represent the structure of algorithmic music compositions [14, 15]. Music code analysis has also been performed in the context of live coding, a performance format in which programmers write algorithmic music in real time. A survey of live coding practitioners on creativity [16] discusses the link between analyzing live coding techniques and the development of a creative software agent. EarSketch has previously been examined for its ability to function as an educational live coding platform [17], and a fully developed CAI system will be able to collaborate with learners in a live coding environment.

3. CODE ANALYSIS

3.1 Code Knowledge Modeling

The code portion of the analysis module combines AST analysis and a computer science learning taxonomy to build a model of user knowledge that will be used by CAI to generate level-appropriate suggestions for EarSketch users. Previous works on computer science assessment [18–20] have adapted general learning taxonomies for computing topics; similarly, we defined a series of knowledge levels for 15 computational concepts from the EarSketch curriculum across 4 knowledge categories (see Table 1) based upon a flattened version of Bloom's Taxonomy [21]. For each concept, we define knowledge levels specific to its usage contexts. Table 2 outlines knowledge levels defined for the "String" and "User-Defined Function" concepts. Level 1 refers to usage of the concept or construct (e.g., a user includes a string in their script). Level 2 is defined as "original" usage of the concept (usage not copied directly from sample code). Our originality measures are described in greater detail in Section 3.2. Subsequent levels focus on increased complexity of use: for example, a user's script could reach level 2 of the "String" concept by merely including an original string in their script, but level 3 requires that the string to be put to use (such as using it as a function argument).

Category	Concepts
Value Types	String, Integer, Float, Boolean
Data Storage	List, Variable
Operations	String Operation, List Operation, Comparison, Boolean Logic, Mathematical Operator
Procedure	For Loop, Conditional Statement, User-defined Function, Console Input

Table 1. Concepts in the analysis module taxonomy.

Level	String	User-Defined Function
0	Does Not Use	Does Not Use
1	Uses	Uses
2	Uses Originally	Uses Originally
3	Uses Originally for Purpose	Uses and Calls Originally
4	Uses Originally and Indexes or Iterates for Purpose	Uses and Calls Originally with Return OR Arguments
5	N/A	Uses and Calls Originally with Return AND Arguments

Table 2. Knowledge levels for two concepts: "String" and "User-Defined Function."

3.2 Code Complexity Analysis

The code analysis module generates knowledge models for student scripts, producing concise information on understanding of each topic. Code knowledge models are generated by analyzing the abstract syntax tree of a user's code, which allows for fast and non-intrusive analysis. The code analysis module searches each AST node for constructs that indicate the user's knowledge level for every concept in our taxonomy.

Prior to analysis, the module performs a series of four passes over the script's AST to gather supporting data. The first pass tests student code for similarity to sample code. We use Andrei Mackenzie's Levenshtein function [1] to calculate the edit distance between each line of a user's code and all lines of EarSketch sample code; if the edit distance is below a manually-defined similarity threshold, the line is marked as "not original." Three subsequent passes gather information about user-defined functions and variable assignments and values. Once this information is collected, each individual node in the hierarchy is checked against discrete rules developed in tandem with the knowledge modeling level table.

Below is an example of a student script progressing through levels of the "user-defined function" concept. In the first code snippet, the user creates and then calls a function to make a section of music, calling `fitMedia()` to place piano and drumpad samples between measures 1 and 16. This corresponds to level 3 of the "user-defined function" item: "Uses and Calls Originally."

```
def sectionA():
  fitMedia(RD_RNB_PIANO_1,1,1,16)
  fitMedia(Y25_DRUMPAD_1,2,1,16)

sectionA()
```

In the second snippet, the function has been modified to take arguments: the function now places the samples between passed "start" and "end" measures. This corresponds to level 4 of the "user-defined function" item: "Uses and Calls Originally with Return OR Arguments."

```
def sectionA(start, end):
  fitMedia(RD_RNB_PIANO_1,1,start,end)
  fitMedia(Y25_DRUMPAD_1,2,start,end)

sectionA(1,16)
```

These node analyses populate an output object with values mapped to knowledge levels, visualized in Table 3. These analyses will be used to support future development of CAI, providing guidance to the system about appropriate code structure for programming and music suggestions when collaborating with a student.

4. SYMBOLIC MUSIC ANALYSIS

4.1 EarSketch Music Representation

The music component of the analysis module uses a simplified symbolic representation generated by EarSketch to apply sounds and effects to the Digital Audio Workstation view and generate audio playback. When a learner runs a script, the parsed abstract syntax tree of the code is represented internally as a dictionary of tracks containing sound and effect usage for each measure in a piece of music.

```
#Setup
from earsketch import *
init()
setTempo(120)

# Create an A section
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_1,1,1,5) # main
fitMedia(RD_WORLD_PERCUSSION_DRUMPART_24,2,1,5) # drums
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_7,3,1,5) # bassline
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_3,4,1,2) # backing
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_3,4,3,4) # backing

# Create a 4 measure B section between measures 5 and 9
fitMedia(RD_WORLD_PERCUSSION_DRUMPART_3,1,5,9) # sparse drums
fitMedia(RD_WORLD_PERCUSSION_SEEDSRATTLE_1,3,5,9) # rattling
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_3,4,5,6) # backing

# Then back to section A at measure 9
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_1,1,9,13) # main
fitMedia(RD_WORLD_PERCUSSION_DRUMPART_24,2,9,13) # drums
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_7,3,9,13) # bassline
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_3,4,9,10)  # backing
fitMedia(RD_WORLD_PERCUSSION_KALIMBA_PIANO_3,4,11,12) # backing

# Effects
setEffect(1,REVERB)
setEffect(1,VOLUME,GAIN,0,4.9,-12,5)
setEffect(1,VOLUME,GAIN,-60,5,0,9)

#Finish
finish()
```

Figure 2. Code in the Code Editor of an example project created in EarSketch.

The track listing for the example project (Figure 2) is an array of tracks, each containing a series of *clip* and *effect* objects reflecting those used in the code. Each clip object contains the name of the sound file used (*RD_WORLD_PERCUSSION_KALIMBA_PIANO_1*), as well as its start measure (*1*), and end measure (*5*). Each effect object contains each instance of a specific effect

(*VOLUME-GAIN*), its starting value and measure (*-60, 5*) and ending value/measure (*0, 9*).

The music analysis tool begins by converting this track representation to a timeline representation, in order to ascertain temporal patterns in the song. The timeline is created by converting the track dictionary to a dictionary of measures, as measure numbers are used in the EarSketch API for audio and effect sequencing. Figure 3 shows this timeline for four measures of the example, which has sounds used throughout the song such as *RD_WORLD_PERCUSSION_KALIMBA_PIANO_1* and sounds used in a single section such as *RD_WORLD_PERCUSSION_SEEDSRATTLE_1*, as well as the value of the gain adjustment at each measure.

```
0: ["RD_WORLD_PERCUSSION_KALIMBA_PIANO_1",
    "VOLUME GAIN 1",
    "REVERB REVERB_DAMPFREQ 8000",
    "RD_WORLD_PERCUSSION_DRUMPART_24",
    "RD_WORLD_PERCUSSION_KALIMBA_PIANO_7",
    "RD_WORLD_PERCUSSION_KALIMBA_PIANO_3"]

4: ["RD_WORLD_PERCUSSION_DRUMPART_3",
    "VOLUME GAIN 0",
    "REVERB REVERB_DAMPFREQ 8000",
    "RD_WORLD_PERCUSSION_SEEDSRATTLE_1",
    "RD_WORLD_PERCUSSION_KALIMBA_PIANO_3"]

6: ["RD_WORLD_PERCUSSION_DRUMPART_3",
    "VOLUME GAIN 0.4995",
    "REVERB REVERB_DAMPFREQ 8000",
    "RD_WORLD_PERCUSSION_SEEDSRATTLE_1"]

8: ["RD_WORLD_PERCUSSION_KALIMBA_PIANO_1",
    "VOLUME GAIN 0.999",
    "REVERB REVERB_DAMPFREQ 8000",
    "RD_WORLD_PERCUSSION_DRUMPART_24",
    "RD_WORLD_PERCUSSION_KALIMBA_PIANO_7",
    "RD_WORLD_PERCUSSION_KALIMBA_PIANO_3"]
```

Figure 3. Timeline representation for measures 1, 5, 7, and 9 of the sample EarSketch project (see Figure 2).

Recognition of patterns in sound and effect usage over time can be used in determining form as described in section 5. It allows CAI to propose changes to sound choices, effects, and parameters at specific points in time, or to suggest optimized code structure to realize those patterns. For example, if a user places the same sound at regular intervals and the code analysis does not observe any loops containing the variables related to that sound in their code, CAI can suggest the use of a loop.

Audio usage requires students only to select sounds from the library; conversely, effects can be manipulated through envelopes and are introduced in the EarSketch curriculum in multiple levels of complexity. The analysis module conducts a hierarchical score analysis for effect usage, while simply recording the selection of audio at each measure to inform its audio analysis tools.

4.2 Effect Usage Scores

Effect envelopes in EarSketch are applied using a start value, end value, start time, and end time. The following code example (found in Figure 2) shows a use of the volume effect on track 1 having its gain parameter changed from -60 dB to 0 dB between measures 5 and 9:

```
setEffect(1, VOLUME, GAIN, -60, 5, 0, 9)
```

The internal track representation stores a single recording of these four values for each effect parameter. Consequently, we use linear interpolation to store the value of each effect parameter at each measure when converting effect envelopes to the timeline.

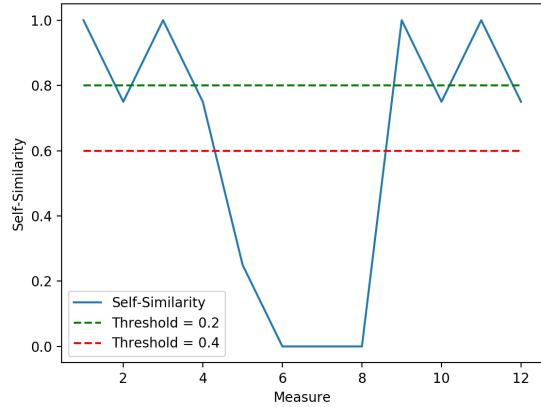
This reorganization allows the analysis module to classify the level of usage the user demonstrates for each audio effect in the library, such as gain, filters, delay, and reverb. The EarSketch curriculum teaches basic effect usage, followed by use of effect parameters, and then the use of envelopes to change parameter values over time. Similarly, the levels of effect usage are *0: Does not use*, *1: Uses standard parameters*, *2: Uses non-standard parameters*, and *3: Changes parameters over time*. EarSketch's goal is to teach coding technique through music production, so students are encouraged to use increasingly complex effect parameter manipulation through increasingly complex algorithmic structure. These scores, along with the scores from the code analysis described in section 3, form a composite score to represent user knowledge.

In addition to the timeline representation and modeling of effects usage, the analysis module records the length of the piece and whether or not the user sets a tempo different than the default 120 bpm. The combination of these music analysis outputs can be used by CAI to characterize a user project and to identify which sounds or effects to include and where to include them, or areas for further improvement in a script.

5. AUDIO FEATURE ANALYSIS

In addition to storing user knowledge modeling, the analysis module is designed to analyze the sound usage, form, and genre of a user project. These are not represented in ordered levels to model conceptual understanding like effects are, but are recorded to display a detailed overview of the piece of music and to better target suggestions made by the CAI system. For example, if a user is primarily choosing sounds of a certain genre in a specific musical section, CAI might suggest other sounds in that genre for that section, while suggesting contrasting sounds for a different section.

5.1 Audio Recommendations

The analysis module includes an expansion of the existing EarSketch recommendation system [22], which uses the code of an active user project to make real-time recommendations. The recommendation system uses audio features Short-time Fourier Transform (STFT) and Mel-Frequency Cepstral Coefficients (MFCC) [23] to represent temporal and non-temporal information, respectively, of each EarSketch library sound whose name is found in the code [24]. Feature vectors for each sound are generated in offline scripts, and feature distances and relative co-usage by EarSketch users between each pair of sound vectors are uploaded to the EarSketch server. This avoids the need to calculate the features, feature distances, and co-usage data in real time. The advantage of this form of analysis in a digital production system such as EarSketch is that audio


feature distances can be measured against metadata tags for artist, genre, and instrument type. The system is able to provide recommendations that either specifically conform to the user project's genre and instrumentation or allow the user to consciously explore other creative options.

The original EarSketch recommendation system [22], which used the source code of a script to generate recommendations for an entire user project. The analysis module expands this system by presenting a series of sound recommendations per measure. These recommendations can be used to increase or decrease musical contrast at specific points throughout a composition, or use stored feature distances to ascertain the best measure to include a sound.

5.2 Form and Structure Analysis

The use of symbolic music representation greatly simplifies the task of determining sections in a song through changes in instrumentation and effects. Sound and effect usage are represented for each measure, and instrument type and genre are included in metadata tags.

Self-similarity can be used in retrieving [25] and visualizing [26] musical structure. An array of self-similarity values for instrumentation at every measure in the timeline view allows the analysis module to infer musical structure from sounds used by marking the first measure in a sequence to pass above or below a threshold of similarity.

Figure 4. Self-similarity of instrumentation for the example EarSketch project (see Figure 2), indicating an A-B-A form. Dotted lines represent similarity thresholds of 0.4 and 0.2 that, when crossed, mark section beginnings.

The threshold of similarity can also be hierarchically defined to determine different granularities of sections and subsections, from a whole piece to the measure level. The example in Figure 4 shows ternary form, a musical structure represented in the EarSketch curriculum. If the similarity threshold is above 0.25, then the analysis module will cross the threshold three times and predict section beginnings at measures 1, 5, and 9. If the threshold is lower, then it will be crossed five times and predict section beginnings at measures 3 and 11 as well. When analyzing a script, the analysis module generates a list of section pre-

dictions for thresholds of every ten percent between 0.9 and 0.1. Any list of a unique length (or with unique values) is recorded. In the example of Figure 4, lists would be generated to form a section prediction of *[1, 5, 9]* with a subsection prediction of *[1, 3, 5, 9, 11]*.

5.3 Genre Analysis

Each sound in the EarSketch sound library is labeled with a tag for one of 21 genres such as Rock, Funk, Hip Hop, and EDM. These tags were manually added to the sounds by the artists and EarSketch developers who uploaded them.

Our music analyzer combines these genre tags with audio features (as described in section 5.1) to predict a genre for each measure in a user project. It applies the k-means genre clustering algorithm [27] to each measure, approximating the closest distance in audio fingerprints between the average for the measure's sounds and the average for a genre found in the EarSketch library. The genre tag for each sound used in a measure is also added to increase the confidence value for that genre. This combination affords our system the knowledge of the original genre label for each sound as presented to the user, but allows it to recognize a user who has creatively used sounds in genre applications separate from their label. This genre analysis is used to determine the likelihood of a user project belonging to a specific genre at the script, section, subsection, or measure level - depending on the granularity of the self-similarity measurement used to determine form.

This genre analysis can be used for CAI to target its audio suggestions to a song's identified genre. If a user is writing a song mainly using sounds tagged with a single genre, such as in the example code (Figure 2), CAI can suggest sounds in that genre or present options for different genres to generate contrast.

6. PRELIMINARY RESULTS, USAGE, AND INSIGHTS

Two informal testing methods have been used to aid in the iterative development of the code analysis module: a review of output correctness, and an ongoing large-scale process to identify bugs in the module.

To evaluate the ability of the module to produce a correct analysis of a script, we ran it on a series of 103 student- and researcher-generated scripts (77 Python, 26 JavaScript). Student scripts were selected to ensure the module could accurately respond to programming choices made by EarSketch users; researcher scripts were selected or written to test the module's ability to respond to complex scenarios. For each test script, the analysis module's output was judged against a researcher-generated score. Any discrepancies between the two indicated a missing component in the module. Modifications were made until the analysis module could correctly score the script. This testing identified a number of situations not originally accounted for in the module.

To efficiently locate bugs in the code analysis script, we have included a version of the Code Analysis module on EarSketch that runs each time any user runs a script. Upon the encounter of an exception while analyzing a project, the module sends a report including the exception and stack trace to an analytics engine. These reports are frequently reviewed to identify bugs and improve the ability of the code analysis module to run without error.

The music analysis tool has been integrated into the EarSketch autograder, an automatic grading tool used in evaluating the complexity of code submissions in previous course projects [4]. This autograder is a separate web page that, given any number of EarSketch script sharing IDs, generates a list of code topics, their categorized scores, the list of section markings, measure-by-measure audio recommendations, and genre predictions. This analysis can be performed on large samples of scripts, such as on multiple instances of a script to track improvement over its history, and is used in ongoing evaluation of the analysis module's ability to model form and genre. As the analysis module undergoes future iterative development, observations of emergent patterns in output will further aid the development and evaluation of the CAI recommendation system as well as its component parts.

Though the CAI system that will make use of this analysis module has yet to be completed, the development of this module has generated insights about the applications of MIR work in tandem with other disciplines, particularly in the context of education. Its combined analysis of symbolic music, audio features, and code knowledge highlights the ability of multimodal analysis to provide a comprehensive body of information to support [systems that do two things]. The use of this combination in an educational context will allow CAI to assist learners in simultaneous musical and programming development and further the goals of educational platforms that intersect domains. Additionally, the development of this module for a co-creative AI indicates potential for additional knowledge to be developed as the module is used to inform the agent's outputs.

7. FUTURE WORK

This analysis module has been implemented in the production version of EarSketch. We are still in the early stages of designing CAI, the agent that will leverage this analysis data to interact with students through dialogue and generate suggestions for their music and code. Over the past year, we have performed studies to better understand how students interact through chat with each other in student-to-student chat experiments. We have also conducted chat experiments between students and researchers posing as AI agents to simulate the intelligence that CAI will eventually provide. We are using the findings from these studies to inform the design of CAI. The initial version of CAI will exist as a chat-style interface within EarSketch, where students will choose prompts from a menu-driven system and receive natural language responses based on their interaction with the system and its analysis of their code and music as described in this paper. Through the addition of CAI to EarSketch, we hope to further increase student engagement and creativity with the platform.

ABSTRACT

This paper presents the Jazz Transformer, a generative model that utilizes a neural sequence model called the Transformer-XL for modeling lead sheets of Jazz music. Moreover, the model endeavors to incorporate structural events present in the Weimar Jazz Database (WJazzD) for inducing structures in the generated music. While we are able to reduce the training loss to a low value, our listening test suggests however a clear gap between the ratings of the generated and real compositions. We therefore go one step further and conduct a series of computational analysis of the generated compositions from different perspectives. This includes analyzing the statistics of the pitch class, grooving, and chord progression, assessing the structureness of the music with the help of the fitness scape plot, and evaluating the model's understanding of Jazz music through a MIREX-like continuation prediction task. Our work presents in an analytical manner why machine-generated music to date still falls short of the artwork of humanity, and sets some goals for future work on automatic composition to further pursue.

1. INTRODUCTION

Music is a heart-touching form of art that strikes a chord with people's emotions, joyful or sorrowful; intense or relieved, through the twists and turns of notes. Despite its ubiquity in our everyday lives, the composition and arrangement of music often requires substantial human effort. This is a major reason why automatic music composition is such a fascinating field of study. Over the years, researchers have sought strenuously ways for machines to generate well-formed music; such methods include meticulously designed non deep learning-based algorithms like the Markov chains [6] and formal grammars [19]; and, a proliferation of deep learning-based solutions in the past decade [8]. In this work, we exclusively study the extension and evaluation of Transformer-based models [43] for

Figure 1. The first 8 bars of a piece (filename `sample_B01.mp3` in Google Drive) composed by the Jazz Transformer, exhibiting clear rests between phrases.

its claimed successes in natural language processing and music generation in recent years [12, 13, 20, 38].

The dataset chosen for our work is the Weimar Jazz Database (WJazzD) [2, 37]. As opposed to the commonly used piano MIDIs in recent works [20, 21], the choice of this dataset represents a fresh endeavor to train the Transformer on Jazz music, and grants us the unique opportunity to integrate structure-related events, precisely annotated in the WJazzD, to the model. However, such an attempt involves no short of technical challenges, including the quantization of the numerous short notes in Jazz improvisations; and, dealing with the complex chord representations used in the WJazzD. In Section 3, we will elaborate on how these difficulties are tackled in a detailed manner.

Furthermore, while recent works in Transformer-based music generation often praised the model's capabilities, like being able to compose "compelling" music, or generate pieces with "expressiveness, coherence, and clear structures" as claimed in [20] and [21] respectively, rarely do we admit that the machine is still far behind humans, as shown in our user study (Section 4), and take a step back to "face the music", in other words, to identify what exactly goes wrong in the model's compositions.

Therefore, the goal of the paper is two-fold. First, to deploy Transformers to a new, more complex music genre, Jazz, asking the model to compose melody lines, chord progression, and structures all at once. Second, to develop a set of objective metrics (Section 5) that evaluate the generated music's pitch usages, rhythmicity, consistency in chord progression, and structureness (see Sec. 5.4 for definition), to discover the culprits behind the model's incompetence (Section 6).

Figure 1 shows an example of a composition generated by our model, in which we may find reasonable combinations of chords and melody; and, clear rests between phrases. Audio samples can be found in a Google Drive folder, [1] which we encourage readers to listen to. We have also open-sourced our implementation of the Jazz Transformer [2] and the proposed objective metrics. [3]

2. RELATED WORK

There has been a great body of research work on computational analysis of human performance of Jazz [3, 4, 15, 18, 44]. One prominent example is the Jazzomat Project [5], which established the WJazzD [2] to study the creative processes underpinning Jazz solo improvisations [37]. Weiss *et al.* [44], for instance, used the dataset to explore the evolution of tonal complexity of Jazz improvisations in the past century. See Sec. 3.1 for more details of the dataset.

The use of Transformer-like architectures for training music composition models has drawn increasing attention recently. These works enhanced the Transformer's capability in modeling music through relative positional encoding schemes [20, 36], cross-domain pre-training [13], and event token design [13, 21]. To the best of our knowledge, this work represents the first attempt in the literature to employ Transformers to compose exclusively Jazz music.

Automatic composition of general lead sheets has been investigated lately, mostly based on recurrent neural network (RNN) models [7, 29, 30]. As for inducing structures in the generated music, several RNN-based solutions have also been proposed [24, 31, 39]. Since Transformers have been shown to outperform RNNs in various tasks [9, 20, 26], we strive to be the forerunner in bringing them to these realms of research.

Relatively little work has been done to train a model for Jazz composition. JazzGAN [42] is a model employing a generative adversarial network (GAN) architecture for chord-conditioned melody composition, using a dataset of only 44 lead sheets, approximately 1,700 bars. Another model presented in [22] explores the use of recurrent variational auto-encoders for generating both the melody and chords of a lead sheet from scratch.

A number of objective metrics have been employed for measuring the performance of deep learning for music composition [10, 14, 41, 45]. However, most of them focused on surface-level statistics only (e.g., pitch class histograms, note onset intervals, etc.). The introduction of structureness indicators and the MIREX-like metric (see Sec. 5.4–5.5) in this paper provide new insights into assessing music's quality at piece level, and evaluating the model's overall understanding of a certain music genre.

3. THE JAZZ TRANSFORMER

Transformers use self-attention modules to aggregate information from the past events when predicting the next

---

	# solos	Total duration	Total # events	Avg. # events per solo
Train	409	11h 19m	1,220 K	2,983
Val.	22	33m	56 K	2,548

Table 1. Statistics of the dataset we compile from the WJazzD [37]. See Section 3.2 for details of the "events".

events [11, 27, 43]. Accordingly, it is natural that we model music as a language, namely, to represent each composition by a sequence of event tokens. In this section, we will explain in detail how we break down the components of the WJazzD [37] to construct the vocabulary of events, and how the pieces are converted into sequences that can be fed into a Transformer-like model for training.

3.1 Dataset

The WJazzD dataset [2, 37] comprises of 456 monophonic Jazz solos. Each solo is arranged in the lead sheet style and comes with two tracks: the melody track and the beat track. The melody track contains every note's pitch, onset time and duration (in seconds), with additional information on loudness (in decibels), phrase IDs and "midlevel units" (MLUs) [17], a structure of finer granularity than a phrase to capture the distinctive short-time ideas in Jazz improvisations. The beat track contains the beat onsets (in seconds), chord progressions and form parts (or sections, e.g., A1, B1). The highlight of this dataset is that all the contents, including the notes, chords, metrical and structural markings, are human-annotated and cross-checked by the annotators [37], ensuring the data cleanliness that is often crucial for machine learning tasks. To simplify the subsequent processings, we retain only the pieces marked solely with 4/4 time signature, resulting in 431 solos. For objective analysis, we leave 5% of the solos as the held-out validation data. See Table 1 for the statistics of the data.

3.2 Data Representation

The event representation adopted here is a modified version of the "REvamped MIDI-derived event representation" recently proposed in [21], extended to integrate the chord system and structural events of WJazzD. The resulting event encodings can be broken down into the following 4 categories: **note-related**—NOTE-VELOCITY, NOTE-ON, NOTE-DURATION; **metric-related**—BAR, POSITION, TEMPO-CLASS, TEMPO; **chord-related**—CHORD-TONE, CHORD-TYPE, CHORD-SLASH; and **structure-related**—PHRASE, MLU, PART, REPETITION.

3.2.1 Note-related Events

Each note in the melody is represented by three events, i.e., NOTE-VELOCITY, NOTE-ON, and NOTE-DURATION.

The NOTE-VELOCITY event decides how hard the note should be played. We derive it according to the estimated loudness (in decibels) provided by the dataset, and quantize it into 32 bins, corresponding to MIDI velocities

[3] https://github.com/slSeanWU/MusDr

$[3, 7, \ldots, 127]$, through $v = \lfloor (80 + 3 \cdot (dB - 65))/4 \rfloor$, where dB is the decibel value of the note, and v, clipped such that $v \in [1, 32]$, is the resulting NOTE-VELOCITY(v) event. This mapping scheme comes in handy in the process of converting the model's compositions to MIDIs.

The NOTE-ON events, ranging from 0 to 127, correspond directly to the MIDI numbers, indicating the note's pitch. The NOTE-DURATION events represent the note's length in 64th note multiples, ranging from 1 to 32, obtained by taking the ratio of the note's duration (in seconds) to the duration of the beat (also in seconds) where the note situates. The reason why we use such a fine-grained quantum, while previous work mainly consider only 16th note multiples (e.g., [20, 21]), is as follows. Most notes in WJazzD are quite short, with a significant portion being 32th and 64th notes (12.9% and 2.7% respectively). The quantum is chosen such that the coverage of the 32 NOTE-DURATION events encompasses the most notes, which is 99.6% with our choice of the 64th note. [4]

3.2.2 Metric-related Events

To model the progression of time, we use a combination of BAR and POSITION events; as demonstrated in [21], this combination leads to clearer rhythmic structure in the generated music compared to using TIME-SHIFT events introduced in [20]. In addition, the pace the music should be played at is set by TEMPO-CLASS and TEMPO events.

A BAR event is added at the beginning of each bar, and a bar is quantized into 64 subunits, each represented by a POSITION event; for example, POSITION(16) marks the start of the 2nd beat in a bar. A POSITION event occurs whenever there is a note onset, chord change, or tempo change. It is worth mentioning that to minimize the quantization error, a note's onset position is justified with the beat it is in through the formula:

$$p_n = p_b + 16 \cdot (t_n - t_b)/d_b, \qquad (1)$$

where p_b, t_b, d_b are the beat's position (note that $p_b \in \{0, 16, 32, 48\}$), onset time, and duration; and t_n is the note's onset time. The resulting p_n is then rounded to the nearest integer to determine the note's onset position.

The TEMPO-CLASS and TEMPO events always co-occur at every beat position. The 5 TEMPO-CLASS events represent the general "feeling" of speed (i.e. fast, or slow) with interval boundaries of $[50, 80, 110, 140, 180, 320]$ beats per minute (bpm), while the 12 TEMPO events assigned to each tempo class in evenly-spaced steps (within the interval, e.g., $50, 52.5, 55$ bpm...) determine the exact pace. The events can be derived simply by taking the reciprocal of a beat's duration (provided by WJazzD). The frequent appearance of these tempo events facilitates smooth local tempo changes common in Jazz performances.

3.2.3 Chord-related Events

Chord progressions serve as the harmonic foundation of Jazz improvisations [25], hence a complex chord representation system is used in the WJazzD dataset. If we were to treat each of the 418 unique chord representations present in the WJazzD as a token, the majority of chord tokens will have very few occurrences—in fact, 287 (69%) of them appear in less than 5 solos, making it hard for the model to learn the meaning of those chords well; plus, the process of translating chords to individual notes during the conversion to MIDIs would be extremely cumbersome.

Fortunately, thanks to the detailed clarification provided in [37], we are able to decompose each chord into 3 events, namely, the CHORD-TONE, CHORD-TYPE, and CHORD-SLASH events, with the help of regular expressions (regex) and some rule-based exception handling.

The 12 CHORD-TONE events, one for each note on the chromatic scale (i.e. C, C#, D, ...), determine the root note, hence the tonality, of the chord. The 47 CHORD-TYPE events affect the chord's quality and emotion by the different combination of notes played relative to the root note (or, *key template* as we call it); e.g., the key template of a Dominant 7th chord (CHORD-TYPE(7)) is $[0, 4, 7, 10]$. Finally, the 12 CHORD-SLASH events allow the freedom to alter the bass note to slightly tweak the chord's quality. If a chord contains no slash, its CHORD-SLASH event will share the same key as its CHORD-TONE. For instance, the chord C7/G, a C Dominant 7th over G, is represented by [CHORD-TONE(C), CHORD-TYPE(7), CHORD-SLASH(G)].

Note that after our decomposition, the number of unique chord-related events is greatly reduced to 71; and, the resulting set of events is still able to represent all 418 chords in WJazzD. It is easy to use the manually-constructed key template accompanying each CHORD-TYPE, together with the CHORD-TONE and CHORD-SLASH events to map each chord to notes during the conversion to MIDIs.

3.2.4 Structure-related Events

For the melodies, we prepend a PHRASE event to the notes marked as the start of a phrase. The presence of phrases may be important as it informs the model to "take a breath" between streams of notes. And, we retain several common types and subtypes of midlevel units (e.g., *line, rhythm, lick* etc.) as MLU events [17], likewise prepended to the starting note of each MLU, hoping that the model could capture the short-term note patterns described by the MLU types. PART and REPETITION events are added to each beginning and end of a form part, [5] guiding the model to generate repetitive chord progression and coherent melody lines for the parts marked with the same letter.

3.3 Model and Training Setups

Due to the large number of events per solo (check Table 1), it is hard to feed the entire pieces into a Transformer at once because of memory constraint. Therefore, we choose as the backbone sequence model the Transformer-XL [11], an improved variant of the Transformer which introduces recurrence to the architecture. It remedies the memory constraint and the resulting context fragmentation issue by caching the computation record of the last segment, and

---

[4] All notes shorter than a 64th note are discarded and those longer than a half note are clipped.

[5] For example, the entire A1 part is represented as [PART-START(A), REPETITION-START(1), ... other events ..., REPETITION-END(1), PART-END(A)].

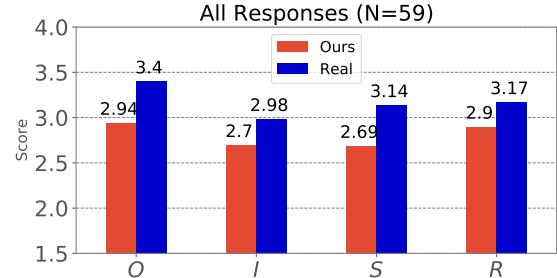
allowing the current segment to attend to the cache in the self-attention process. This allows information to flow across the otherwise separated segments, inducing better coherence in the generated music.

To evaluate the effectiveness of adding the structure-related events (cf. Section 3.2.4), we consider the following two variants in our objective analysis:

- **Model (A)**: trained with no structure-related events.

- **Model (B)**: trained with the complete set of events.

They both consist of 12 layers, 8 attention heads and about 41 million learnable parameters. We train them on a single NVIDIA GTX 1080-Ti GPU (with 11 GB memory) with Adam optimizer, learning rate $1e-4$, batch size 8, segment length 512 and 100% teacher forcing. Besides, following the Music Transformer's data augmentation setting [20], we randomly transpose each solo in the range of -3 to $+3$ keys in every epoch. It takes roughly a full day for the negative log-likelihood losses of the models to drop to 0.25, a level at which they are able to produce music of distinctive Jazz feeling (see Section 6 for justifications).

4. SUBJECTIVE STUDY


To discover how users feel about the Jazz Transformer's compositions, we set up a blind listening test in which test-takers listen to four one-minute long pieces, two from the Model (B)'s compositions (at loss level 0.25), and two from real data. We do not include Model (A) here to reduce the burden on the test-takers, assuming that Model (B) is better. We inform them that the pieces are independent of one another, and they will be asked the same set of questions after listening to each piece, namely, to rate it in a five-point Likert scale on the following aspects:

- **Overall Quality (O):** Does it sound good overall?

- **Impression (I):** Can you remember a certain part or the melody?

- **Structureness (S):** Does it involve recurring music ideas, clear phrases, and coherent sections?

- **Richness (R):** Is the music diverse and interesting?

We distribute five test suites to our social circles and collect responses from 59 anonymized subjects, of which 27 are classified as "pros" for they rate their musical background (in general, not restricted to Jazz) as $4/5$ or $5/5$ (i.e., also on a five-point scale). The result shown in Figure 2 indicates that the Jazz Transformer receives mediocre scores and falls short of humans in every aspect, especially in *overall quality* (**O**) and *structureness* (**S**). Moreover, performed *one-tailed Z-tests for the difference of means* also suggests the significance of the gaps ($p < 0.05$ for all aspects), providing concrete evidence of the model's defeat.

5. OBJECTIVE EVALUATION METRICS

The result of our subjective study poses to us an intriguing question: If the machine is still inferior to humans in creating music, then what exactly are the causes? To unravel the

Figure 2. Result of subjective study (**O:** Overall Quality, **I:** Impression, **S:** Structureness, **R:** Richness), comparing from-scratch compositions created by the proposed model with structure-related events (i.e., 'Model (B)') against the real pieces from the WJazzD. We note that the gaps in all aspects are statistically significant ($p < 0.05$).

mystery, we develop a set of objective metrics which enables us to scrutinize the Jazz Transformer's compositions from various perspectives, and make comparisons with real data. These metrics include the analyses of event distributions, namely, the pitch class histogram, the grooving pattern, and the chord progressions; assessing the structureness with the help of the fitness scape plot; and, judging the model's performance on a discriminative task through the MIREX-like continuation prediction challenge.

5.1 Pitch Class Histogram Entropy

To gain insight into the usage of different pitches, we first collect the notes appeared in a certain period (e.g., a bar) and construct the 12-dimensional pitch class histogram $\overrightarrow{\mathbf{h}}$, according to the notes' pitch classes (i.e. C, C#, ..., A#, B), normalized by the total note count in the period such that $\sum_i h_i = 1$. Then, we calculate the entropy of $\overrightarrow{\mathbf{h}}$:

$$\mathcal{H}(\overrightarrow{\mathbf{h}}) = -\sum_{i=0}^{11} h_i \log_2(h_i). \qquad (2)$$

The entropy, in information theory, is a measure of "uncertainty" of a probability distribution [40], hence we adopt it here as a metric to help assessing the music's quality in tonality. If a piece's tonality is clear, several pitch classes should dominate the pitch histogram (e.g., the tonic and the dominant), resulting in a low-entropy $\overrightarrow{\mathbf{h}}$; on the contrary, if the tonality is unstable, the usage of pitch classes is likely scattered, giving rise to an $\overrightarrow{\mathbf{h}}$ with high entropy.

5.2 Grooving Pattern Similarity

The grooving pattern represents the positions in a bar at which there is at least a note onset, denoted by $\overrightarrow{\mathbf{g}}$, a 64-dimensional binary vector in our setting.[6] We define the similarity between a pair of grooving patterns $\overrightarrow{\mathbf{g}}^a$, $\overrightarrow{\mathbf{g}}^b$ as:

$$\mathcal{GS}(\overrightarrow{\mathbf{g}}^a, \overrightarrow{\mathbf{g}}^b) = 1 - \frac{1}{Q} \sum_{i=0}^{Q-1} \text{XOR}(g_i^a, g_i^b), \qquad (3)$$

---

[6] For example, if a bar contains only two note onsets, at the beginning of the 1st beat and 2nd beat respectively, then the corresponding $\overrightarrow{\mathbf{g}}$ will have $g_0, g_{16} = 1$, and the rest dimensions 0.

where Q is the dimensionality of $\overrightarrow{\mathbf{g}}^a$, $\overrightarrow{\mathbf{g}}^b$, and $\text{XOR}(\cdot, \cdot)$ is the exclusive OR operation. Note that the value of $\mathcal{GS}(\cdot, \cdot)$ would always lie in between 0 and 1.

The grooving pattern similarity helps in measuring the music's rhythmicity. If a piece possesses a clear sense of rhythm, the grooving patterns between pairs of bars should be similar, thereby producing high $\mathcal{GS}$ scores; on the other hand, if the rhythm feels unsteady, the grooving patterns across bars should be erratic, resulting in low $\mathcal{GS}$ scores.

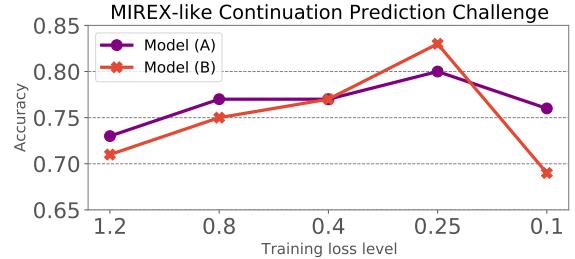
5.3 Chord Progression Irregularity

To measure the irregularity of a chord progression, we begin by introducing the term *chord trigram*, which is a triple composed of 3 consecutive chords in a chord progression; for example, (`Dm7`, `G7`, `CM7`). Then, *the chord progression irregularity* ($\mathcal{CPI}$) is defined as the percentage of *unique chord trigrams* in the chord progression of an entire piece. Please note that 2 chord trigrams are considered different if any of their elements does not match.

It is common for Jazz compositions to make use of 8- or 12-bar-long templates of chord progressions (known as the *8-*, or *12-bar blues*), which themselves can be broken down into similar substructures [25, 35], as the foundation of a section, and more or less "copy-paste" them to form the complete song with, say, `AABA` parts. Therefore, a well-composed Jazz piece should have a chord progression irregularity that is not too high.

5.4 Structureness Indicators

The *structureness* of music is induced by the repetitive musical content in the composition. It can involve multiple granularities, ranging from an instant musical idea to an entire section. From a psychological perspective, the appearance of repeated structures is the essence of the catchiness and the emotion-provoking nature of music [28].

The fitness scape plot algorithm [32, 33] and the associated SM Toolbox [34] offer an aesthetic way of detecting and visualizing the presence of repeating structures in music. The fitness scape plot is a matrix $S_{N \times N}$,[7] where $s_{ij} \in [0, 1]$ is the *fitness*, namely, the degree of repeat in the piece derived from the *self-similarity matrix* (SSM) [16], of the segment specified by (i, j).


Our *structureness indicator* is based on the fitness scape plot and designed to capture the most salient repeat within a certain duration interval. For brevity of the mathematical representation, we assume the sampling frame rate of S is 1 Hz (hence N will be the piece's duration in seconds), and define the structureness indicator as follows:

$$\mathcal{SI}_l^u(S) = \max_{\substack{l \leq i \leq u \\ 1 \leq j \leq N}} S, \tag{4}$$

where l, u [8] are the lower and upper bounds of the duration interval (in seconds) one is interested in. In our experiments, we choose the structureness indicators of $\mathcal{SI}_3^8$, $\mathcal{SI}_8^{15}$, and $\mathcal{SI}_{15}$ to examine the short-, medium-, and long-term structureness respectively.

---

[7] N is the number of frames sampled from the audio of a piece, the 1st axis represents the segment duration (in frames), and the 2nd axis represents the center of segment (in frames).

[8] If present, otherwise l defaults to 1, and u defaults to N.

Figure 3. Result of the MIREX-like continuation prediction challenge, each checkpoint is asked 100 questions. Notice that the accuracy of both Model (A) and (B) peaks at the loss level of 0.25, at 80% and 83% respectively.

5.5 MIREX-like Continuation Prediction Challenge

Being inspired by the "Patterns for Prediction Challenge" held as part of the Music Information Retrieval Evaluation eXchange (MIREX) 2019 [1, 23], we developed a method to test the model's capability to predict the correct continuation given a musical prompt. The challenge is carried out as follows: First, the model is fed with the beginning 8 bars of a piece, denoted by $\overrightarrow{\mathbf{s}}$; then, it is presented with a set of four 8-bar continuations $\mathcal{X} = \{\overrightarrow{\mathbf{x}}^0, \overrightarrow{\mathbf{x}}^1, \overrightarrow{\mathbf{x}}^2, \overrightarrow{\mathbf{x}}^3\}$, in which one is the true continuation, and the rest are wrong answers randomly drawn from other pieces. The way the model attempts to answer the multiple choice question is by calculating the average probability of generating the events of each continuation:

$$\mathcal{P}(\overrightarrow{\mathbf{x}}^i) = \frac{1}{L} \sum_{j=0}^{L-1} p(x_j^i \mid \tilde{x}_{j-1}, \ldots, \tilde{x}_0; \overrightarrow{\mathbf{s}}), \ i \in \{0, 1, 2, 3\},$$
$$\tag{5}$$

where L is the length of the shortest given continuation (in # events) in $\mathcal{X}$, x_j^i is the j-th event token in $\overrightarrow{\mathbf{x}}^i$, and $\tilde{x}_{j-1}, \ldots, \tilde{x}_0$ are the events sampled from the model's output, hence the conditional probability $p(x_j^i)$ at each timestep can be obtained straightforward. Finally, the model returns $\arg\max_i \mathcal{P}(\overrightarrow{\mathbf{x}}^i)$ as its answer, of which the correctness we can check.

If the model can achieve high accuracy on this continuation prediction task, we may say it possesses a good overall understanding of Jazz music, enough for it to tell right from wrong when given multiple choices.

6. EXPERIMENT RESULTS AND DISCUSSIONS

We begin with the evaluation on the MIREX-like challenge (Section 5.5). We pick 5 checkpoints of both Model (A) and Model (B) at different training loss levels to ask each of them 100 multiple choice questions (the prompt and continuation choices of each question are randomly drawn from the held-out validation data). The result shown in Figure 3 indicates that, similarly for both models, the accuracy steadily goes up as the training loss decreases, peaks at the loss level of 0.25, and drops afterwards. This shows that the models are gradually gaining knowledge about Jazz music along the training process until a certain point, where they potentially start to overfit.
	Model (A)		Model (B)			Real
loss	*0.80*	*0.25*	*0.80*	*0.25*	*0.10*	- -
$\mathcal{H}_1$	2.29	2.45	2.26	2.20	**2.17**	1.94
$\mathcal{H}_4$	3.12	3.05	3.04	**2.91**	2.94	2.87
$\mathcal{GS}$	**0.76**	0.69	0.75	**0.76**	**0.76**	0.86
$\mathcal{CPI}$	81.2	77.6	79.2	**72.6**	75.9	40.4
$\mathcal{SI}_3^8$	0.18	0.22	0.25	**0.27**	0.26	0.36
$\mathcal{SI}_8^{15}$	0.15	0.17	**0.18**	**0.18**	0.17	0.36
$\mathcal{SI}_{15}$	0.11	**0.14**	0.10	0.12	0.11	0.35

Table 2. Results of objective evaluations. $\mathcal{H}_1$, $\mathcal{H}_4$ are the 1-, and 4-bar pitch class histogram entropy (see Sec. 5.1); $\mathcal{GS}$ is the grooving pattern similarity (Sec. 5.2) measured on all pairs of bars within a piece; $\mathcal{CPI}$ is the chord progression irregularity (in %; Sec. 5.3); finally, $\mathcal{SI}_3^8$, $\mathcal{SI}_8^{15}$, and $\mathcal{SI}_{15}$ are the short-, medium-, and long-term structureness indicators (Sec. 5.4). **Bold** texts indicate the model checkpoint performing the closest to real data, which is considered to be the best. It is observed that Model (B) (i.e., the model trained with structure-related events) with a loss of 0.25 outperforms its counterparts at other loss levels and Model (A) on most of the metrics. Moreover, consistent with the result of the MIREX-like challenge (Fig. 3), the performance of Model (B) plunges when the loss goes too low (0.1 in this case).

Following the MIREX-like challenge, we pick several checkpoints of both Models (A) and (B) for objective evaluations described in Sections 5.1–5.4. The chosen checkpoints are at loss levels 0.8, 0.25, and 0.1 (for Model (B) only, since in the MIREX-like challenge (Fig. 3), its accuracy drastically drops when the loss reduces from 0.25 to 0.1). In the experiments, 50 32-bar-long from-scratch compositions from each checkpointed model are compared against the 409 pieces in the training dataset.

From the results (Table 2), we can summarize the model's deficiencies as follows: 1) the *erraticity* of the generated musical events; and, 2) the *absence* of medium- and long-term repetitive structures. Comparing with the real data, the first argument can be justified by the higher $\mathcal{H}_1$ and $\mathcal{H}_4$, manifesting the unstable usage of pitches at local scale; and, the lower $\mathcal{GS}$ and higher $\mathcal{CPI}$ of the entire pieces, marking the lack of consistency in rhythm and harmony from a global point of view; meanwhile, the second argument can be explained directly by the significantly lower values of structureness indicators $\mathcal{SI}_8^{15}$ and $\mathcal{SI}_{15}$, suggesting that while the model might be able to repeat some short fragments of music, creating structures of a longer time span is still beyond its capability.

Much to our delight, the introduction of structure-related events seems to be functional to some extent, noticeable from the numbers that Model (B) at 0.25 loss level is for most of the time the closest competitor to humans, with a substantial lead on the metrics focusing on shorter timespans (i.e., $\mathcal{H}_1$, $\mathcal{H}_4$, and $\mathcal{SI}_3^8$) when placed in comparison with Model (A). This suggests that the use of PHRASE and MLU events provides some assistance to the model in modeling music. Furthermore, resonating with the accu-

Figure 4. The fitness scape plots of Model (B)'s best composition (according to the *structureness* (**S**) score in our subjective study, see Sec. 4) versus a human composition in the WJazzD. Note that the piece by Model (B) contains almost no signs of repetition longer than 10 seconds, while the real piece's repetitive structures extend well into the 20–30 seconds range.

racy trend in the MIREX-like challenge, the performance worsens when the loss is reduced to an overly low level.

To visualize the deficiency in structureness of the model's compositions, we choose the piece which scores the highest, 3.14, in the *structureness* (**S**) aspect in our subjective study; and, a human composition of the same duration, receiving 3.54 in the aspect **S**, for a head-to-head comparison of their fitness scape plots. The rivalry (see Figure 4) reveals the stark contrast between their fitness values across all timescales. In the model's work, all traces of repetitive structures disappear at the timescale of 10 seconds; whereas in the human composition, not only do the fitness values stay high in longer timespans, but a clear sense of section is also present, as manifested by the 2 large, dark "triangles" in its scape plot.

7. CONCLUSION AND FUTURE WORK

In this paper, we have presented the Jazz Transformer, whose incorporation of structure-related events has been shown useful here in enhancing the quality of machine-generated music. Moreover, we have proposed a series of objective metrics that shed light on the shortcomings of machine-composed pieces, including the erratic usage of pitch classes, inconsistent grooving pattern and chord progression; and, the absence of repetitive structures. These metrics not only show that the Transformer is in fact not that good a music composer, but also serve as effective quantitative measures for future efforts in automatic music composition to assess their models' performance, which by now still relies heavily on human evaluation.

In the future, we plan to carry out larger-scale studies to explicate the correlations between those quantitative metrics and the aspects of subjective evaluation; and, to continue working on inducing structures in machine-composed music; such endeavors may not stay on revamping events that fit into Transformers as done, but involve a complete redesign of the Transformer architecture, enabling it to read the structural information directly computable from data, say, the fitness scape plot, to grasp the blueprint of a piece before composing music at finer scales.

ABSTRACT

Dynamic prediction of perceived emotions of music is a challenging problem with interesting applications. Utilization of relevant context in audio sequence is essential for effective prediction. Existing methods have used LSTMs with modest success. In this work we describe three attentive LSTM based approaches for dynamic emotion prediction from music clips. We validate our models through extensive experimentation on standard dataset annotated with arousal-valence values in continuous time, and choose the best performer. We find that the LSTM based attention models perform better than the state of the art transformers for the dynamic emotion prediction task, both in terms of R^2 and Kendall-τ metrics. We explore individual smaller feature sets in search of a more effective one and to understand how different features contribute to perceived emotion. The spectral features are found to perform at par with the generic ComPare feature set [1]. Through attention map analysis we visualize how attention is distributed over music clips' frames for emotion prediction. It is observed that the models attend to frames which contribute to changes in reported arousal-valence values and chroma to produce better emotion predictions, effectively capturing long-term dependencies.

1. INTRODUCTION

Automatic determination of perceived emotion in music is an active and major area of focus for the music information retrieval (MIR) community. The aim of dynamic perceived emotion prediction task is to output a sequence of time-synchronized arousal-valence labels when a music clip is given as input. It finds varied applications in the domains of personalized and/or generalized music recommendations, organizing music databases, automatic music creation, mood based music search etc. This task is challenging because: 1) perceived emotion might depend on

the inherent relationship between different frames of music, distributed over time, and 2) emotion perception is inherently subjective in nature, highly contextual and personal. Thus, it is understandable that the emotions related to music are a time-continuous process, where the context of the sequential music frames play an immense role on the associated emotion. Relating this to the machine learning perspective, one can discern the need of context sensitive models like recurrent neural networks (RNNs) for the task at hand. In this study, we use attention mechanism with a deep RNN-LSTMs (Long Short Term Memory) and the Transformer [2], to predict the perceived emotion in each defined time frame of music continuously. We compare our approach with recent works [3] using only LSTM. We also attempt to understand the importance of types of features contributing to dynamic perceived emotion. Lastly, attention is visualized with the help of attention map analysis. The following are the major contributions of this work: 1) The LSTM based attention models are found to perform better than the state of the art Transformers for the dynamic emotion prediction task. 2) Spectral features are found to perform at par with the generic ComPare feature set [1]. 3) Attention maps are interpreted to observe that the attention models are able to focus on relevant music frames for dynamic emotion prediction task.

This paper is organized as follows. In section 2, relevant literature regarding music emotion recognition and attention is reviewed. Section 3 provides details of the attention based models and Transformer used in this work. All the experiments carried out and the observations are reported in section 4. Finally, the conclusions drawn from the present study are detailed in section 5.

2. RELATED WORK

2.1 Music Emotion Recognition

In the past, most music emotion prediction systems used features of timbre, pitch, MFCCs and/or lyrics and applied to classifiers like SVMs [4]. Current state-of-the-art methods for music emotion prediction are mostly based on deep neural networks like RNN-LSTMs. Coutinho et al. [5] proposed the use of this model for this task. Weninger et al. [3, 6, 7] used RNN-LSTM networks successfully to perform continuous time music emotion regression, using

a modified cost function, on the *1000 Songs for Emotional Analysis of Music* dataset [8]. Giamusso et al. [9] used neural networks to predict playlist emotions based on lyrics. Fan et al. [10] performed ranking based emotion recognition from experimental music. Delbouys et al. [11] used LSTM and ConvNet models on the Million Song Dataset [12] for audio and lyrics based bimodal music emotion detection.

2.2 Emotion Representation

Over the years, Discrete and Dimensional models of emotion representation have been used in MIR. Studies using discrete model either tag their musical data with single [13] or cluster [14] of simple tags. In dimensional models like Russel's Circumplex model [15], emotion is mapped into a 2-D plane, spanned by two axes denoting *arousal* and *valence*. Using this well known and satisfyingly exhaustive emotion representation, the problem of emotion recognition/prediction is turned into a two dimensional regression problem [16].

2.3 Attention in MIR tasks

Recently, attention mechanism and Transformer models have found application in a wide range of MIR tasks, with success. Balke et al. [17] used a soft-attention mechanism on input of synthesized piano data for audio sheet music retrieval. Their results indicate that attention increases the robustness of the retrieval system by focusing on different parts of the input representation based on the tempo of the audio. The improved results led them to argue for the potential of attention models as a very general tool for many MIR tasks. Gururani et al. [18] explored an attention mechanism for handling weakly labeled data for multi-label instrument recognition. Their results show that incorporating attention leads to overall improvement in classification accuracy metrics and enables models to *attend to* specific time segments in the audio relevant to each instrument label leading to interpretable results. Donahue et al. [19] used the Transformer architecture to improve performance for the task of generating multi-instrumental music scores. Chen et al. [20] proposed the Harmony Transformer, a multi-task music harmony analysis model aiming to improve chord recognition. Park et al. [21] utilized a bi-directional Transformer for chord recognition (BTC) which showed competitive performance. Through attention map, they visualized how attention was performed, and it was observed that the model was able to divide segments of chords by utilizing adaptive receptive field of the attention mechanism and capture long-term dependencies. These and other works have explored various feature sets like CQT (in [21]), Chroma (in [20]), along with other standard feature sets [1] (in [3]). These recent successes in varied MIR tasks in terms of model accuracy and interpretability, motivated us to apply the same in the music emotion regression task. To the best of our knowledge, neither attention models nor Transformers have been applied before to the task under examination.

3. ATTENTION BASED MODELS FOR EMOTION PREDICTION IN MUSIC

3.1 Attention Model (AT)

In the past, traditional LSTM-RNN approach has provided good results in music emotion regression [3]. In this work we propose the use of attention mechanism for dynamic emotion prediction in music. According to the *attention* model [22], to compute each output of a encoder-decoder architecture, a distinct *context vector* is used, which is a function of all the hidden states at the encoder side and not just the last one. The encoder encodes the input into a set of hidden states and attention is applied on them to produce target arousal and valence values over fixed length segments or time frames of the music audio signal. The encoder reads the input sequence $\mathbf{x} = (x_1, x_2, \ldots, x_T)$, which is a sequence of vectors, and produces the hidden states $(h_1, h_2, \ldots, h_T)$, using some RNN approach. In this work LSTM is used. In traditional attention mechanism [22], the whole set of hidden states $(h_1, h_2, \ldots, h_T)$ are available to compute the context vectors. Each time, the context vector c_i is calculated as a weighted sum of all the hidden states. Let the output be $\mathbf{y} = (y_1, y_2, \ldots, y_T)$. For the current problem, $\mathbf{y}$ can be defined as set of arousal or valence values associated with each music time frame. The tth output, y_t, will be a function $\mathbf{g}()$ of a) the present hidden state h_t, b) the previous output y_{t-1}, c) the unique context vector c_t, as given by equation 1.

$$p(y_t|y_1, y_2, \ldots, y_{t-1}, \mathbf{x}) = g(h_t, y_{t-1}, c_t) \qquad (1)$$

The unique context vector c_t depends on the sequence of annotations $(h_1, h_2, \ldots, h_T)$, and is computed as a weighted sum of these annotations h_j, as given in equation 2.

$$c_t = \sum_{j=1}^{T} \alpha_{tj} h_j \qquad (2)$$

So, the model at time t, *attends* to each h_j corresponding to each of the inputs, with a weight of α_{tj}. To obtain each weight α_{tj} for each output y_t, the alignment between the corresponding h_t and each of h_j need to be calculated, where $1 \leq j \leq T$. So, the alignment model, when attending to h_j, is given by equation 3.

$$e_{tj} = a(h_{t-1}, h_j), 1 \leq j \leq (t-1) \qquad (3)$$

This alignment is the measure of how well the inputs around position j and the output at position t match. Then, each of these scores e_{tj} are used to calculate the attention weights for each h_j as given in equation 4.

$$\alpha_{tj} = \frac{exp(e_{tj})}{\sum_{k=1}^{T} exp(e_{tk})} \qquad (4)$$

So, for each output, the context vector will *attend* or focus on those parts of the entire input sequence, which are more relevant for that particular output, by assigning higher weights to the associated encoder-side hidden states, using an *alignment* model. These models are referred to as the *AT* models from hereon. The naming convention of the models is the acronym *AT* for attention, followed by the hidden layer dimensions.

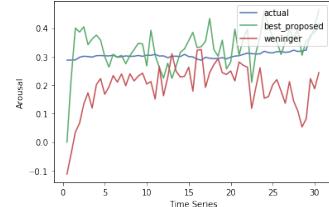
Transformer	1-Layer, 2-Layer, 4-Layer	1-Layer	0.12	0.11	0.10

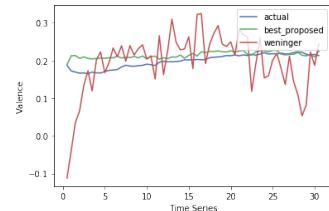
3.2 Backward Attention Model (BAT)

A modified form of the traditional attention mechanism [22] is also used in the current work, called Backward Attention (BAT) models. In these models, for emotion prediction at each tth time frame, attention is distributed only among h_k hidden states, where, $1 \le k \le (t-1)$.

3.3 Transformers

The transformer architecture as proposed in Vaswani et. al. [2] is used in this work, with changes in the number of encoder side layers, as appropriate for the experiments. Attention is calculated as in equation 5.


$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (5)$$

where, Q, K and V are matrices representing the set of queries, keys and values respectively and d_k is the key dimension.


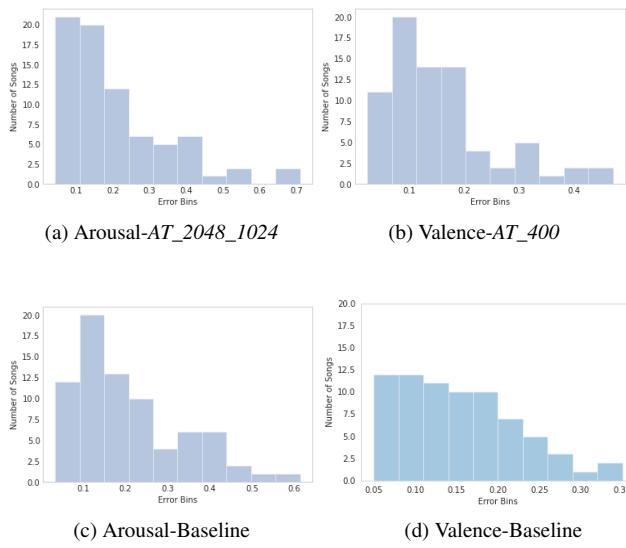
4. EXPERIMENTS

4.1 Data Description and Experimental Setup

We use the *1000 Songs for Emotional Analysis of Music* dataset [8] for all experiments. Of the thousand clips, the dataset provides arousal and valence annotations for only 744 clips, which are used as *ground truth* values. According to the dataset manual [8], arousal-valence continuous annotations for each song (second 15-45), with 2Hz sampling frequency are available in the dataset. We define each non-overlapping 500ms of the clips as *one music frame*. Thus, the last 30s or the last 61 frames of each clip are used for this work, since only those 61 emotion (arousal-valence) tags are available. 10-fold cross validation was used on the training and test sets. We used the Mean squared error (MSE) as the loss function. RMSProp, with the default learning rate of 0.001 was used for optimizing

(a) Arousal Comparison

(b) Valence Comparison

Figure 1: Dynamic Emotion Predictions for Clip 584


the loss with a batch size 20, and maximum 50 epochs. An early stopping strategy is also used, if validation error shows no improvement over 10^{-4} after 5 epochs, processing is stopped. Sequences are presented in random order during training. All hyper-parameters not explicitly mentioned here are left to their default values as in Tensorflow 1.14. The feature sets used for different experiments are described below.

4.1.1 ComPare Feature Set

The 2013 Computational Paralinguistics Evaluation (ComParE) tasks featureset [1], containing 6670 features is used for all experiments in sections 4.2 and 4.4. TUM's opensource *openSMILE* feature extractor [23] is used to extract the ComParE featureset for each frame of each clip. Standard normalization was performed on the extracted feature values before the experiments. So, each clip is characterised by 61 feature vectors, each of size 6670.

4.1.2 Other Feature Sets

In experiments reported in section 4.3, subsets of the Compare feature set [1] and some other features are explored. These features extracted using Librosa [24] are detailed here. The *Chroma(STFT+CQT)* features [24] consist of chroma values derived using both STFT analysis and constant-Q transform (CQT) analysis implementations. The *CQT on Audio clip* features [24] are derived from the core Spectrogram operations of Librosa [24] suitable for pitch-based signal analysis. The *Spectral Features* [24] denote the distributions of energy over a set of frequencies and are very important in many MIR analysis techniques. These consist of: Chroma(24), CENs (12) MFCC (20), RMS (1), Mel-scaled spectrogram (128), spectral centroid (1), spectral bandwidth (1), spectral contrast (7), spectral flatness (1), spectral roll-off (1), zero crossing rate (1). All clips were re-sampled to 44100 Hz before feature extraction. All features were extracted for non-overlapping frames of 500 ms each, corresponding to the available arousal-valence labels of the dataset.

Figure 2: Emotion Error Histograms over Validation Set

4.1.3 Metrics

The metrics used for reporting the results are Coefficient of determination (R^2), average Kendall's τ per song ($\overline{\tau}$)and mean absolute error (MAE). The determination coefficient (R^2) is a key output of regression analysis, which provides a measure of how well observed outcomes are replicated by the model, based on the proportion of total variation of outcomes explained by the model. It can vary between 0 and 1. If a data set has n values marked ($y_1 \ldots y_n$), and each associated with a predicted value ($f_1 \ldots f_n$). So, R^2 is defined as $R^2 \equiv 1 - \frac{SS_{res}}{SS_{tot}}$ where, $SS_{res} = \sum_i (y_i - f_i)^2$ and $SS_{tot} = \sum_i (y_i - \overline{y})^2$, given $\overline{y} = \frac{1}{n} \sum_{i=1}^{n} y_i$. Kendall's τ per song ($\overline{\tau}$) is a measure of how well the emotional profile of each song is captured by the regressor, as opposed to overall correlation. It measures the correspondence between two rankings. Values close to 1 indicate strong agreement, values close to -1 indicate strong disagreement. It is defined $\overline{\tau} = \frac{P-Q}{\sqrt{(P+Q+T)*(P+Q+U)}}$ where, P is the number of concordant pairs, Q the number of discordant pairs, T the number of ties only in target set ($y_1 \ldots y_n$), and U the number of ties only in predicted set ($f_1 \ldots f_n$). The mean absolute error (MAE) is given for reference. In the next section, we report the results of applying the proposed model for dynamic music emotion regression.

Baseline: It has been shown by Weninger et. al. [3, 6] that LSTMs can be used to produce good performance in emotion prediction, using the ComParE featureset. We try to reproduce their results using single layer LSTM-RNNs with hidden layer size of 400 units. These results are considered as *Baseline* in this work and are reported in the "Baseline" annotated rows of Table 1 and Table 2 for arousal and valence respectively.

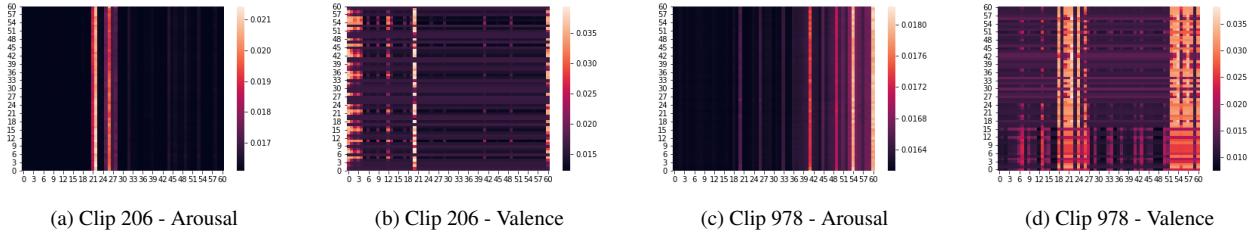
4.2 Experiment 1: Model Selection

In the first set of experiments, we aim to find the best model for dynamic arousal and valence prediction, among the

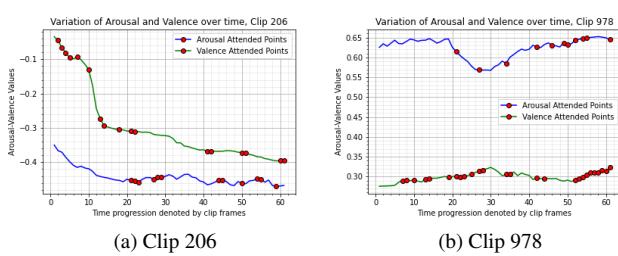
Table 3: Feature Sets for Arousal Prediction

Features Used	# Features	Best Model	R^2_A	$\overline{\tau}_A$	MAE_A
Chroma(STFT+CQT)	24	AT_64	0.15	0.04	0.19
CQT on Audio clip	252	AT_64	0.45	0.06	0.17
Chroma+CQT	276	AT_64	0.57	0.07	0.14
Spectral Features	197	AT_64	**0.70**	0.03	0.12

Table 4: Feature Sets for Valence Prediction

Features Used	# Features	Best Model	R^2_V	$\overline{\tau}_V$	MAE_V
Chroma(STFT+CQT)	24	AT_64	0.01	0.002	0.09
CQT on Audio clip	252	AT_64	0.07	0.01	0.17
Chroma+CQT	276	AT_64	0.17	0.06	0.14
Spectral Features	197	AT_128	**0.35**	0.07	0.16


ones proposed in section 3. Accordingly, the models with attention (*AT*, *BAT*, *Transformers*) and without attention (*LSTM*) are executed with varying layer sizes and layer numbers. The findings for arousal and valence are reported in Table 1 and Table 2 respectively. For dynamic arousal prediction (Table 1) using the ComPare feature set [1] (sec 4.1.1), the best result is obtained with the multi-layer attention model *AT_2048_1024*. Comparable result is also obtained with single-layer attention model *AT_300*. The best model for dynamic valence prediction (Table 2) is found to be the single-layer attention model *AT_400*. Comparable result is also obtained with multi-layer attention model *AT_300_128*.

The following are observed from this experiment: a) The best prediction performances reported in this section are better than that reported by the baseline methods (sec 4.1.3). b) Among all the experiments conducted, *AT* models fare best in dynamic arousal-valence prediction using the full ComPare feature set [1]. c) The best single and multi layer *AT* models' performances are comparable. d) Performance for arousal prediction (R^2_A and $\overline{\tau}_A$) in general is much better than valence (R^2_V and $\overline{\tau}_V$) - across all models tested. Though performance with respect to MAE are comparable.


In the following subsections, we demonstrate an illustrative example of dynamic emotion prediction using a clip chosen at random, followed by an error analysis of the predictions by the best proposed models, over the validation set clips.

4.2.1 Illustrative examples

In this section, we demonstrate an illustrative example of dynamic emotion prediction pattern, with respect to ground truth (sec 4.1) and baseline (sec 4.1.3), using a clip chosen at random from the dataset [8]. The best models, *AT_2048_1024* for arousal and *AT_400* for valence, obtained in section 4.2 are used for dynamic (per 500 ms) arousal and valence prediction of music clip *584.mp3*. This is presented in Figure 1. Figure 1a and Figure 1b denote the time varying arousal and valence predictions respectively. In the figures, X-axis denote the time (in seconds), and the Y-axis denote arousal and valence values respectively. It is seen that the proposed best models follow the pattern of reported emotions more closely than baseline model.

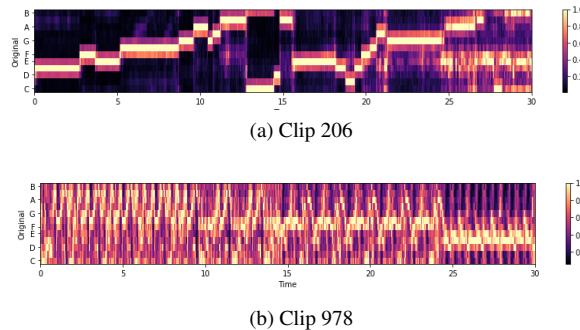
(a) Clip 206   (b) Clip 978

Figure 4: Comparing attended frames with ground truth Emotion ratings of dataset [8]


4.2.2 Errors Analysis

In this section we aim to observe patterns and biases in the best proposed models' (sec 4.1) emotion predictions, with respect to the baseline (sec 4.1.3). The respective predictions are utilized to group the validation set clips into error bins for this study. These are shown as histograms in figure 2. The X-axis denote the error bins of the models over the validation set clips. The Y-axis denote the number of clips of the validation set, which fall into each error bin. Comparing Figure 2a and Figure 2c, it can be seen that, for the proposed model, the number of clips with higher values of errors are less, in case of arousal. In case of valence, for the proposed model, almost all the clips are grouped into the error bins ≤ 0.05 (Figure 2b). Whereas for the baseline model ((Figure 2d)), a significant number of clips across bins are present.

4.3 Experiment 2: Exploring Other Feature Sets

In section 4.2, all the experiments use the full ComPare feature set [1]. Though it performs well in dynamic emotion prediction in music, it might be noted that it is generic, not music specific. It is large, which causes models to have large number of parameters. Also, there might be other relevant features, which might be used for this task, eg. Constant Q Transform features. In this section, we explore some smaller feature sets detailed in section 4.1.2, which might possibly produce similar or better results, over the same dataset [8], with the additional benefit of being smaller in size.

Single layer *AT* models were used to train on these new feature sets, since, it was observed in section 4.2 that they perform best and at par with multi layer models for emo-

(a) Clip 206

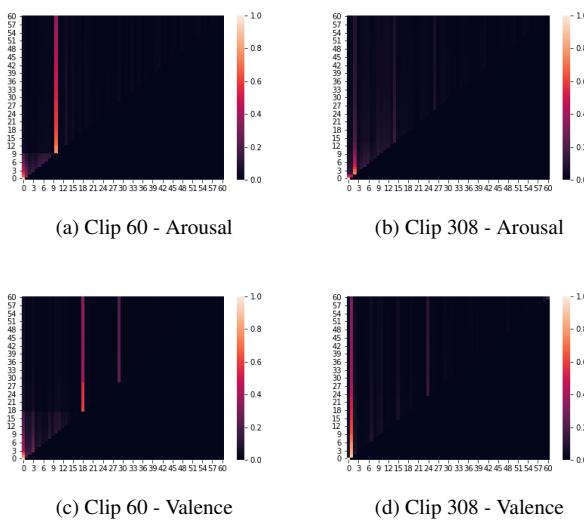
(b) Clip 978


Figure 5: Chromagrams for Attention Map Analysis. X-axis = time (in seconds), Y-axis = Chroma. Vertical bars=Chroma intensities

tion prediction. The results are presented in Table 3 and Table 4 for arousal and valence respectively. For arousal (Table 3), it is observed that *AT_64* performs well, when using the *Spectral Features* set, with a R_A^2 comparable to the best model *AT_2048_1024* using full ComPare [1] feature set. It is evident that Chroma features alone have negligible contribution in arousal prediction. *CQT* set performs moderately. For valence prediction (Table 4) also, *Spectral features* set performs best among all. *CQT* set does not contribute much to valence prediction. Thus, we conclude that there might be a possibility of a smaller featureset for emotion prediction.

4.4 Attention Maps for Emotion Prediction

Attention maps demonstrate the relative importance of layer activations at different 2D spatial locations with respect to arousal and valence predictions. In this section, the best *AT* and *BAT* models are used to generate the attention maps for both arousal and valence, for some clips chosen at random from the dataset [8], presented in Figure 3 and Figure 6. These maps provide information about those frames of the clip, which are attended to during emotion prediction. This in turn can yield valuable insights into specific audio features of those frames, conducive to certain emotion perception. For all the maps, X-axis signifies the attention points, which are the 500 ms frames of the clip the model attends to. The Y-axis signifies the prediction points, the clip's progression through time. It is to be noted that these 61 frames in the maps, correspond to the

(a) Clip 60 - Arousal
(b) Clip 308 - Arousal
(c) Clip 60 - Valence
(d) Clip 308 - Valence

Figure 6: Attention Maps using BAT models. X-axis = attention points (500ms clip frames), Y-axis = prediction points (clip's progression through time)

last 30 seconds of each clip, as per the dataset [8]. So, the sth frame of a clip, is actually the $(15 + \frac{x-1}{2})^{th}$ second of the entire 45 second clip. The vertical bars on the right of each attention map give the attention weight values present in each map. The observations are discussed in the following subsections.

4.4.1 Attention Maps Using AT models

The attention maps for arousal and valence prediction, generated using *AT_2048_1024* and *AT_400*, for clips 128.mp3, 171.mp3, 206.mp3, and 978.mp3 from the dataset [8] are presented in Figure 3. Figure 3a and Figure 3b demonstrates the attention maps for arousal and valence prediction in clip 206.mp3 . As evident from the figure 3a, the model attends mostly to the clip frames 20-22, 26-28, and then again frames between 43-44, 49, 53-54 and 58 to predict arousal. From figure 3b, it is observed that the model attends to the frames 1-4, 6, 9, 12-13, 17, 20-21, 40-41, 49-50 and 59-61 to predict valence. Similar observations can be made about the other clips as well from Figure 3.

Observations: For arousal prediction, the model attends to comparatively fewer frames of the clip. These attended frames are observed to occur around 10 seconds (20 frames) after the clip has started. It can be concluded that the arousal generated in the later part of the music clip plays a significant role in determining the arousal perception of the entire clip. The attended frames have arousal ratings which are approximately average of all the arousal ratings for a particular clip. On the other hand, for valence prediction, attention is distributed across the clip, whenever there is perceptible change in valence ratings. Thus it can be concluded that reports of valence depends on momentary perception. Even small changes are registered. The attended frames have quite varied valence rating values within a particular clip.

For further investigation, we juxtapose our findings with a) The dynamic arousal and valence ratings provided by the dataset [8] - ground truth, given in Figure 4, and b) Chromagrams of the clips obtained using Librosa [24], presented in Figure 5. In each line graph of Figure 4, the X-axis denotes time frames, and Y-axis denotes the arousal and valence values.

It is to be noted here that the clips 206 and 978 are so chosen that they have significantly different arousal and valence ground truth values. In clip 206, the arousal values are lesser than the valence values. In clip 978, the reported arousal values are greater than the valence values. The blue and green lines denote arousal and valence respectively, the red dots highlight the time frames attended to by the *AT* models, as evident from Figure 3. In each subplot of Figure 5, the X-axis denotes time (in seconds), and the Y-axis denotes the Chroma. The vertical bars indicate the intensities of the Chroma. Figure 5a demonstrates the chromagram for clip 206.mp3.
Observations: For arousal prediction, the model attends on those frames with stable presence of higher notes (eg. A, B). For valence prediction, model attends all over the chroma bins, specially when there is a change in notes in the chroma sequence of the clip. Similar observations might be made from the other chromagrams as well.

4.4.2 Attention Maps using BAT models

The attention maps generated using the BAT models, *BAT_2048_1024* for arousal are presented in Figure 6. Figure 6a gives the attention map for arousal prediction in clip 60.mp3 of the dataset [8]. As evident from the figure, the attention of the model shifts continuously throughout the clip, as it progresses in time, though Segments 11-12 receive maximum attention overall. Similar trends are observed in Figure 6c as well, which represents the map for valence prediction for the same clip. Initially, the first few segments are attended to. As the clip progresses in time, the attention is shifted to later segments, with segments 18-19 and 29-30 being more prominent. As the clip progresses, the attention to initial segments reduces, rendering the lower right triangular region of the maps devoid of any attention traces.

5. CONCLUSION

We demonstrate that the state of the art models for continuous-time emotion prediction perform modestly, thus emphasizing the need for further research in this area. We have proposed an attentive LSTM based model which improves the state of the art performance significantly, on standard benchmark dataset with standard metrics. Further, we observe that a reduced, music-specific feature set achieves similar performance to the new state of the art model on arousal prediction, leading to much smaller models. Finally, we analyse attention maps for the full attention model to conclude that the model indeed attends to critical portions of the music in order to predict the dynamic emotions. We also observe that the nature of attention is different in case of arousal and valence prediction tasks.

ABSTRACT

The COVID-19 pandemic causes a massive global health crisis and produces substantial economic and social distress, which in turn may cause stress and anxiety among people. Real-world events play a key role in shaping collective sentiment in a society. As people listen to music daily everywhere in the world, the sentiment of music being listened to can reflect the mood of the listeners and serve as a measure of collective sentiment. However, the exact relationship between real-world events and the sentiment of music being listened to is not clear. Driven by this research gap, we use the unexpected outbreak of COVID-19 as a natural experiment to explore how users' sentiment of music being listened to evolves before and during the outbreak of the pandemic. We employ causal inference approaches on an extended version of the LFM-1b dataset of listening events shared on Last.fm, to examine the impact of the pandemic on the sentiment of music listened to by users in different countries. We find that, after the first COVID-19 case in a country was confirmed, the sentiment of artists users listened to becomes more negative. This negative effect is pronounced for males while females' music emotion is less influenced by the outbreak of the COVID-19 pandemic. We further find a negative association between the number of new weekly COVID-19 cases and users' music sentiment. Our results provide empirical evidence that public sentiment can be monitored based on collective music listening behaviors, which can contribute to research in related disciplines.

1. INTRODUCTION

Music listening has various functions in people's daily lives, especially in terms of psychological aspects. Mood management and regulation are two major psychological

uses of music listening [31, 41–43] and have been widely investigated in previous studies [18,21,40,44]. In the literature, there are mainly two kinds of music mood being addressed. One is "expressed" mood, the other is "induced" mood. The former refers to the mood that is intended to be expressed by a piece of music whereas the latter refers to listeners' emotional state or feeling induced by listening to a music piece or situations with which people associate a song [5, 58]. Both kinds of music mood have been extensively studies in the field of Music Information Retrieval (MIR) in recent decades [59]. It is well known that people often search and select music based on the mood of music that fits their current (emotional) needs [12] and it has been found that people's mood is responsive to events in daily life [10, 25]. However, the influence of real-world events, such as human or natural disasters, on users' mood-based music selection remains less explored, especially in the scale of collective choices of users in a society.

As of May 4, 2020, with 3.57 million cases and over 250 thousand deaths reported, COVID-19 has posed a severe threat to public health. To contain the virus, multiple measures have been taken, such as city lock-downs, social distancing, travel restrictions, and university closures, disrupting people's daily life and routine. High unemployment and the economic damages caused by COVID-19 make people suffer from increasing economic stress [17, 24]. Causing economic and social pressure, the pandemic is putting enormous stress on all of us and might trigger feelings of distress and anxiety [8, 56]. Large-scale disasters are often accompanied by increases in depression, a broad range of other psychological stress and behavioral disorders [16, 20, 34]. Investigating whether and the extent to which collective sentiment inferred from music listening behavior is influenced by the pandemic can not only deepen our understanding of the relationship between real-world events and users' sentiment reflected by the music they listen to, but also contribute to mitigating negative mental health impacts caused by the pandemic, and help people adapt, and be resilient during distress times.

Inspired by the research gap and driven by the emerging pandemic, this study aims to explore the association between real-world events and the sentiment of music being listened to based on users' music listening history at

a large scale. In this study, we use the term *users' music sentiment* to refer to the aggregated collective sentiment of music listened to by a population of users. We use the difference in differences (hereafter DD) method [2], a widely used causal inference approach, and base our analysis on an extension of the LFM-1b dataset [45]. This dataset provides us with a substantial set of listening histories of users from around the world as well as user-generated tags that we derive sentiment information from. We use the unanticipated outbreak of COVID-19 as a natural experiment to investigate the causality between pandemics and collective sentiment reflected by music people choose to listen to.

Specifically, we aim to answer the following research questions:

RQ1: How did the first COVID-19 case in a country affect the music sentiment of users in that country?

RQ2: How did the number of new COVID-19 cases and hence, the spread of the disease in a country affect the music sentiment of users in that country?

Using the DD model, our analyses can reveal causal relationship between real-world events, a pandemic in our case, and users' music sentiment. Results of this study could shed light on designs of music recommenders to be more sensitive to real-life events. More importantly, our results provide convincing evidence that collective sentiment is hampered by the pandemic. Beyond the field of MIR, findings of this study could provide empirical evidence on the extent to which public sentiment could be monitored by music listening behaviors of a concerned population. This could contribute to science in related disciplines such as social psychology, sociology, and journalism.

2. RELATED WORK

Two streams of research show a possible relationship between real-world events and users' sentiment of music being listened to, while the causal pathway remains unexplored. Links between real-worlds events and people's mood have been widely documented in previous research [50, 51]. However, to our best knowledge, there has been no study on the association between real-world events and users' collective sentiment as reflected by music they listen to.

2.1 Real-world events linked to mood

Mood indicates a set of transient, fluctuating affective states in terms of individuals' feelings [4, 26]. A variety of factors are related to individuals' mood state, including personality [14], ongoing events, experiences, or the environmental milieu [57]. Real-world events or the daily experiences, conceptualized as situational or contextual factors, have long been recognized as important determinants of daily mood in abundant research [50, 51].

Pioneering studies on the association between daily events and mood are often based on self-reported data on the same day. For example, Lewinsohn and colleagues [29] found a negative correlation between the number of pleasant events and depression by exploiting subjects' self-reported data on daily experiences and self-ratings of mood

states. Similar results have been found by Rehm [36] and Stone [49, 51]. In particular, Stone found a same-day association between major daily events and mood, based on self-reported events and moods of 50 men [51]. However, studies based on self-reported data in the same-day context are not sufficient to demonstrate a causal relationship because mood could impact the reliability of event reporting [9]. More convincing evidence of the causal relationship between real-world events and mood could be provided based on longitudinally self-reported data on events and moods over a period of time.

The occurrences of events have an impact on changes in positive and negative mood, respectively. Pleasant events are normally related to positive mood, such as exercise [13, 28], family, friends, and leisure time [50] and other pleasant daily events [27]. There is also evidence of the links between various negative daily events and negative mood, such as interpersonal conflict [6], negative interpersonal interactions [38], stressful work-related events [38], daily hassle [11], undesirable daily events [1], and other daily stressors [15, 52]. For instance, using the data extracted from diaries, Zuckerman demonstrated that young adults reported significantly higher levels of depression when they reported interpersonal conflicts [7].

Current research on the effect of major real-world events on mood is limited [47]. The majority of previous work is built on the self-reported data of small samples. On one hand, it is unclear whether small samples were sufficiently representative; on the other hand, the self-rating of mood state can be subjective.

2.2 Real-world events and music listening

Schedl et al. [46] took an initial step to explore the correlation between real-world events and music consumption behavior by leveraging listening events from Last.fm and world-wide events from Google Trends. Performing an intervention time series analysis, the authors found that changes in listening behavior might be correlated to real-world events. However, only two variables were taken into account: the number of events identified by Google Trends and the absolute number of listening events. Whether or not real-world events are linked to users' music sentiment remains uncovered.

Inspired by this research gap , this study aims to examine the association between real-world events (the COVID-19 pandemic) and the collective sentiment reflected in people's music listening behaviors. Based on (an extension of) the LFM-1b dataset, one of the largest datasets of music listening histories available to date, this study examines the relationship between the outbreak of COVID-19 and the collective music sentiment.

3. DATA AND METHODOLOGY

In the following, we present the data utilized and subsequently, we describe the methods underlying our analyses.

3.1 Data

We built upon the LFM-1b dataset [45] to explore the relationship between the outbreak of the COVID-19 pandemic

and users' music sentiment. More precisely, we gathered the listening records of users in the LFM-1b dataset between November 1, 2019, one month before the first COVID-19 case in the world was confirmed in China [1], and March 27, 2020. Even though the outbreaks are still ongoing in many places as of the writing of this paper, this time frame captures the times of first confirmed COVID-19 cases in all countries involved in this study. We obtained more than 28 million listening events shared during this period of time, 21 weeks in total, generated by 12,278 Last.fm users from 40 countries from the LFM-1b dataset. From the Our World in Data website, [2] we collected data on confirmed COVID-19 new cases by date for these countries. In particular, we identified the date of the first confirmed COVID-19 case in each country and define it as the date when the COVID-19 outbreak started in this country.

3.2 Measuring music sentiment

In Last.fm, tracks and artists are associated with tags created by users. To capture the sentiment of music listened to by our users, we collect the artists whose music pieces are included in our dataset, that is, have been listened to by included users during the concerned period of time. Although tracks also have tags, track-level tags indicating sentiment might be too sparse as there are a much larger number of tracks than artists. Therefore, using artist sentiment (as opposed to track sentiment) provides us with a substantially larger set of tags with sentiment. The sentiment of an artist can then be calculated by methods described in the next paragraphs.

We capture the sentiment values assigned to all artists by crawling the user-created tags assigned to those artists from Last.fm. Subsequently, we follow Zangerle et al.'s [60] approach for the computation of sentiment values based on the tags. Specifically, we utilize sentiment lexica, a widely used unsupervised sentiment detection method for the extraction of sentiment information from the tags. A sentiment lexicon is a list of words, where each word is assigned a sentiment value (e.g., on a scale from 0 to 1, describing a range of sentiments from negative to positive) [54]. We rely on a set of widely used dictionaries that have been shown to provide the best coverage and accuracy according to Ribeiro's benchmark of sentiment dictionaries [39]: AFINN [32], Opinion Lexicon [22], SentiStrength [55], and Vader [23]. The different lexica provide different notions of polarity and strength of polarity. Hence, we normalize the set of sentiments to a range between 0 and 1 by using linear min-max feature scaling.

The following steps are taken to perform the sentiment computation based on these dictionaries. First, we employ whitespace as delimiters to tokenize the tags as tags may consist of several words such as in "nothing left to fear". We then use the tokens as the input to the matching step between tokens and dictionaries. To do so, we apply lemmatization to the tokens contained in the sentiment dictionaries (utilizing the lemmatization method of

the Python's NLTK package). Next, we match each tag token to the set of dictionaries. For each matched token, we extract the assigned sentiment value. In the case that a token matches multiple entries of the dictionaries (i.e., if it is contained in multiple dictionaries), we utilize the arithmetic mean of those values as the sentiment value of the token. After having computed the sentiment value for each token, we assign the tag the mean of the sentiment values of all tokens contained in the original tag.

The sentiment of an artist is then defined as the weighted average sentiment values of the tags assigned to the artist, as shown in Equation 1:

$$AS_j = \sum_{i=1}^{n} v_i \cdot \frac{f_i}{F} \qquad (1)$$

where (AS_j) stands for the sentiment value of the jth artist; v_i denotes the sentiment value of the ith tag for artist j; f_i refers to the frequency of tag i for this artist, and F denotes the total frequency of tags for the artist.

We consider this a reasonable estimate as the tags applied to each artist reflect the collective sentiment a large number of listeners had towards the artist over a long period of time. It can thus be assumed that tags are not biased by certain (subgroups of) users or any short term events.

3.3 Difference in differences approach

To capture the relationship between the outbreak of the COVID-19 pandemic and the sentiment of music listened to by users, the DD model is used [2]. This method measures the differential effect of certain changes on the dependent variable of treatment groups versus that of control groups [19]. One distinct advantage of the DD model is that it can disclose causality. In this study, the concerned change is the outbreak of COVID-19. The dependent variable is the users' music sentiment extracted from their listening behaviors (cf. Section 3.2). In this study, for a given period of observation (i.e., a specific week), users in countries with confirmed COVID-19 cases are in the treatment group, whereas users in countries without confirmed cases form the control group.

Besides, to control for users' other characteristics that may affect their sentiment of music, we introduce fixed effects regression, the major method for regression analysis of panel data. It is an extension of multiple regression that exploits panel data to control for variables that differ across entities but are constant over time [48]. This allows controlling unobserved changes during our observation period. We incorporate user gender, age, and country as control variables.

The DD model employed for the COVID-19 pandemic is shown in Equation 2.

$$Y_{it} = \alpha + \beta_1 (I_{it}) + \beta_2 Gender_i + \\ \beta_3 Age_i + C_i + D_t + \epsilon_{it} \qquad (2)$$

where Y is a dependent variable, I are the independent variables, it indicates observations for user i in week t and ϵ_{it} indicates the error term in the equation. We detail the utilized dependent and independent variables in

---

[2] https://ourworldindata.org/covid-cases

Sections 3.4 and 3.5, respectively. Furthermore, the equation also contains controls and fixed-effect variables as described above. Specifically, fixed-country effects (C_i in the equation) allow controlling the time-invariant, country-specific characteristics of users as e.g., socio-cultural background may be related to users' artist listening behavior. The observable changes of global events that might influence users' listening behavior worldwide can be controlled by adding a week fixed effect (D_t). Controls of gender and age of users are also included in Equation 2.

The coefficient for the dependent variable is an effective difference-in-differences estimate of the average impact of the COVID-19 outbreak on the sentiment of music listened to by users. The effect of the outbreak of COVID-19 on user's music sentiment in a week is estimated using the Ordinary Least Squares method, which is appropriate for the continuous dependent variable.

3.4 Dependent variables

We use two dependent variables to build two models, by which we can cross check robustness of the results. Both are on user's music sentiment calculated based on the measure of music sentiment described in Section 3.2. The first dependent variable is the average sentiment of artists a user listened to (hereafter referred to as *USE*) in a given week. The values of USE range from 0 to 1. The larger the USE value is, the more positive the user's music sentiment. USE captures the average sentiment of artists the user listened to in each day, weighted by the relative consumption frequency of the artists, as shown by Equation 3:

$$USE = \sum_{i=1}^{n} AS_i \cdot \frac{c_i}{C} \qquad (3)$$

where AS_i denotes the sentiment value of the ith artist the user listened to on the given day; c_i indicates the playcount (number of times the user listened to artist i); and C denotes the total playcount of the user on that day. Based on daily USE values, we then aggregate this user's daily USE to the weekly level through averaging. The weekly average USE of a user is the first dependent variable.

The second dependent variable we propose to use is whether the music sentiment of a user in a given week is extremely positive (i.e., whether or not the weekly USE value of a user is in the 90th percentile of USE values of all users in our dataset). We refer to this variable as *POS*.

3.5 Independent variables

For our DD analyses, we propose to use the outbreak of COVID-19, denoted as *COVID-19* hereafter, as the independent variable. Specifically, it is a binary variable indicating whether or not the first COVID-19 case has been confirmed in a given country in a given week. The variable is 0 for observations (a.k.a samples) before the outbreak in a country and 1 for observations/samples after the outbreak. In addition, to explore the association between the number of new COVID-19 cases and user's music sentiment, we also include the weekly number of new COVID-19 cases in a country as the second independent variable, denoted as *COVID19 cases*.

Variable	Mean	Std. Dev.	Min	Max
USE	0.3332	0.0782	0	0.9813
POS	0.0976	0.2967	0	1
COVID-19	0.2038	0.4028	0	1
COVID-19 cases	0.8344	1.9249	0	10.0542
Age	32.3674	13.1637	6	126
Gender	0.1731	0.3783	0	1

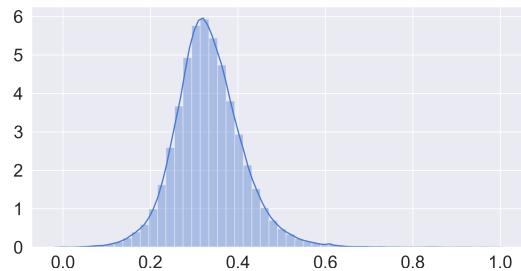
Table 1. Descriptive statistics of variables modeled in this study; N =184,277 (weekly observations of 12,278 users for 21 weeks); gender indicates male (0) or female (1).


Table 1 summarizes the descriptive statistics of dependent and independent variables in this study. The distribution of USE for the samples is presented in Figure 1.

3.6 Interaction effect between the COVID-19 and gender

To explore whether there is a gender difference regarding the effect of the COVID-19 pandemic on user' music sentiment, we generate two interaction terms between gender and the independent variables respectively, *COVID#Gender* and *Case#Gender*. Specifically, we multiply COVID-19 and COVID-19 cases with gender respectively and add each of the interaction terms to Equation 2 for separate modeling.

Besides, after running regression models on all sampled users, we conduct DD analysis for females and males separately, to further examine possible gender differences.

In sum, for each dependent variable (USE, POS), we run four regression models on each independent variable (COVID-19 and COVID19 cases): the original one indicated by Equation 2, the one with added interaction term, and two on female and male users only.

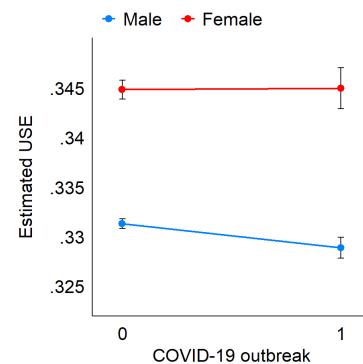
Figure 1. Distribution of USE (average sentiment of artists the user listened to), with USE on x-axis and probability density on y-axis.

4. RESULTS

4.1 COVID-19 outbreak and users' music sentiment

The effects of the independent variable, COVID-19, on dependent variable, weekly USE (user's music sentiment) are shown in columns 1 to 4 in Table 2 (Panel 1). We observe a significant and negative association between the outbreak of COVID-19 in a country and users' music sentiment (USE): The coefficient on COVID-19 for USE is -0.002 ($p < 0.01$, t-test) in column 1 of Table 2 (Panel 1),

suggesting that the sentiment values of the users in countries with COVID-19 outbreak is 0.002 lower than that of the users in countries where COVID-19 has not appeared yet. In other words, compared to sentiment of artists listened to by users in countries without COVID-19, that of users exposed to this pandemic is more negative.

In the USE model, the coefficient for Gender in column 1 (Panel 1) is 0.014 at the significance level of 0.01, indicating that the sentiment of artists listened to by females is more positive than that of males. The coefficient for age is significantly negative in column 1 (Panel 1), suggesting that younger users' average weekly music sentiment is more positive than older users, though the difference is small and nearly close to zero.


Gender differences are also found in the model of USE with the intersection term (column 2, Panel 1). With a value of 0.0025 ($p < 0.05$), the coefficient on the interaction term between COVID-19 outbreak and gender, COVID#Gender, is significantly positive, indicating that females are less influenced by the pandemic, as compared to their male peers. In column 2 of Table 2 (Panel 1). The estimated USE for females and males before and after the outbreak of COVID-19 is shown in Figure 2. The figure suggests a very slight decrease in USE after the outbreak of COVID-19 for females, as compared to a clear decline in users' USE for males. The regression results are consistent based on the models that only include either female (column 3, Panel 1) or male users (column 4, Panel 1): there is no significant impact of COVID-19 outbreak on USE in the model of females (column 3), while there is a significantly negative effect for males as shown in column 4 of Table 2 (Panel 1).

The results of the analyses of the POS variable (i.e., whether music sentiment of users is extremely positive) provide consistent findings that user's music sentiment turns more negative after the outbreak of COVID-19. Column 5 of Table 2 (Panel 1) reveals that there is a significantly negative relationship between the outbreak of COVID-19 and the positiveness of users' music sentiment (POS). After the outbreak of COVID-19, the probability that users' weekly averaged music sentiment reaches extremely positive values decreased by nearly 2.8% ($p < 0.01$). The coefficient on the interaction term between COVID-19 and gender is not significant (column 6, Panel 1). Columns 7 and 8 in Panel 1 both show that the likelihood that the weekly USE for females and males get extremely positive declines by 1.6% ($p < 0.05$) and 3.2% ($p < 0.01$), respectively.

4.2 COVID-19 cases and users' music sentiment

Users' sentiment of music is negatively associated with the number of COVID-19 cases in a country. In other words, in a country where a larger number of people are infected with COVID-19 in a given week, the weekly average sentiment of artists the user listened to becomes more negative. From column 1 in Table 2 (Panel 2), one unit growth in COVID-19 new cases in the week leads to a decrease of 0.05 in weekly USE of users , i.e., 64.10% (i.e., 0.05 divided by standard deviation of USE) standard deviation of

users' USE. Again, we find the negative effect of COVID-19 cases only for males, as shown in column 4 of Table 2 (Panel 2). For the dependent variable POS, results in column 5 of Table 2 (Panel 2) shows that, one unit increase in COVID-19 new cases in the week is related to a 67% lower probability that the weekly user sentiment reaches extremely positive values. There is no gender difference regarding the effect of new COVID-19 cases on users' POS as the interaction term between new COVID-19 cases and Gender is not significant (column 6, Panel 2), and the coefficients of COVID-19 cases on POS for females and males are very close, as shown in columns 7 and 8 of Table 2 (Panel 2).

Figure 2. Estimated interaction effect between COVID-19 outbreak and gender.

5. DISCUSSION

Our results show that, after the outbreak of COVID-19 in a country, the weekly sentiment of artists users listened to turns more negative. These results are robust regardless of whether the dependent variable is the weekly average sentiment value of users' artist listening (USE) or whether or not users' music sentiment is extremely positive (POS). The findings hence show significant causality between the real-world event (i.e., the COVID-19 pandemic) and users' music sentiment. We find that, after the first COVID-19 case in a country was confirmed, the weekly sentiment of artists users listened to decreased by 0.002, nearly 3% of standard deviation of users' USE (column 1 Panel 1 in Table 2. This negative effect is pronounced for males, whereas females' music emotion is less influenced by the outbreak of the COVID-19 pandemic. We further find a negative association between the number of COVID-19 new cases in the current week and users' music sentiment: one unit growth in COVID-19 new cases in a given week brings a decrease of 0.05, i.e., 64.10% of standard deviation of user's weekly music sentiment (column 1, Panel 2 in Table 2. One unit increase in COVID-19 new cases in a week is related to a 67% lower probability that user's weekly music sentiment reaches extremely positive (column 5, Panel 2 in Table 2).

We provide convincing evidence to show a negative impact of public health crisis on collective sentiment using the unexpected outbreak of COVID-19 pandemic as

Table 2. Estimated effect of the outbreak of COVID-19 (Panel 1) and number of new COVID-19 cases (Panel 2) on users' music sentiment. Robust standard errors are in parentheses; gender indicates female (1) or male (0). All models employ country and week-fixed effects (*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$). For columns (1) to (4), the dependent variable is USE. From columns (5) to (8), the dependent variable is POS. Columns (1) and (5) report the regression results based on the models that include control variables, i.e., gender and age for all sampled users; columns (2) and (6) indicates the regression results based on the models with control variables and an interaction term between COVID-19/Case and gender; columns (3), (4) and columns (7), (8) show the results based on the models with either female or male users.

an example that ensures a causal relationship through the different of differences method. Wide spread outbreaks of infectious diseases often cause psychological distress and symptoms of mental illness [3, 35]. Our results suggest that the average sentiment of artists users listened to becomes more negative after the first COVID-19 case was confirmed in a country, which is consistent with reported detrimental effect of pandemics on public mental health [30, 33, 37]. We further find that in countries where more new COVID-19 are confirmed, users' music sentiment turns more negative. During this acute public health crisis, people might experience fears of infection and worry about the pandemic's consequences. The disruption of daily routines and the social isolation imposed by the "stay at home orders" adopted in many countries also cause compounding personal stress and anxiety. The unemployment and financial losses caused by physical isolation may also strengthen feelings of distress. These negative emotions, as shown by our results, have been reflected by the sentiment of artists users listened to during the pandemic.We find that females' music sentiment is less influenced by the outbreak of COVID-19, which is probably due to the gender differences in socio-economic roles that

females might be less financially stressed than males [53].

6. CONCLUSION

This study applies the difference of differences method to find that, after the first COVID-19 case in a country was confirmed, the weekly sentiment of artists users listened to became more negative. This negative effect is pronounced for males. We further find a negative association between the number of new COVID-19 cases in a week and users' music sentiment. The results could provide useful implications for the design of music recommendation systems during public health crises or other disasters, which could help manage users' mood, enhance mental health, and mitigate negative psychological impacts of pandemics. The findings also provide empirical evidence that large-scale aggregation of music listening data can help monitor collective sentiment of listener populations.

Paper Session 2

IMPROVING POLYPHONIC MUSIC MODELS WITH FEATURE-RICH ENCODING

Omar Peracha

Humtap (research conducted independently)

omar.peracha@gmail.com

ABSTRACT

This paper explores sequential modelling of polyphonic music with deep neural networks. While recent breakthroughs have focussed on network architecture, we demonstrate that the representation of the sequence can make an equally significant contribution to the performance of the model as measured by validation set loss. By extracting salient features inherent to the training dataset, the model can either be conditioned on these features or trained to predict said features as extra components of the sequences being modelled. We show that training a neural network to predict a seemingly more complex sequence, with extra features included in the series being modelled, can improve overall model performance significantly. We first introduce TonicNet, a GRU-based model trained to initially predict the chord at a given time-step before then predicting the notes of each voice at that time-step, in contrast with the typical approach of predicting only the notes. We then evaluate TonicNet on the canonical JSB Chorales dataset and obtain state-of-the-art results.

1. INTRODUCTION

Computational modelling of polyphonic music is now a decades-old practice, with documented attempts dating back over sixty years [1]. Recent years have seen great progress in these models' ability to capture the semantics of a musical corpus, with much of this progress due to advances in artificial neural network algorithms and their application to the music domain.

Some of the most significant breakthroughs of late have experimented with applying newly-developed architectures to the problem of modelling symbolic music [2-3], training or pre-training on a large cross-domain corpus [2][4], or introducing Gibbs-like sampling methods to orderless models [5-6]. We instead focus on the sequence being modelled itself, and provide observations and enhancements that might improve results across a wide range of approaches.

We conduct experiments with two architectures: a multi-layer Transformer encoder [7] with input masking

and a model based on the Gated Recurrent Unit [8] to which we give the nickname TonicNet. Using the JSB chorales dataset, split into training, validation and test sets as per [9], the models are trained to predict each token of the samples one-by-one in a sequential manner.

We observe that increasing the amount of musical information these models are trained to predict tends to improve overall performance of both models as measured by validation set loss. In particular, by training to first predict the chord at a given time step before then predicting the notes of each voice at that time step, both models show improvements in validation loss, despite the modelled sequences being longer and containing a larger possible output space than would be the case if predicting only the notes. We also train TonicNet on smaller subsets of the samples by restricting the number of voices being modelled, and again observe that results improve when more musical information is contained in the sequence being predicted.

These observations allow better results to be achieved without the need to use models with an ever-larger number of parameters. Concretely, TonicNet is approximately an order of magnitude smaller than Music Transformer, yet obtains a lower validation set loss on the JSB chorales dataset than that reported by [3] as a result of being trained to predict both chords and notes. It also generates samples much faster than reported in [5] by avoiding Gibbs-like sampling, and achieves state-of-the-art validation loss without requiring pre-training on a larger cross-domain corpus, saving a significant amount of training time.

All code for this paper is made publicly available, including the ability to load and sample from the pre-trained TonicNet model. [1] Samples generated by TonicNet are also made available in both MIDI and audio form.

2. RELATED WORK

Recurrent Neural Networks have been noted for their ability to model sequential data, with the LSTM [10] in particular being a favoured approach for a number of applications. RNNs have been widely-used in recent attempts to model musical data, which lends itself well to a sequence-based representation. The earliest such examples used RNNs to model monophonic music [11-12].

In [9] RNNs were combined with Restricted Boltzmann Machines to model polyphonic music, while RNNs and LSTMs were combined with Deep Belief Networks for the

---

[1] https://github.com/omarperacha/TonicNet

same task by [13] and [14] respectively. BachBot [15] also uses an LSTM-based neural network, and both the architecture and hyperparameters described in their paper are influential in this work. All of these polyphonic models have been evaluated on the Bach chorales, although not all with the same dataset split. BachBot is trained to predict not only the notes, but also whether a fermata, the symbol used by Bach to mark phrase endings, coincides with each given note. This is deemed to improve sample quality, however the version of the dataset used in this work does not contain information regarding presence of fermatas.

The Transformer and its derived architectures have been popular choices for more recent polyphonic music models, and are emerging as strong alternatives to RNNs more broadly due to the self-attention mechanism demonstrating great effectiveness at capturing long-term dependencies in training data [7]. Music Transformer adds a novel relative attention mechanism to the vanilla Transformer and is evaluated on the JSB chorales dataset. LakhNES [4] uses the Transformer-XL architecture [16] and is pretrained on a large corpus of four-part music before being fine-tuned on the NES Music Database [17]. An event-based encoding is preferred which allows for more precise rhythm than the most commonly seen approach of slicing the input sample along a 16th-note (or some other suitable, dataset-dependent value) grid. MuseNet [2] is based on the GPT-2 Transformer model [18] and is trained on a massive corpus of polyphonic music. The data representation used has similar qualities to the event-based representation described by [4], and allows the trained model to sample while taking into account specific instrumentation and musical style. The encoding also includes information relating to note loudness.

Chords have been used in some previous approaches to improve the quality of monophonic music models. Chords are used as extra inputs to aid the generation of melodies by [19], who use a dual LSTM network Product of Experts system [20], and by [21], who propose training a convolutional generative adversarial network to generate melodies one bar at a time. However, neither of methods learn to predict the chords being used as input for each proceeding step, but rather provide them as fixed inputs.

HARMONET [22], comprises an ensemble of multiple neural networks trained with the ultimate goal of harmonising a given melody in the style of Bach. The first step is to derive the chords at each quarter-note step from the melody, relative to the key, including the inversion (and therefore the bass part). The inner parts are then predicted in a second step.

In the method proposed in this paper, chords are in fact included in the sequence as a de facto extra voice which must be predicted along with the other four voices, rather than being used as a secondary conditioning input. Inversions are not encoded in the chord representation, as the bass part is included later in the sequence.

DeepBach [5] is also trained on a representation including extra musical features as added voices. In this case, it is the presence of a fermata at each time step. The model is not trained to predict this, however, but fermata information is instead provided as a fixed input which helps guide the musical structure of the generated samples. Chord tokens are not used by the DeepBach model.

Both DeepBach and COCONET [6] are trained with the primary goal of completing partially-filled musical scores, for example harmonising a given melody, though both are able to generate entire four-voice samples from an empty or randomly-initialised score. They do both require the length of the sample in time-steps to be preset in order to facilitate the orderless Gibbs-like sampling methods used, and DeepBach further requires fermata information to be provided. TonicNet instead uses ancestral sampling to generate scores, and is trained to predict successive tokens in a purely autoregressive fashion, requiring absolutely no pre-set information relating to length or phrasing. This ultimately inhibits sample quality as the phrase lengths may not display the consistent symmetry over time observed in the training corpus, however the model still obtains a lower validation set loss on the JSB chorales dataset than the upper bound reported by [3] for orderless evaluation of CO-CONET (i.e. evaluating COCONET's ability to correctly fill in the missing notes in partially-completed scores), when averaging purely over the note predictions and ignoring the chords which do not originally appear in the benchmark dataset.

A powerful advantage of DeepBach and COCONET is that they lend themselves far more naturally to interactive applications. Theoretically one could fix the chords or the notes of a given voice when sampling from TonicNet by ignoring predicted output for the relevant part, instead using the token from the corresponding time-step of the fixed sequence as input to the model at the next time-step. However, this kind of forced sampling has not been tested empirically and so sample quality under these conditions cannot be attested.

3. DATASET

3.1 JSB Chorales

The JSB chorales are the most commonly-used benchmark for measuring the performance of polyphonic music models to date. They are a set of short, four-voice pieces well-noted for their stylistic homogeneity. The chorales were originally composed by Johann Sebastian Bach in the 18th century. He wrote them by first taking pre-existing melodies from contemporary Lutheran hymns and then harmonising them to create the parts for the remaining three voices. The version of the dataset used here consists of 382 such chorales, with a train/validation/test split of 229, 76 and 77 samples respectively. [2]

---

[2] The version of the dataset used can be accessed at https://github.com/czhuang/JSB-Chorales-dataset

3.2 Representation

3.2.1 Serialisation

The dataset is pre-serialised onto a 16th-note grid, which captures full resolution of the original chorales. Only the pitch information of the four voices at each time-step is encoded in the canonical dataset; other symbolic data that may appear in a musical score, such as loudness or fermata, are absent. Furthermore, information regarding note boundaries in the case of repeated pitches is not present. The consequence of this is that it is not possible to truly accurately model Bach's original rhythms, unlike other approaches, e.g. [5], where the version of the dataset used allows note boundary information to be preserved using a special 'hold' token, despite 16th-note serialisation. A partial workaround to lack of repeated note boundaries during sampling is to simply tie together consecutive occurrences of the same pitch in a voice, which we refer to as rhythmic 'smoothing', however this inevitably sacrifices some rhythmic integrity of the original chorales. While it may seem unideal to serialise music onto a fine-resolution rhythmic grid, as this has the consequence of vastly extending the length of the sequences being modelled, it in fact acts as a highly effective form of data augmentation; brief experiments which encoded the true duration values of the notes, using the Bach chorales as made available by the music21 toolkit [23], ultimately performed significantly worse than the representation presented in this work, both in terms of validation loss and sample quality.

We include chords in our encoding. We first derive the chords for each 16th-note time-step by analysing the pitches of the four voices at said time-steps, using the music21 chord module. We then create a single ordered sequence for each sample in the form C_0, S_0, B_0, A_0, T_0, C_1, S_1, B_1, A_1, T_1... C_{N-1}, S_{N-1}, B_{N-1}, A_{N-1}, T_{N-1}, <END>, where C, S, A, T and B represent the Chord, Soprano, Alto, Tenor and Bass inputs at each respective step, and N is the total number of 16th-note time-steps in the given sample. The model is fed the elements of the sequence one-by-one and tasked with predicting the next element in each case, thus it must predict the chord governing each 16th-note time-step before then predicting the actual pitch values observed in the dataset at that time-step. The effect of predicting the Bass note before the Alto and Tenor notes seems to be negligible, but has not been thoroughly tested and so may be considered arbitrary. The longest sequence observed in the dataset given the described representation, is 2,881 tokens in length, taking into account the appended <END> token, but the lengths vary quite considerably across the dataset.

3.2.2 Symbolic Encoding

Pitches and chords are all represented by distinct integer values. We restrict pitches purely to those observed in the dataset (MIDI values 36-81 inclusive assuming a value of 60 to be Middle C). The MIDI pitch value 37, despite not in fact appearing in the dataset, is included so as to better facilitate data augmentation by transposition, described in the next section. Chords are represented as belonging to one of 50 classes, comprised by 12 major chords (one chord per pitch class in the western chromatic scale), 12 minor chords, 12 diminished chords, 12 augmented chords and a special <OTHER> token which accounts for any chord which is not interpreted as fitting into the previous 48 classes. A <CHORD REST> token completes the set used to represent chord classes, and denotes instances when all four voices have rests at that time-step. Any voice-wise occurrence of a rest in the dataset is itself represented by a distinct <REST> token, and finally the <END> token completes the set of possible model input/output classes, taking the total to 98.

3.3 Conditioning

In addition to chord/pitch inputs, which we refer to as X-input, we condition the model a second input that relays information about note repetition. Concretely, alongside each X-input value $X_{n,i}$, where i is used to index the chords and voices, we also input an integer, $Z_{n,i}$, corresponding to the number of consecutive times the value represented by $X_{n,i}$ has so far appeared in voice i, resetting to 0 each time a new value is observed in that voice or if $Z_{n,i}$ exceeds 79 (equating to 5 bars in 4/4 timing). This value was chosen because only one sample features Z-input values greater than 79, with this sample's maximum Z-input value of 143 being a clear outlier.

The motivation for this is that we might more explicitly capture some of the inter-voice rhythmic relationships that exist in the music, and indeed we observe that it improves model performance (Table 1). We also experimented with instrument labelling, as in [3], and found that while it somewhat improved model performance, repetition encoding had a more significant impact and combining both repetition encoding and instrument labels did not perform better than repetition encoding alone. From this we can infer that repetition encoding, as well as helping the model to better learn timing information relating to note and chord changes, also fulfils a role similar to instrument labelling. We refer to repetition encoding inputs as Z-inputs.

3.4 Augmentation

We perform two kinds of dataset augmentation on the training set alone, leaving the validation and test sets unchanged. Firstly, we transpose all pieces as many times as possible so that each piece only contains pitches that are within the set of pitches observed in the original dataset, and so that there are no instances of a pitch exceeding the natural range of the voice-type in which it appears. This takes the total number of training examples up to 1,968. We found that transposition makes a significant impact on the model's ability to generalise (Table 1).

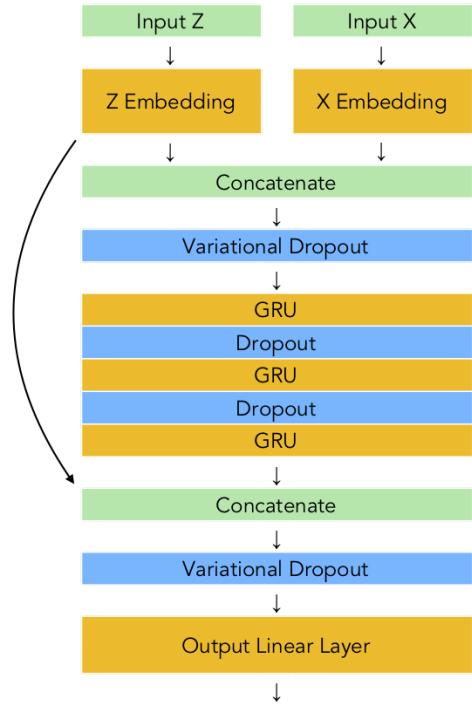
We also crudely convert all major pieces to minor, and vice versa, by raising all occurrences of the minor 3rd, 6th and 7th in minor pieces and flattening occurrences of the major 3rd and 6th in major pieces, leaving the 7th raised. This ultimately had negligible impact on model performance and harmed sample quality, while significantly in-

creasing the training time due to effectively doubling the number of samples. We therefore do not consider this an effective technique for dataset augmentation in the context of the JSB chorales. We hypothesise that this weakness may be due to the use of chromaticism and presence of key modulations within samples in the dataset, which may not maintain their stylistic integrity when the overall mode of the piece is converted in the naive manner described.

4. MODELS

4.1 TonicNet

TonicNet takes two inputs: the integer corresponding to the previous time-step's class label (X-input) and the integer corresponding to its repetition count (Z-input). These inputs are each converted to one-hot vector representations and by a 256-dimension and 32-dimension embedding respectively. The embedding outputs are then endconcatenated. Both the X embedding and the Z embedding are learned during training.

The concatenated embedding outputs have Variational Dropout [24] applied with a rate of 0.1, before then being input to a three-layer, 256-unit GRU, with dropout applied after each of the first two GRU layers, using a rate of 0.3.


The Z embedding output is reintroduced by endconcatenating with the GRU output, before applying Variational Dropout with a probability of 0.3. The resulting tensor is then fed to a final 98-unit affine layer.

We train TonicNet using a batch size of one for 60 epochs, employing the 1cycle policy [25] with Stochastic Gradient Descent as the optimiser. We begin training with an initial learning rate of 0.008, which is increased to 0.2 over the first 18 epochs. The learning rate is then decreased to 0.0002 over the remaining epochs via cosine annealing. We also cycle momentum inversely to the learning rate between values of 0.8 and 0.95. During training we clip the norm of the gradients to 5, which prevents gradient explosion. Training on the transposed dataset took roughly 3.25hrs on a T4 Tensor Core GPU.

Model hyperparameters, including number of recurrent layers, hidden units and dropout rate, were inspired by [15], and corroborated by initial experimentation. The sizes of both the Z and X embeddings were chosen naively and the effect of varying these has not been determined through experimentation, so there may be room to further tune the parameters of this model and improve results, which we leave to future work.

4.2 Transformer

We use a 5-layer Transformer encoder model. We encode absolute position in the sequence using a fixed sinusoidal position embedding as described in [7], with 256 dimensions. The model also learns a 256-dimension input embedding. The outputs of the two embeddings are endconcatenated. We use 8 attention heads and set the model dimension, D, to 512. The feedforward layer within the encoder module has 1024 units, and dropout is set to 0.1. The hyperparameters of this model are largely derived from the

Figure 1. Diagram of the TonicNet model architecture..

Vanilla Transformer decoder model used as a baseline in [3]. Input is masked to ensure the model can only attend to previous time-steps when making a prediction. Neither instrument labelling or repetition encoding are used when training this model.

We again utilise a batch size of one and employ the 1cycle policy with SGD. In this case we train for 30 epochs, increasing the learning rate from 0.0006 to 0.06 over the first 9 epochs before decreasing to 0.00006 with cosine annealing over the remaining epochs. Momentum is cycled inversely to learning rate between values of 0.8 and 0.95, and the gradient norm is clipped to 5. This model trains faster than TonicNet when measuring time taken per batch, but direct comparison is not possible as it was trained on CPU in our experiments.

4.3 Common Implementation Details

In both cases, we derive the maximum learning rate used during training by first performing an LR Range Test [26]. The models are trained using cross-entropy as the objective function, and always see the ground truth values for the previous steps of the sequence when predicting the current step.

While the benchmark dataset contains only notes, and therefore we are arguably more interested in minimising the loss when predicting the pitches of the voices than when predicting chords, we train the model to minimise the average loss across the entire sequence with no bias shown to steps including note predictions. Both models are implemented and trained using the PyTorch library [27].

5. EVALUATION

5.1 Quantitative Evaluation

The Transformer model is evaluated only on the un-augmented dataset, due to resource constraints. We compare performance when training on just notes of the four voices (SATB), and when training on sequences also including chords (CSATB). TonicNet is tested on a wider range of related tasks including modelling a variety of part combinations, from one part only up to the maximum five parts. We also show the effect of repetition encoding and training set augmentation. Table 1 shows the results of these experiments as measured by validation set loss, and compares performance against two high-performing baselines on the dataset, namely COCONET and Music Transformer.

In Table 1, each model variant shows the parts trained and evaluated on in parentheses, where NLL = Negative Log Likelihood, C = Chords, S = Soprano, A = Alto, T = Tenor and B = Bass. NCL stands for No Chord Loss, indicating that the model was only evaluated on the note predictions, ignoring the loss at time-steps corresponding to chord predictions when averaging NLL. The use of transposition to augment the dataset is denoted by Tr, and MM signifies training set augmentation via major-to-minor key conversion (and vice versa). TonicNet_Z here indicates the inclusion of repetition encoding Z-inputs when training the model.

The results show a trend whereby training the network to predict more musical information improves overall performance. Both models perform better when trained to predict chords before predicting notes at each 16th-note time-step, as compared with training to predict only the notes. Even when evaluating on the entire CSATB sequence, including the chords in the reported loss, we see that TonicNet_Z with transposition outperforms Music Transformer, the previous highest-performing ordered model as evaluated on the pure SATB dataset, despite being an order of magnitude smaller. When we ignore loss on chord time-steps, the average NLL is significantly lower, performing better than the upper bound for unordered evaluation of COCONET. The improvement when comparing performance on pitch-wise loss alone is echoed by the Transformer (CSATB) model. From this we can derive that predicting the chords has the impact of significantly improving model confidence when predicting pitches, which is perhaps intuitive.

5.2 Qualitative Evaluation

We evaluate the quality of samples from TonicNet via human domain expert analysis. We define a domain expert as someone holding a post-graduate degree in a subject directly related to Western Classical Music, and who has formally studied Bach's chorales as part requirement for obtaining an academic qualification. This is favoured as it allows for a more objective, thorough and strict criticism than a layperson-targeted listening test. We use random sampling to generate chorales from TonicNet, after first

Table 1. Validation loss on JSB chorales at 16th-note time-steps.

selecting a starting minor or major chord at random. Experiments with beam search decoding tended to produce overly-short samples, even when normalising sample probability for length, therefore random sampling according to the output probability distribution is preferred. Stochasticity during beam search has not been subject to experimentation.

We find that TonicNet_Z (CSATB, Tr) produces the best samples. Voice leading is typically stylistic, especially on a local scale, as is the generated melodic contour, although there is a tendency to diverge from what is clearly the intended phrase within a part for a single 16th-note, usually by a single scale degree or semitone, before then returning, causing an undesirable ornamentation effect.

Harmonisation and harmonic trajectory is also consistently plausible, however there are occasional instances of a phrase which clearly starts in a major key suddenly modulating to a minor key, or vice versa, in a manner that is uncharacteristic to the corpus. The worst generated samples may in fact display poor, overly-chromatic harmonisation and lack stylistic harmonic direction. Some instances of sample weakness may be artefacts of the exposure bias introduced by using teacher forcing when training TonicNet.

The most significant issue detected in samples ultimately relates to phrasing; Bach's chorales feature symmetric phrases, typically two, four or eight bars long, ending in a cadence. Generated pieces have a tendency to feature asymmetry between consecutive phrases, which is not stylistic. Including fermata or other phrase-based information in the modelled sequence could help mitigate this issue, as demonstrated in [5] and [15]. Samples do consistently end on a perfect cadence as expected, and voices never misalign due to a misordering in the generated se-

quence; rather, each voice clearly completes its phrase, and the duration of each voice's phrase coincides exactly with the others. Samples displaying a range of quality are included in the code repository for fair analysis.

6. CONCLUSIONS

We first extracted salient features from the existing dataset, in the form of chords and intra-voice token repetition, and then included these extra features among the training inputs. The fact that exposing the model to more features should improve results is unsurprising; more unexpected is that including new features as extra elements within the series being modelled should dramatically enhance performance. Furthermore, it was noted that confidence when predicting pitches is much higher if the model is first tasked with predicting chords. This suggests a worthwhile area for further research is to improve confidence when predicting the chords, and we conjecture that a method to achieve this may be to include yet more related features in the sequences themselves, such as fermata information or a representation of floating tonality, given our findings.

State-of-the-art validation loss on the JSB chorales dataset was achieved with a variation of TonicNet and effective dataset augmentation, and we demonstrated that despite this there are still some specific weaknesses in sample quality which other approaches have mitigated. We also noted the superior human interactability of COCONET and DeepBach, which we believe gives those proposals a greater potential for real-world application. However, the findings presented in this paper could be applicable to a wide range of approaches to statistical modelling of polyphonic music, and their merit was demonstrated on two such approaches.

We also surveyed the effects of serialising music by splitting notes across a fine-resolution temporal grid. While the benefit of this in terms of data augmentation was noted, we also presented weaknesses relating to true rhythmic integrity in the case of repeated note boundaries, and vast extension of sequence length which has the effect of increasing both training and sampling time. Ultimately we would like to move towards utilising encodings including true rhythmic duration, with the aim of being able to train more general polyphonic music models that are not confined to a temporal grid, and therefore to styles of music whose rhythmic resolution can be encompassed by this grid. It is not viable to simply serialise music into increasingly finer-resolution rhythmic units in order to accommodate datasets which include some occurrences of tuplet du-

rations, for example, as this continues to extend the overall sequence length. Future work will explore solutions to this drawback.

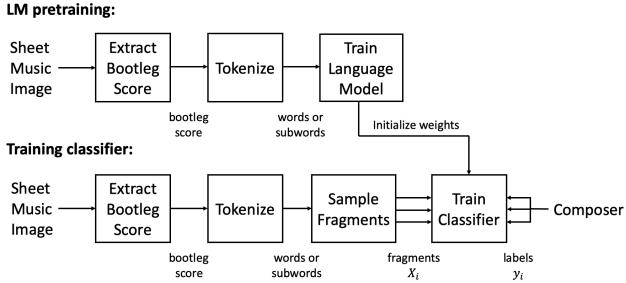
ABSTRACT

This paper studies composer style classification of piano sheet music images. Previous approaches to the composer classification task have been limited by a scarcity of data. We address this issue in two ways: (1) we recast the problem to be based on raw sheet music images rather than a symbolic music format, and (2) we propose an approach that can be trained on unlabeled data. Our approach first converts the sheet music image into a sequence of musical "words" based on the bootleg feature representation, and then feeds the sequence into a text classifier. We show that it is possible to significantly improve classifier performance by first training a language model on a set of unlabeled data, initializing the classifier with the pretrained language model weights, and then finetuning the classifier on a small amount of labeled data. We train AWD-LSTM, GPT-2, and RoBERTa language models on all piano sheet music images in IMSLP. We find that transformer-based architectures outperform CNN and LSTM models, and pretraining boosts classification accuracy for the GPT-2 model from 46% to 70% on a 9-way classification task. The trained model can also be used as a feature extractor that projects piano sheet music into a feature space that characterizes compositional style.

1. INTRODUCTION

We've all had the experience of hearing a piece of music that we've never heard before, but immediately recognizing the composer based on the piece's style. This paper explores this phenomenon in the context of sheet music. The question that we want to answer is: "Can we predict the composer of a previously unseen page of piano sheet music based on its compositional style?"

Many previous works have studied the composer classification problem. These works generally fall into one of two categories. The first category of approach is to construct a set of features from the music, and then feed the features into a classifier. Many works use manually designed features that capture musically meaningful information (e.g. [1] [2] [3] [4]). Other works feed minimally


preprocessed representations of the data (e.g. 2-D piano rolls [5] [6] or tensors encoding note pitch & duration information [7] [8]) into a convolutional model, and allow the model to learn a useful feature representation. The second category of approach is to train one model for each composer, and then select the model that has the highest likelihood of generating a given sequence of music. Common approaches in this category include N-gram language models [9] [10] [11] and Markov models [12] [13].

Our approach to the composer classification task addresses what we perceive to be the biggest common obstacle to the above approaches: lack of data. All of the above approaches assume that the input is in the form of a symbolic music file (e.g. MIDI or **kern). Because symbolic music formats are much less widely used than audio, video, and image formats, the amount of training data that is available is quite limited. We address this issue of data scarcity in two ways: (1) we re-define the composer classification task to be based on sheet music images, for which there is a lot of data available online, and (2) we propose an approach that can be trained on unlabeled data.

Our work takes advantage of recent developments in transfer learning in the natural language processing (NLP) community. Prior to 2017, transfer learning in NLP was done in a limited way. Typically, one would use pretrained word embeddings such as word2vec [14] [15] or GloVe [16] vectors as the first layer in a model. The problem with this paradigm of transfer learning is that the entire model except the first layer needs to be trained from scratch, which requires a large amount of labeled data. This is in contrast to the paradigm of transfer learning in computer vision, where a model is trained on the ImageNet classification task [17], the final layer is replaced with a different linear classifier, and the model is finetuned for a different task. The benefit of this latter paradigm of transfer learning is that the entire model except the last layer is pretrained, so it can be finetuned with only a small amount of labeled data. This paradigm of transfer learning has been widely used in computer vision in the last decade [18] using pretrained models like VGG [19], ResNet [20], Densenet [21], etc. The switch to ImageNet-style transfer learning in the NLP community occurred in 2017, when Howard et al. [22] proposed a way to pretrain an LSTM-based language model on a large set of unlabeled data, add a classification head on top of the language model, and then finetune the classifier on a new task with a small amount of labeled data. This was quickly followed by sev-

Figure 1. Overview of proxy classifier training. A language model is first trained on a set of unlabeled data, the classifier is initialized with the pretrained language model weights, and then the classifier is finetuned on a small set of labeled data.

Figure 2. A short section of sheet music and its corresponding bootleg score. Staff lines in the bootleg score are shown for reference, but are not present in the actual feature representation.

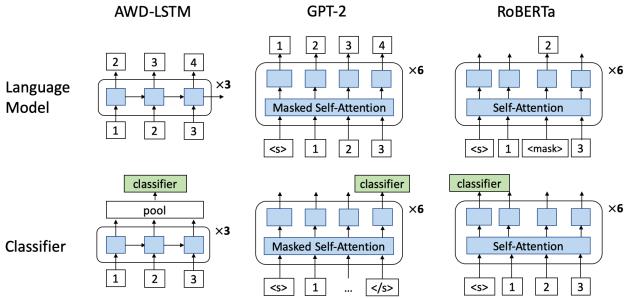
eral other similar language model pretraining approaches that replaced the LSTM with transformer-based architectures (e.g. GPT [23], GPT-2 [24], BERT [25]). These pretrained language models have provided the basis for achieving state-of-the-art results on a variety of NLP tasks, and have been extended in various ways (e.g. Transformer-XL [26], XLNet [27]).

Our approach is similarly based on language model pretraining. We first convert each sheet music image into a sequence of words based on the bootleg score feature representation [28]. We then feed this sequence of words into a text classifier. We show that it is possible to significantly improve the performance of the classifier by training a language model on a large set of unlabeled data, initialize the classifier with the pretrained language model weights, and finetune the classifier on a small amount of labeled data. In our experiments, we train language models on all piano sheet music images in the International Music Score Library Project (IMSLP) [1] using the AWD-LSTM [29], GPT-2 [24], and RoBERTa [30] language model architectures. By using pretraining, we are able to improve the accuracy of our GPT-2 model from 46% to 70% on a 9-way classification task. [2]

2. SYSTEM DESCRIPTION

We will describe our system in the next four subsections. In the first subsection, we give a high-level overview and rationale behind our approach. In the following three subsections, we describe the three main stages of system development: language model pretraining, classifier finetuning, and inference.

2.1 Overview

Figure 1 summarizes our training approach. In the first stage, we convert each sheet music image into a sequence of words based on the bootleg score representation [28], and then train a language model on these words. Since this task does not require labels, we can train our language


model on a large set of unlabeled data. In this work, we train our language model on all piano sheet music images in the IMSLP dataset. In the second stage, we train a classifier that predicts the composer of a short fragment of music, where the fragment is a fixed-length sequence of symbolic words. We do this by adding one or more dense layers on top of the language model, initializing the weights of the classifier with the language model weights, and then finetuning the model on a set of labeled data. In the third stage, we use the classifier to predict the composer of an unseen scanned page of piano sheet music. We do this by converting the sheet music image to a sequence of symbolic words, and then either (a) applying the classifier to a single variable length input sequence, or (b) averaging the predictions of fixed-length crops sampled from the input sequence. We will describe each of these three stages in more detail in the following three subsections.

The guiding principle behind our approach is to maximize the amount of data. This impacts our approach in three significant ways. First, it informs our choice of data *format*. Rather than using symbolic scores (as in previous approaches), we instead choose to use raw sheet music images. While this arguably makes the task much more challenging, it has the benefit of having much more data available online. Second, we choose an approach that can utilize unlabeled data. Whereas labeled data is usually expensive to annotate and limited in quantity, unlabeled data is often extremely cheap and available in abundance. By adopting an approach that can use unlabeled data, we can drastically increase the amount of data available to train our models. Third, we use data augmentation to make the most of the limited quantity of labeled data that we do have. Rather than fixating on the page classification task, we instead define a proxy task where the goal is to predict the composer given a fixed-length sequence of symbolic words. By defining the proxy task in this way, we can aggressively subsample fragments from the labeled data, resulting in a much larger number of unique training data points than there are actual pages of sheet music. Once the proxy task classifier has been trained, we can apply it to the full page classification task in a straightforward manner.

2.2 Language Model Pretraining

The language model pretraining consists of three steps, as shown in the upper half of Figure 1. These three steps will be described in the next three paragraphs.

The first step is to convert the sheet music image into a bootleg score. The bootleg score is a low-dimensional feature representation of piano sheet music that encodes the position of filled noteheads relative to the staff lines [28]. Figure 2 shows an example of a section of sheet music and its corresponding bootleg score representation. The bootleg score itself is a $62 \times N$ binary matrix, where 62 indicates the total number of possible staff line positions in both the left and right hands, and where N indicates the total number of estimated simultaneous note onset events. Note that the representation discards a significant amount of information: it does not encode note duration, key signature, time signature, measure boundaries, accidentals, clef changes, or octave markings, and it simply ignores non-filled noteheads (e.g. half or whole notes). Nonetheless, it has been shown to be effective in aligning sheet music and MIDI [28], and we hypothesize that it may also be useful in characterizing piano style. The main benefit of using the bootleg score representation over a full optical music recognition (OMR) pipeline is processing time: computing a bootleg score only takes about 1 second per page using a CPU, which makes it suitable for computing features on the entire IMSLP dataset. [3] We use the code from [28] as a fixed feature extractor to compute the bootleg scores.

The second step is to tokenize the bootleg score into a sequence of word or subword units. We do this differently for different language models. For word-based language models (e.g. AWD-LSTM [29]), we consider each bootleg score column as a single word consisting of a 62-character string of 0s and 1s. We limit the vocabulary to the $30,000$ most frequent words, and map infrequent words to a special unknown word token <unk>. For subword-based language models (e.g. GPT-2 [24], RoBERTa [30]), we use a byte pair encoding (BPE) algorithm [32] to learn a vocabulary of subword units in an unsupervised manner. The BPE algorithm starts with an initial set of subword units

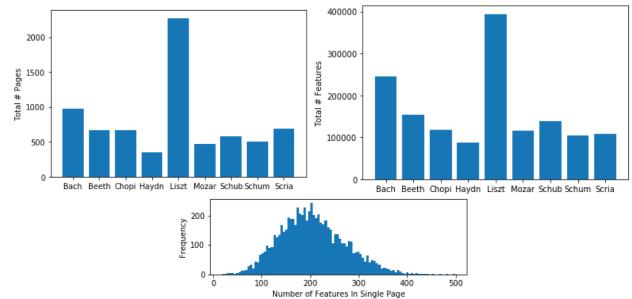
(e.g. the set of unique characters [33] or the $2^8 = 256$ unique byte values that comprise unicode characters [34]), and it iteratively merges the most frequently occurring pair of adjacent subword units until a desired vocabulary size has been reached. We experimented with both character-level and byte-level encoding schemes (i.e. representing each word as a string of 62 characters vs. a sequence of 8 bytes), and we found that the byte-level encoding scheme performs much better. We only report results with the byte-level BPE tokenizer. For both subword-based language models explored in this work, we use the same shared BPE tokenizer with a vocabulary size of $30,000$ (which is the vocabularly size used in the RoBERTa model). At the end of the second step, we have represented the sheet music image as a sequence of words or subword units.

The third step is to train a language model on a set of unlabeled data. In this work, we explore three different language models, which are representative of state-of-the-art models in the last 3-4 years. The top half of Figure 3 shows a high-level overview of these three language models. The first model is AWD-LSTM [29]. This is a 3-layer LSTM architecture that makes heavy use of regularization techniques throughout the model, including four different types of dropout. The output of the final LSTM layer is fed to a linear decoder whose weights are tied to the input embedding matrix. This produces an output distribution across the tokens in the vocabulary. The model is then trained to predict the next token at each time step. We use the fastai implementation of the AWD-LSTM model with default parameters. The second model is openAI's GPT-2 [24]. This architecture consists of multiple transformer decoder layers [35]. Each transformer decoder layer consists of a masked self-attention, along with feed-forwards layers, layer normalizations, and residual connections. While transformer encoder layers allow each token to attend to all other tokens in the input, the transformer decoder layers only allow a token to attend to previous tokens. [4] Similar to the AWD-LSTM model, the outputs of the last transformer layer are fed to a linear decoder whose weights are tied to the input embeddings, and the model is trained to predict the next token at each time step. We use the huggingface implementation of the GPT-2 model with default parameters, except that we reduce the vocabulary size from $50,000$ to $30,000$ (to use the same tokenizer as the RoBERTa model), the amount of context from 1024 to 512, and the number of layers from 12 to 6. The third model is RoBERTa [30], which is based on Google's BERT language model [25]. This architecture consists of multiple transformer encoder layers. Unlike GPT-2, each token can attend to all other tokens in the input and the goal is not to predict the next token. Instead, a certain fraction of the input tokens are randomly converted to a special <mask> token, and the model is trained to predict the masked tokens. We use the huggingface implementation of RoBERTa with default parameter settings, except that we reduce the number of layers from 12 to 6.

---

[3] In contrast, the best performing music object detectors take 40-80 seconds to process each page at inference time using a GPU [31].

[4] This is because, in the original machine translation task [35], the decoder generates the output sentence autoregressively.

2.3 Classifier Finetuning


In the second main stage, we finetune a classifier based on a set of labeled data. The labeled data consists of a set of sheet music images along with their corresponding composer labels. The process of training the classifier is comprised of four steps (lower half of Figure 1).

The first two steps are to compute and tokenize a bootleg score into a sequence of symbolic words. We use the same fixed feature extractor and the same tokenizer that were used in the language model pretraining stage.

The third step is to sample short, fixed-length fragments of words from the labeled data. As mentioned in Section 2.1, we define a proxy task where the goal is to predict the composer given a short, fixed-length fragment of words. Defining the proxy task in this way has three significant benefits: (1) we can use sampling to generate many more unique training data points than there are actual pages of sheet music in our dataset, (2) we can sample the data in such a way that the classes are balanced, which avoids problems during training, and (3) using fixed-length inputs allows us to train more efficiently in batches. Our approach follows the general recommendations of a recent study on best practices for training a classifier with imbalanced data [36]. Each sampled fragment and its corresponding composer label constitute a single (X_i, y_i) training pair for the proxy task.

The fourth step is to train the classifier model. The bottom half of Figure 3 shows how this is done with our three models. Our general approach is to add a classifier head on top of the language model, initialize the weights of the classifier with the pretrained language model weights, and then finetune the classifier on the proxy task data. For the AWD-LSTM, we take the outputs from the last LSTM layer and construct a fixed-size representation by concatenating three things: (a) the output at the last time step, (b) the result of max pooling the outputs across the sequence dimension, and (c) the result of average pooling the outputs across the sequence dimension. This fixed-size representation (which is three times the hidden dimension size) is then fed into the classifier head, which consists of two dense layers with batch normalization and dropout. For the GPT-2 model, we take the output from the last transformer layer at the last time step, and then feed it into a single dense (classification) layer. Because the GPT-2 and RoBERTa models require special tokens during training, we insert special symbols <s> and </s> at the beginning and end of every training input, respectively. Because of the masked self-attention, we must use the output of the last token in order to access all of the information in the input sequence. For the RoBERTa model, we take the output from the last transformer layer corresponding to the <s> token, and feed it into a single dense (classification) layer. The <s> takes the place of the special [CLS] token described in the original paper.

We integrated all models into the fastai framework and finetuned the classifier in the following manner. We first select an appropriate learning rate using a range test, in which we sweep the learning rate across a wide range of

Figure 4. Statistics on the target dataset. The top two histograms show the distribution of the number of pages (top left) and number of bootleg score features (top right) per composer. The bottom figure shows the distribution of the number of bootleg score features per page.

values and observe the impact on training loss. We initially freeze all parameters in the model except for the untrained classification head, and we gradually unfreeze more and more layers in the model as the training converges. To avoid overly aggressive changes to the pretrained language model weights, we use discriminative finetuning, in which earlier layers of the model use exponentially smaller learning rates compared to later layers in the model. All training is done with (multiple cycles of) the one cycle training policy [37], in which learning rate and momentum are varied cyclically over each cycle. The above practices were proposed in [22] and found to be effective in finetuning language models for text classification.

2.4 Inference

The third main stage is to apply the proxy classifier to the original full page classification task. We explore two different ways to do this. The first method is to convert the sheet music image into a bootleg score, tokenize the bootleg score into a sequence of word or subword units, and then apply the proxy classifier to a single variable-length input. Note that all of the models can handle variable-length inputs up to a maximum context length. The second method is identical to the first, except that it averages the predictions from multiple fixed-length crops taken from the input sequence. The fixed-length crops are the same size as is used during classifier training, and the crops are sampled uniformly with 50% overlap. [5]

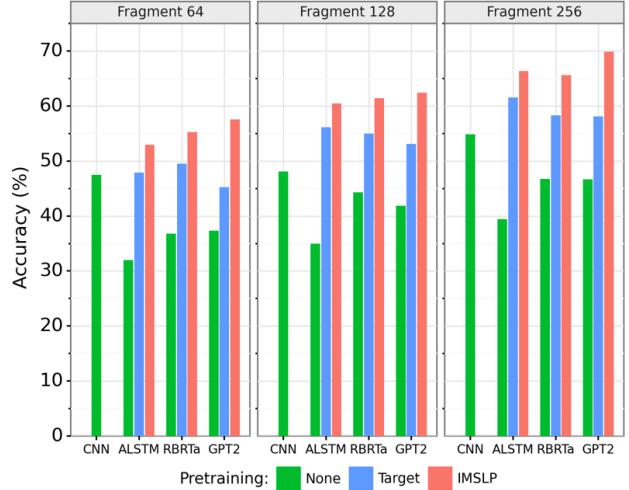
3. EXPERIMENTAL SETUP

In this section we describe the data collection process and the metrics used to evaluate our approach.

The data comes from IMSLP. We first scraped the website and downloaded all PDF scores and accompanying metadata. [6] We filtered the data based on its instrumentation in order to identify a list of solo piano scores. We

---

[5] We also experimented with applying a Bayesian prior to the classifier softmax outputs, as recommended in [36], but found that the results were not consistently better.

[6] We downloaded the data over a span of several weeks in May of 2018.


then computed bootleg score features for all of the piano sheet music images using the XSEDE supercomputing infrastructure [38], and discarded any pages that had less than a minimum threshold of features. This latter step is designed to remove non-music pages such as the title page, foreword, or table of contents. The resulting set of data contained $29,310$ PDFs, [7] $255,539$ pages and a total of 48.5 million bootleg score features. This set of data is what we refer to as the IMSLP dataset in this work (e.g. the IMSLP pretrained language model). For language model training, we split the IMSLP data by piece, using 90% for training and 10% for validation.

The classification task uses a subset of the IMSLP data. We first identified a list of composers with a significant amount of data (composers shown in Figure 4). We limited the list to nine composers in order to avoid extreme class imbalance. Because popular pieces tend to have many sheet music versions in the dataset, we select one version per piece in order to avoid over-representation of a small subset of pieces. Next, we manually labeled and discarded all filler pages, and then computed bootleg score features on the remaining sheet music images. This cleaned dataset is what we refer to as the target data in this work (e.g. the target pretrained language model). Figure 4 shows the total number of pages and bootleg score features per composer for the target dataset, along with the distribution of the number of bootleg score features per page. For training and testing, we split the data by piece, using 60% of the pieces for training (4347 pages), 20% for validation (1500 pages), and 20% for testing (1304 pages). To generate data for the proxy task, we randomly sampled fixed-length fragments from the target data. We sample the same number of fragments for each composer to ensure class balance. We experimented with fragment sizes of 64/128/256 and sampled 32400/16200/8100 fragments for training and 10800/5400/2700 fragments for validation/test, respectively. This sampling scheme ensures the same data coverage regardless of fragment length. Note that the classification data is carefully curated, while the IMSLP data requires minimal processing.

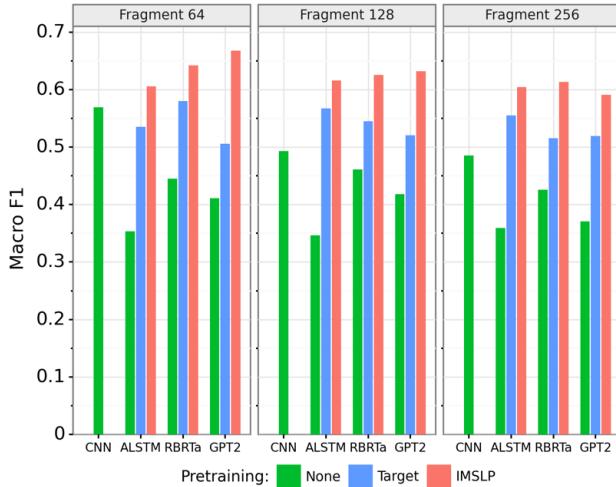
We use two different metrics to evaluate our systems. For the proxy task, accuracy is an appropriate metric since the data is balanced. For the full page classification task – which has imbalanced data – we report results in macro F1 score. Macro F1 is a generalization of F1 score to a multi-class setting, in which each class is treated as a one-versus-all binary classification task and the F1 scores from all classes are averaged.

4. RESULTS & ANALYSIS

In this section we present our experimental results and conduct various analyses to answer key questions of interest. While the proxy task is an artificially created task, it provides a more reliable indicator of classifier performance than the full page classification. This is because the test set of the full page classification task is both imbalanced and

Figure 5. Model performance on the proxy classification task. This comparison shows the effect of different pretraining conditions and fragment sizes.

very small (1304 data points). Accordingly, we will report results on both the proxy task and full page classification task.

4.1 Proxy Task


We first consider the performance of our models on the proxy classification task. We would like to understand the effect of (a) model architecture, (b) pretraining condition, and (c) fragment size.

We evaluate four different model architectures. In addition to the AWD-LSTM, GPT-2, and RoBERTa models previously described, we also measure the performance of a CNN-based approach recently proposed in [7]. Note that we cannot use the exact same model in [7] since we do not have symbolic score information. Nonetheless, we can use the same general approach of computing local features, aggregating feature statistics across time, and applying a linear classifier. The design of our 2-layer CNN model roughly matches the architecture proposed in [7].

We consider three different language model pretraining conditions. The first condition is with no pretraining, where we train the classifier from scratch only on the proxy task. The second condition is with target language model pretraining, where we first train a language model on the target data, and then finetune the classifier on the proxy task. The third condition is with IMSLP language model pretraining. Here, we train a language model on the full IMSLP dataset, finetune the language model on the target data, and then finetune the classifier on the proxy task.

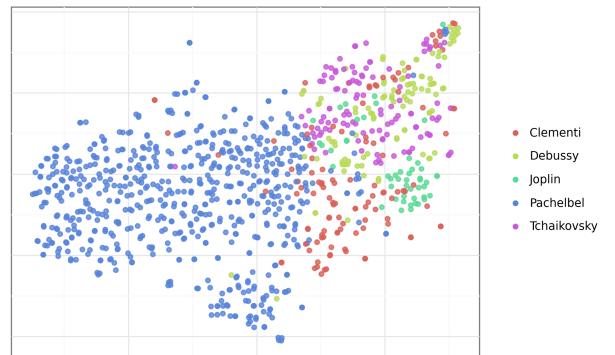
Figure 5 shows the performance of all models on the proxy task. There are three things to notice. First, regarding (a), the transformer-based models generally outperform the LSTM and CNN models. Second, regarding (b), language model pretraining improves performance significantly across the board. Regardless of architecture, we see a large improvement going from no pretraining (condition 1) to target pretraining (condition 2), and another


Figure 6. Results on the full page classification task.

Figure 7. t-SNE plot of the RoBERTa model activations for five novel composers. Each data point corresponds to a single page of sheet music for a composer that was *not* considered in the classification task.

large improvement going from target pretraining (condition 2) to IMSLP pretraining (condition 3). For example, the performance of the GPT-2 model increases from 37.3% to 45.2% to 57.5% across the three pretraining conditions. Because the data in conditions 1 & 2 is exactly the same, the improvement in performance must be coming from more effective use of the data. We can interpret this from an information theory perspective by noting that the classification task provides the model $log_2 9 = 3.17$ bits of information per fragment, whereas the language modeling task provides $log_2 V$ bits of information *per bootleg score feature* where V is the vocabulary size. The performance gap between condition 2 and condition 3 can also be interpreted as the result of providing more information to the model, but here the information is coming from having additional data. Third, regarding (c), larger fragments result in better performance, as we might expect.

4.2 Full Page Classification

Next, we consider performance of our models on the full page classification task. We would like to understand the effect of (a) model architecture, (b) pretraining condition, (c) fragment size, and (d) inference type (single vs. multicrop). Regarding (d), we found that taking multiple crops improved results with all models except the CNN. This suggests that this type of test time augmentation does not benefit approaches that simply average feature statistics over time. In the results presented below, we only show the optimal inference type for each model architecture (i.e. CNN with single crop, all others with multi-crop).

Figure 6 shows model performance on the full page classification task. There are two things to notice. First, we see the same general trends as in Figure 5 for model architecture and pretraining condition: the transformer-based models generally outperform the CNN and LSTM models, and pretraining helps substantially in every case. The macro F1 score of our best model (GPT-2 with fragment size 64) increases from 0.41 to 0.51 to 0.67 across the three pretraining conditions. Second, we see the *opposite* trend

as the proxy task for fragment size: smaller fragments have *better* page classification performance. This strongly indicates a data distribution mismatch. Indeed, when we look at the distribution of the number of bootleg score features in a single page (Figure 4), we see that a significant fraction of pages have less than 256 features. Because we only sample fragments that contain a complete set of 256 words, our proxy task data is biased towards longer inputs. This leads to poor performance when the classifier is faced with short inputs, which are never seen in training. Using a fragment size of 64 minimizes this bias.

4.3 t-SNE Plots

Another key question of interest is, "Can we use our model to characterize the style of any page of piano sheet music?" The classification task forces the model to project the sheet music into a feature space where the compositional style of the nine composers can be differentiated. We hypothesize that this feature space might be useful in characterizing the style of *any* page of piano sheet music, even from composers not in the classification task.

To test this hypothesis, we fed data from 5 novel composers into our models and constructed t-SNE plots [39] of the activations at the second-to-last layer. Figure 7 shows such a plot for the RoBERTa model. Each data point corresponds to a single page of sheet music from a novel composer. Even though we have not trained the classifier on these five composers, we can see that the data points are still clustered, suggesting that the feature space can describe the style of new composers in a useful manner.

5. CONCLUSION

We propose a method for predicting the composer of a single page of piano sheet music. Our method first converts the raw sheet music image into a sequence of musical words based on the bootleg score feature representation, and then feeds the sequence into a text classifier. We show that by pretraining a language model on a large set of unlabeled data, it is possible to significantly improve the performance of the classifier.

USING WEAKLY ALIGNED SCORE–AUDIO PAIRS TO TRAIN DEEP CHROMA MODELS FOR CROSS-MODAL MUSIC RETRIEVAL

Frank Zalkow, Meinard Müller

International Audio Laboratories Erlangen, Germany

{frank.zalkow,meinard.mueller}@audiolabs-erlangen.de

ABSTRACT

Many music information retrieval tasks involve the comparison of a symbolic score representation with an audio recording. A typical strategy is to compare score–audio pairs based on a common mid-level representation, such as chroma features. Several recent studies demonstrated the effectiveness of deep learning models that learn task-specific mid-level representations from temporally aligned training pairs. However, in practice, there is often a lack of strongly aligned training data, in particular for real-world scenarios. In our study, we use weakly aligned score–audio pairs for training, where only the beginning and end of a score excerpt is annotated in an audio recording, without aligned correspondences in between. To exploit such weakly aligned data, we employ the Connectionist Temporal Classification (CTC) loss to train a deep learning model for computing an enhanced chroma representation. We then apply this model to a cross-modal retrieval task, where we aim at finding relevant audio recordings of Western classical music, given a short monophonic musical theme in symbolic notation as a query. We present systematic experiments that show the effectiveness of the CTC-based model for this theme-based retrieval task.

1. INTRODUCTION

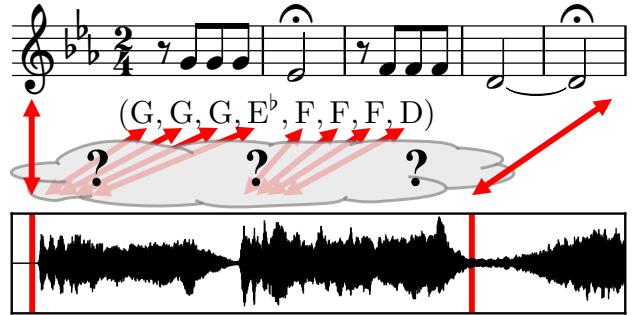
Music appears in many different modalities, for example, as audio or video recordings, in the form of symbolic representations, or as graphical sheet music [1]. In particular, audio recordings and symbolic representations are of great importance in many music information retrieval (MIR) tasks. An example is cross-modal retrieval, where a symbolic score is given as a query, and the task is to identify relevant audio recordings [2–4]. A general strategy for matching such different modalities is to use a common mid-level representation. In music processing, chroma features are widely used as mid-level [1, 5, 6]. These features, which capture the energy in the twelve chromatic pitch class bands, are robust against changes in octave, instrumentation, and timbre.


Figure 1. Illustration of a weakly aligned score–audio pair.

In recent years, many studies have shown the benefits of deep learning models to compute task-specific mid-level representations [7–10]. These learned features have proven their effectiveness in many scenarios, for example, audio–audio retrieval [11–13], chord recognition [9, 10, 14], or pitch tracking [7, 15, 16]. Training deep neural networks (DNNs) usually requires aligned training pairs, i.e., in MIR, music recordings with temporally aligned annotations. For example, the training pairs for a deep salience model by Bittner et al. [7] consist of time–frequency representations (more details in Section 2.2) with fundamental frequency annotations, where inputs and annotations correspond to each other for all time frames. For popular music, annotated data sets [17] have led to significant advances in research on pitch salience representations. However, creating such strongly aligned training pairs is labor-intensive, and, for many music scenarios, such data is hardly available. In contrast to the difficulty in annotating local alignments, it may be much easier to annotate global correspondences. In this paper, we use training pairs, where only global correspondences have been annotated. We denote these pairs as weakly aligned.

In our contribution, we use a deep learning model to compute enhanced chroma features, which we then use as a mid-level representation for a cross-modal retrieval task. Given a symbolic representation of a monophonic musical theme as a query and an audio database of Western classical music, the task is to find all audio recordings in which the theme is played [18, 19]. To obtain a task-specific chroma variant, we train a deep learning model with weakly aligned score–audio pairs, where only the beginning and end of a musical theme is annotated in an audio recording. Figure 1 illustrates such a pair for the famous first theme of Beethoven's Symphony No. 5. As our

main contribution, we combine a deep salience model [7] with a training procedure for weakly aligned data. [1] This procedure, called *Connectionist Temporal Classification* (CTC) [20], allows us to use training pairs of audio excerpts (in the form of spectral features) as input and musical themes (as sequences of chroma labels) as output. Using this CTC-based strategy, we train a model to compute enhanced chroma features for musical themes. We evaluate these features using more than 2000 themes and 1000 audio recordings and show that they improve the state of the art for our cross-modal retrieval scenario.

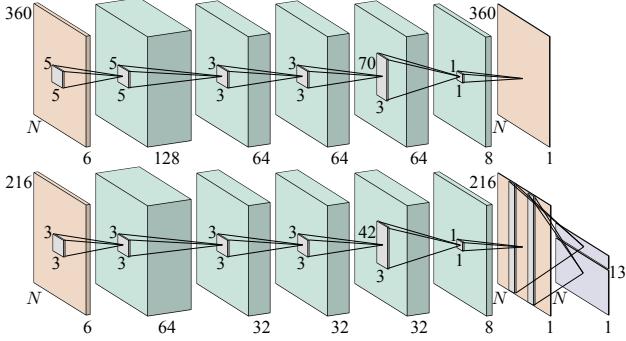
In Section 2, we review several prerequisites, such as cross-modal retrieval (Section 2.1), deep salience and deep chroma models (Section 2.2), and the CTC loss (Section 2.3). Then, in Section 3, we describe our adaption of the deep salience model, which computes chroma features and can be trained with the CTC loss. We present our experiments in Section 4 and conclude with Section 5.

2. PRIOR WORK AND PREREQUISITES

2.1 Cross-Modal Retrieval

For our retrieval scenario, we use a data set based on "A Dictionary of Musical Themes" by Barlow and Morgenstern (BM) [21], which contains roughly 10000 musical themes of instrumental Western classical music. Most of these themes have also been available as symbolic versions (MIDI) on the internet. [2] For a subset of the themes, we annotated their occurrences in audio recordings. In these annotations, a theme corresponds to exactly one recording, which, in turn, can correspond to several themes. The annotations comprise global correspondences, i.e., the beginning and end of the occurrences, as well as transpositions. Table 1 shows some statistics for our data set, which consists of 2048 themes from the BM book and 1114 corresponding recordings. The BM book already inspired several MIR studies [22, 23]. Some of them [18, 19] used the same subset for retrieval. We slightly corrected some annotations for this paper. A previous study [18] pointed out the challenges of the task, which are due to the differences in modality (symbolic vs. audio), tuning, transposition, tempo, and polyphony between the query and the recordings. The last point means that the themes are monophonic, but they usually appear in polyphonic context in the recordings (further discussion in Section 5). Previous work [19] has shown that pitch salience representations are capable of overcoming the differences in polyphony. In

this paper, building upon these findings, we introduce an approach for learning a task-specific salience representation.

2.2 Deep Salience and Deep Chroma Models


Many studies have demonstrated the effectiveness of using deep learning models to compute task-specific feature representations. One example is the use of deep salience models to compute enhanced time–frequency representations (measuring the saliency of frequencies over time) for tasks such as melody or multi-pitch tracking [7, 15, 16]. Another example is the use of deep chroma models for computing enhanced chroma features (encoding the energy in the twelve chromatic pitch class bands) for chord recognition [9, 10, 14].

This paper is inspired by the deep salience approach by Bittner et al. [7]. They introduced a feature representation named harmonic CQT (HCQT) as input for a convolutional DNN. The HCQT is a three-dimensional tensor, where the three dimensions are time, frequency (logarithmic scaling), and harmonics. The third dimension ensures that harmonically related frequency bins are neighbors across the depth of the tensor. This way, the convolutional kernels of the network can easily exploit harmonic relationships. Many studies use this deep salience representation as a baseline [16, 24] or build upon this model for diverse tasks such as dominant melody estimation [8], instrument recognition [25], tempo estimation [26], or chord recognition [27]. In Section 3, we describe how we adapt the deep salience model for computing enhanced chroma features.

The study of Wu et al. [27] is related to ours in two respects. First, they also use the HCQT representation, and, second, they use weakly aligned training data. However, they aim for chord recognition instead of learning a mid-level representation for cross-modal retrieval. Unlike us, they take a three-step approach: First, they use a pre-trained deep chroma extractor to compute features. Second, they strongly align their annotations to the chroma features using a hidden Markov model. Third, they use a frame-wise DNN classifier for chord recognition. In our paper, we present a single-step approach to realize the alignment within the DNN training procedure.

2.3 CTC Loss

Graves et al. [20] originally introduced *Connectionist Temporal Classification* (CTC) as the task of labeling unsegmented feature sequences with recurrent DNNs in the context of speech recognition. However, their training technique can be used with any DNN architecture. Furthermore, the task can be generalized to any scenario, where the aim is to map feature sequences to sequences of symbols. If the training data consisted of strongly aligned pairs of feature and symbol sequences (i.e., each vector of the feature sequences is labeled with a symbol), then a standard classification approach could be taken. The key aspect of CTC is that there is no need for strongly aligned training data, i.e., the feature and symbol sequences may be of

different length, and the temporal correspondence between both sequences is unknown and may be non-linear.

Several studies from the MIR community used CTC, e.g., for optical music recognition [28], monophonic audio-to-score transcription [29], lyrics alignment [30], and audio tagging [31]. An alternative to CTC for sequence learning without aligned training data is the usage of an attention mechanism, which, e.g., was used for monophonic singing voice transcription [32].

In the following, we give the main idea of the CTC loss function introduced by Graves et al. [20] We describe the computation of the CTC loss for a single pair consisting of an audio feature sequence and a symbol sequence. Let

$$X = (x_1, x_2, \ldots, x_N) \tag{1}$$

denote the feature sequence of length $N \in \mathbb{N}$, which consists of feature vectors $x_n \in \mathbb{R}^D$ for $n \in [1 : N] :=$ $\{1, 2, \ldots, N\}$ of dimensionality $D \in \mathbb{N}$. The second sequence of the pair is a symbol sequence

$$Y = (y_1, y_2, \ldots, y_M) \tag{2}$$

of length $M \in \mathbb{N}$, which consists of elements $y_m \in \mathbb{A}$ for $m \in [1 : M]$. The alphabet $\mathbb{A}$ of size $A := |\mathbb{A}|$ is the set of symbols that can occur in the symbol sequence. Typically $M \ll N$. For example, in the case of lyrics alignment, the alphabet is the set of all considered characters [30]. In our case, it is the set of the twelve different chroma labels. The feature sequence X is transformed by a DNN f_θ with parameters θ to a sequence of probability vectors

$$f_\theta(X) = P = (p_1, p_2, \ldots, p_N) \tag{3}$$

having the same length N as the feature sequence and consisting of probability vectors $p_n \in [0, 1]^A$. We interpret the probability vector element $p_{n,a}$ for $a \in [1 : A]$ as the probability that the nth feature vector x_n corresponds to the ath symbol in $\mathbb{A}$ (assuming an order of the set).

We can now compute the probability of the symbol sequence Y given the feature sequence X. For a fixed alignment between X and Y, one multiplies all values of the probability sequence P that correspond to that alignment. Since the alignment is unknown, instead of a specific one, all possible alignments between X and Y are taken into

account. Let us denote this overall probability as $\hat{p} \in \mathbb{R}$. Graves et al. [20] described how to compute $\hat{p}$ in a differentiable and efficient way using dynamic programming similar to the forward algorithm for hidden Markov models [33]. The final CTC loss for a single training pair is

$$L_\theta(X, Y) = -\log \hat{p}. \tag{4}$$

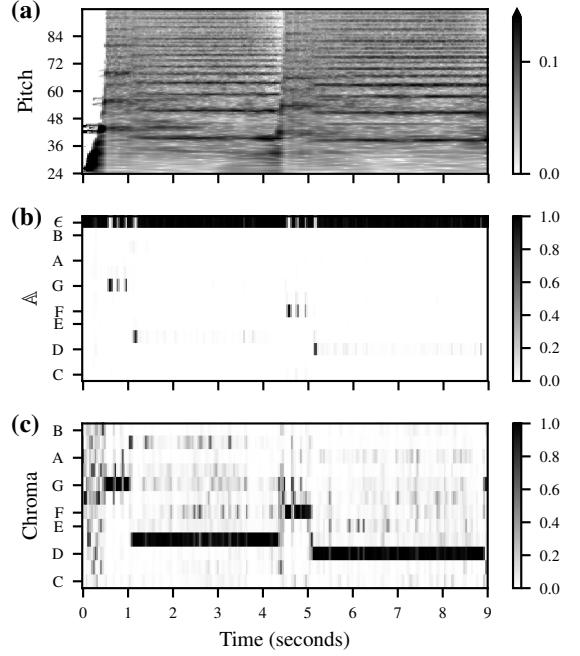
This loss function is used in batch gradient descent to update the parameters θ by averaging the loss value over multiple training pairs in a batch. By this procedure, the parameters of the network improve to produce probability sequences that make the ground-truth symbol sequences more probable.

In our explanation, we left out a crucial detail of the procedure. For a fixed alignment between X and Y, the aligned symbol sequence can be represented by an "unfolded" sequence of length N that contains the active symbol for each time step. Let us consider the case of an unfolded sequence having multiple neighboring time steps with the same active symbol. So far, we cannot tell if this means one symbol occurrence with a long duration or multiple successive occurrences of the same symbol with shorter durations. To solve this ambiguity, an additional symbol named blank ϵ is part of the alphabet $\mathbb{A}$. This symbol serves two purposes: First, it means that no symbol is active. Second, it indicates a repeated occurrence of the same symbol if a succession of the same active symbol in the unfolded sequence is only interrupted by ϵ.

3. DEEP SALIENCE MODEL ADAPTATION

The DNN model used in this paper is inspired by the deep salience model proposed by Bittner et al. [7]. In this section, we explain our adaption of the model.

Bittner et al. [7] approached the task of melody and multi-pitch tracking, using a strongly aligned data set of 10 hours. In our case, we aim to learn an enhanced chroma representation for cross-modal retrieval, employing our weakly aligned 5-hour data set of 2048 themes. We simplified the original model in several ways to reduce the number of parameters and memory requirements. Additionally, we adapted the network so that it can be trained with the CTC loss and used as a deep chroma extractor. Figure 2 illustrates the original network architecture and our adapted version, and Table 2 gives further details for our version. Compared to the model by Bittner et al. [7],

we introduce the following modifications: First, we use a frame rate of 25 Hz instead of 86 Hz. Second, we use a frequency resolution of a third semitone instead of a fifth semitone. This resolution results in 216 instead of 360 frequency bins. Third, we reduced the number of filter kernels as well as the size of some of the filter kernels. The latter reduction accounts for the decreased frequency resolution. Forth, we use leaky ReLU activations instead of ReLU activations to avoid zero gradients [34]. Fifth, we do not use batch normalization at all, which was used at the input to each layer in the original model. Instead, we ℓ^2-normalize all columns of the input to the network for being invariant to dynamic changes. Sixth, we add a pooling layer at the end, which we explain in the next paragraph.


After the last convolutional layer (with sigmoid activation), we obtain a representation that we could interpret as a kind of pitch salience of size $N \times 216$. In our case, we aim for an output size of $N \times 13$, where the N columns are probability vectors over the set of the twelve chroma labels and an additional ϵ symbol:

$$\mathbb{A} := \{C, C^{\#}, D, \ldots, B\} \cup \{\epsilon\}. \tag{5}$$

Let us consider a single column of size 216 as input, which we want to transform to a probability vector of size 13. To compute the first twelve entries, we add up all pitch bins corresponding to the respective chroma bins. This fixed pooling has no learnable parameters. To compute the last entry for the ϵ symbol, we apply a standard dense layer (linear activation) to the input column. This layer has 217 learnable parameters (216 weights and a bias). Finally, we apply the softmax function to the resulting 13-dimensional vector. We repeat this process for all columns of the input.

In summary, our adapted model differs from the original model [7] in two important aspects: First, we reduced the number of parameters from 407 thousand to 73 thousand. Second, the output of the model is a probability matrix over the set $\mathbb{A}$ instead of a pitch salience representation.

We train this adapted model with the CTC loss, as described in Section 2.3. The input to the network is an HCQT tensor computed for an excerpt from an audio recording, where a musical theme is played. Figure 3a shows a slice of the HCQT features for a recording of the first theme of Beethoven's Fifth Symphony. The corresponding symbol sequence is the sequence of chroma labels of the theme with neither any rhythmic information nor any temporal alignment to the input. For our Beethoven example (see also Figure 1), this sequence is $Y = (G, G, G, E^{\flat}, F, F, F, D)$. Figure 3b visualizes the probability sequence for the Beethoven example after training. We see that the ϵ symbol has the largest probability for most of the time, and the chroma labels only have large probabilities at the beginning of the corresponding note events. To use the network output as a feature representation, we remove the row corresponding to the ϵ symbol and interpret the resulting matrix as chroma features. Finally, we ℓ^2-normalize the 12-dimensional chroma vectors to increase the energies in the time segments, where ϵ was dominating. Figure 3c shows the normalized chroma features, which correspond well with the symbol sequence.

4. EXPERIMENTS

4.1 Training Details

We split our data set into five folds, where we use three folds for training, one for validation, and another one for testing. We ensure that all themes by a composer are part of precisely one fold. As a consequence, we do not use themes from the same composer for training and evaluation, thus avoiding a "composer overfitting." For the training folds, we perform transpositions (up to a minor third upwards and downwards) as data augmentation. We perform batch gradient descent with a batch size of eight using the Adam optimizer [35] and a learning rate annealing procedure. In the first phase of this procedure, the initial learning rate is 0.001, and we train the model until the loss for the validation fold does not improve for five epochs. In the next phase, we halve the learning rate and continue the training with the model that has the lowest validation loss among the models of all previous epochs. We repeat ten such phases. When we finished training, we use the model with the lowest validation loss as a chroma feature extractor, and evaluate its effectiveness in the retrieval scenario, using the query themes from the test fold.

4.2 Retrieval-Based Evaluation

We shortly describe our retrieval pipeline and our evaluation measures following [18, 19]. First, we have a set $\mathbb{Q}$ of symbolic (MIDI) encodings of musical themes, which serve as *queries*. Furthermore, we have a collection of audio recordings, which we denote as database *documents*. These are actual recordings, not synthesized MIDI files. For each query, there is exactly one audio document that

Table 4. Retrieval results for $\mathcal{C}_{\text{CTC}}$.

contains a globally corresponding rendition of the query theme (i.e., matching duration and transposition). For a fixed symbolic query, the aim is to retrieve the corresponding audio document. To compare the query with a document, we convert both into chroma sequences. For the symbolic query, we simply compute a binary chroma representation. For converting the audio recording, we employ a salience representation (from our CTC or a baseline approach). Then, we use Subsequence Dynamic Time Warping (SDTW) to compare the query with subsequences of the document [1]. In particular, we use the cosine distance, the step size condition $\Sigma := \{(2,1),(1,2),(1,1)\}$, as well as the weights $w_{\text{vertical}} = 2$ and $w_{\text{horizontal}} = w_{\text{diagonal}} = 1$. As a result of SDTW, one obtains a matching function, where local minima point to locations with a good match between the query and a document subsequence. We consider the minimal value of the matching function as the distance between query and document.

To solve the retrieval task, we compute distances between all documents and the query. We then order the documents according to ascending distance values. The document's position in this ordered list is called the *rank* $r \in \mathbb{N}$ of the document. The top-K evaluation metric yields a value of one if the relevant document is among the top K matches, i.e., $r \leq K$. We then average this metric across all queries. Furthermore, we report the *mean reciprocal rank* (MRR), which is the average of $1/r$ across all queries.

In the cross-validation iterations of our evaluation, we only use the query themes from the respective test fold to search within the 1114 documents of our database. The reported average evaluation measures (⌀) are weighted with the number of queries from the respective test fold.

4.3 Baseline

As for our baselines, we consider the best-performing representations from a previous study [19], namely $\mathcal{C}_{\text{Bit}}$, using the original deep salience model for melody estimation by Bittner et al. [7][3], and $\mathcal{C}_{\text{BG1}}$, using a model-based salience representation by Bosch and Gómez [36]. The latter one is a combination of a source-filter model with harmonic summation, using threshold parameters (named "BG1") that are particularly suited for orchestral music [37].

Table 3a cites the results from the previous study [19], where a $10\,\text{Hz}$ feature rate was used. Since we use an in-

creased feature rate of $25\,\text{Hz}$ in this paper, we reproduced the experiments with this rate. The results are shown in Table 3b. Just by changing the feature rate, we see a substantial improvement of the results. For example, for $\mathcal{C}_{\text{Bit}}$, the top-1 rate increases from 0.693 to 0.763, which means that 7 % more themes achieved a rank of 1. Since we corrected some errors in the data set, an improvement of up to 2 % may be due to the revision, but the main improvements are due to the increased time resolution. The reason for this may be the following: A fast tempo of *Presto* corresponds to up to $200\,\text{BPM}$. Having a quarter-note beat, in such a tempo, a sixteenth note has a duration of $75\,\text{ms}$, which is shorter than the length of a frame given the feature rate of $10\,\text{Hz}$. In such cases, the increased feature rate is necessary to represent the musical content in a more meaningful way.

For both feature rates, the representation $\mathcal{C}_{\text{BG1}}$ performs better than $\mathcal{C}_{\text{Bit}}$. For example, the respective top-1 rates are 0.820 and 0.763 for the $25\,\text{Hz}$ rate. The results for $\mathcal{C}_{\text{Bit}}$ may be lower because the training data of the underlying DNN consisted mainly of popular music (for overall 240 training tracks, only 22 are tagged as "classical" in version 1 of MedleyDB [17]). Another possible reason is that the saliency characteristics in the training data (coming from the "Melody 2" definition of MedleyDB) are different from the characteristics of musical themes.

4.4 CTC-Based Results

We now discuss the results we achieved with our CTC-based approach $\mathcal{C}_{\text{CTC}}$. Table 4 shows the evaluation results for the five cross-validation iterations. The second column ($|\mathbb{Q}|$) gives the number of query themes in the respective test fold. This number is larger in the first fold (559) because this fold contains all BM themes by Ludwig van Beethoven, which is the most prominent composer of our data set. The other folds have fewer queries (372 or 373) and are more diverse in terms of composers, having 12 or 13 different composers each. The retrieval results have some diversity, ranging from a top-1 rate of 0.823 for test fold 2 up to 0.903 for test fold 4. The last row of the table shows an average of the results, weighted by the number of queries used. Overall, we see a substantial improvement compared to the baseline approaches (Table 3b). For example, the average top-1 rate is 0.865 for $\mathcal{C}_{\text{CTC}}$, compared to 0.763 for $\mathcal{C}_{\text{Bit}}$ and 0.820 for $\mathcal{C}_{\text{BG1}}$. Improvements for larger ranks can also be seen, such as in the top-50 rate (0.968 compared to 0.931 and 0.952, respectively). The results show that our approach is able to outperform the baselines, which have been the state of the art for the task [19].

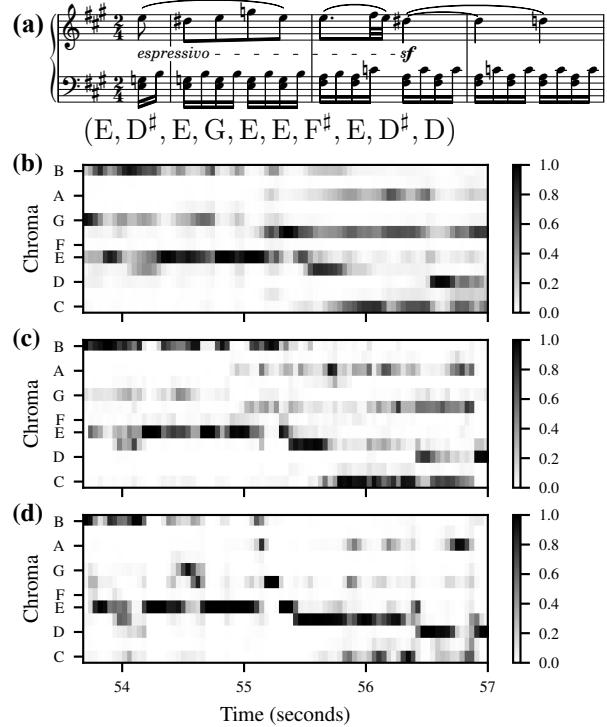
Table 6. Retrieval results ($\varnothing$) for an oracle of the baseline by Bosch and Gómez [36] and our CTC approach.

4.5 Importance of CTC-Alignment

To verify the need for the CTC procedure in our scenario, we performed an additional experiment, where we assumed a linear temporal alignment between the symbolic themes and the corresponding excerpts in the audio recordings. Here, we changed the training procedure from our CTC strategy to a standard classification approach, using categorical cross-entropy (CCE). As output labels, we used binary chroma representations that we obtained by linearly scaling the symbolic themes to the same length as the corresponding audio excerpts. The ϵ symbol here only indicates rests in a theme. Note that, in this experiment, we used the rhythm information and note durations from the MIDI files, which we did not use in the CTC approach.


The trained model was used as chroma extractor and then evaluated in the theme retrieval context. The first row of Table 5 repeats the average evaluation measures from Table 4 for convenience and the second row presents the average results for the CCE approach. The evaluation measures are lower compared to the CTC-based results, e.g., having a top-1 rate of 0.814 compared to 0.865. This difference is due to the non-linear temporal correspondence between audio recordings and the symbolic themes.

4.6 Oracle Experiment

The model-based approach $\mathcal{C}_{\text{BG1}}$ also shows excellent performance for this task. To investigate the relationship between $\mathcal{C}_{\text{BG1}}$ and the $\mathcal{C}_{\text{CTC}}$, we evaluated both strategies with an oracle procedure. For each query, we took the better rank: either achieved with $\mathcal{C}_{\text{BG1}}$ or $\mathcal{C}_{\text{CTC}}$. Table 6 repeats the results for the baseline and CTC approaches for convenience and shows the oracle results in the third row. The oracle further improves the results for $\mathcal{C}_{\text{CTC}}$. For example, the top-1 rate is 4 % larger (0.904 instead of 0.865). For top-K rates with larger K, there are still some small improvements. The oracle indicates that for some queries, $\mathcal{C}_{\text{BG1}}$ is a slightly better feature representation than $\mathcal{C}_{\text{CTC}}$.

5. CONCLUSION

In this paper, we showed the potential of CTC [20] for training a deep salience model with weakly aligned data. Adapting a model by Bittner et al. [7] to compute a task-specific mid-level representation, we improved state-of-the-art results for a cross-modal retrieval task for musical

Figure 4. Second theme of Beethoven's Piano Sonata Op. 2, No. 2, first movement. **(a)** Full score with the chroma sequence of the theme, **(b)** standard chroma features using the full spectral content, **(c)** $\mathcal{C}_{\text{BG1}}$, **(d)** $\mathcal{C}_{\text{CTC}}$.

themes. To achieve these improvements, the feature computation procedure has to reduce the potential polyphony of the audio recording, which is a major challenge. We close our paper with a qualitative example to show the feature's properties for a representative polyphonic example.

Figure 4a shows the full score and the chroma sequence for the second theme in the first movement of Beethoven's Piano Sonata Op. 2, No. 2. In this case, the theme is played by the right hand (upper staff), and the left hand (lower staff) plays an accompaniment. The sixteenth notes of the accompaniment present a minor triad (E, G, B) in the first half and a diminished triad $(F^\sharp, A, C)$ in the second half. Ideally, for our retrieval scenario, we aim for a chroma representation that only captures energy from the theme and not from the accompaniment. Figures 4b, 4c, and 4d show chroma features for the full spectral content, the baseline salience approach $\mathcal{C}_{\text{BG1}}$, and our CTC strategy $\mathcal{C}_{\text{CTC}}$, respectively. In all representations, the main notes of the theme are well represented. However, some shorter notes of the theme (e.g., fourth note G or seventh note $F^\sharp$) are most evident in $\mathcal{C}_{\text{CTC}}$. In general, $\mathcal{C}_{\text{CTC}}$ attenuates the energy in the chroma bands corresponding to the accompaniment. The ability to represent the chroma energy of a musical theme is the main reason why our CTC-based features are a powerful tool for cross-modal retrieval.

In this study, we excluded the challenges due to differences in transposition. This could be taken into account by circularly shifting the chroma features [18], or by incorporating it into the learning procedure [38]. Furthermore, our oracle experiment suggests a possible next step of combining our strategy with traditional salience approaches [36].

ABSTRACT

Singing Voice Separation (SVS) tries to separate singing voice from a given mixed musical signal. Recently, many U-Net-based models have been proposed for the SVS task, but there were no existing works that evaluate and compare various types of intermediate blocks that can be used in the U-Net architecture. In this paper, we introduce a variety of intermediate spectrogram transformation blocks. We implement U-nets based on these blocks and train them on complex-valued spectrograms to consider both magnitude and phase. These networks are then compared on the SDR metric. When using a particular block composed of convolutional and fully-connected layers, it achieves state-of-the-art SDR on the MUSDB singing voice separation task by a large margin of 0.9 dB. Our code and models are available online. [1]

1. INTRODUCTION

Singing Voice Separation (SVS), a special case of Music Source Separation (MSS), aims at separating singing voice from a given mixed musical signal. Recently, many machine learning-based methods have been proposed for SVS and MSS tasks. They can be categorized into two groups: waveform-to-waveform models and spectrogram-based models. While the former tries to generate the vocal waveforms directly, the latter estimates spectrograms (usually magnitude) of vocal waveforms.

Typical spectrogram-based models apply Short-Time Fourier Transform (STFT) on a mixture waveform to obtain the input spectrograms. Then, they estimate the vocal spectrograms based on these inputs and finally restore the vocal waveform with inverse STFT (iSTFT). A variety of spectrogram-based models have been proposed in

the music information retrieval community and the machine learning community. For example, [1] employed the U-Net [2] architecture, an encoder-decoder structure with symmetric skip connections. These symmetric skip connections allow models to recover fine-grained details of the target object during decoding effectively. Several works [3–6] also used similar architectures.

They have revealed that U-Net-like architectures can provide promising performance for SVS and MSS. Existing works have proposed various types of neural networks for intermediate blocks. While some models [1, 3] used simple Convolutional Neural Networks (CNNs) for intermediate blocks, other advanced models tried more complex intermediate blocks. For instance, MMDenseLSTM [6] used densely connected CNNs followed by Long Short-Term Memory (LSTM) networks to efficiently model long-term structures, where LSTM is a variant of Recurrent Neural Networks (RNNs). However, a thorough search of the relevant literature indicated that there were no existing works that evaluate and directly compare these different types of blocks.

In this paper, we conduct a comparative study of U-Nets on various intermediate blocks. We designed several types of blocks based on different design strategies, which we present in section 3. For each type of block, we implemented at least one SVS model, which are all based on an identical U-Net framework for fair comparisons. In section 4, we summarize the experimental results and discuss the effect of each design choice. We validate hypotheses such as that inserting time-distributed operations (see §3.1) into intermediate blocks can significantly improve performance, which led to state-of-the-art (SOTA) performance on the MUSDB [7] SVS task.

Finally, our U-Net framework directly estimates the target complex-valued spectrogram (viewing real and imaginary as separate channels), when many existing models estimate the target magnitude without phase. In general, considering phase information improves the separation quality, as discussed in [8, 9]. Several phase-aware methods have been proposed for speech enhancement, such as phase reconstruction methods [8,9], or using raw complex-valued STFT outputs [10, 11]. In section 4, we show that the latter method is an efficient way to improve magnitude-only models, only needing a few minor adjustments.

2. U-NET-BASED SVS FRAMEWORK

In this section, we describe a U-Net-based SVS framework, which is shared by several models in §4. We first introduce the 'Complex as Channel framework' (CaC), a spectrogram-based SVS framework, and then define our U-Net architecture for spectrogram estimation in CaC.

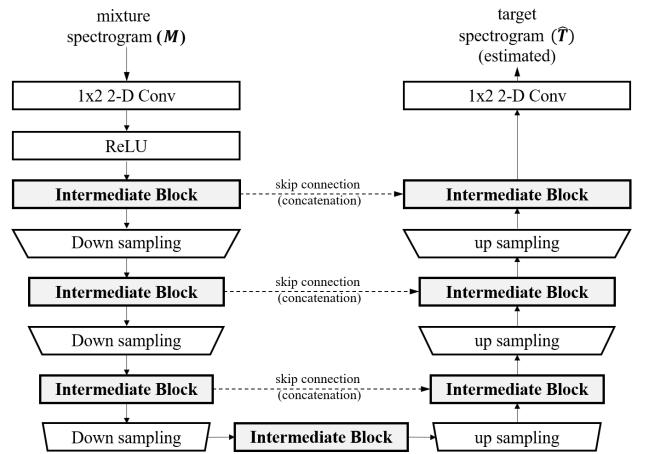
2.1 Complex as Channel Framework

CaC is a singing voice separation framework based on complex-valued spectrogram estimation. It takes a c-channeled mixture signal, and outputs c-channeled singing voice signal. As shown in Figure 1, CaC consists of three parts as follows:

1. The *spectrogram extraction layer* extracts a mixture spectrogram by applying STFT to the c-channeled input signal. The output of STFT is a complex-valued spectrogram with c-channels. Considering the imaginary and real parts as separate real-valued channels, we view the mixture spectrogram $M_{complex} \in \mathbb{C}^{c \times T \times F}$ as a $(2c)$-channeled real-valued spectrogram $M \in \mathbb{R}^{(2c) \times T \times F}$, where T denotes the number of frames and F denotes the number of the frequency bins in the spectrogram.

2. The *complex-valued spectrogram estimation network* is a neural network that takes the spectrogram $\mathbf{M}$ of a mixture signal as input and estimates the target spectrogram $\hat{T} \in \mathbb{R}^{(2c) \times T \times F}$, which is used for reconstructing the vocal signal later.

3. The *signal reconstruction layer* reshapes the estimated spectrogram $\hat{T}$ into the complex-valued spectrogram $\hat{T}_{complex} \in \mathbb{C}^{c \times T \times F}$, as shown in Figure 1. It then restores the estimated singing voice signal via inverse-STFT on $\hat{T}_{complex}$.

Figure 1. The Complex as Channel Framework


For a given mixture spectrogram $\mathbf{M}$, we train the complex-valued spectrogram estimation network in a supervised fashion to minimize the mean square error between the output $\hat{T}$ and the ground-truth spectrogram $\mathbf{T}$ of the singing voice signal.

It should be noted that the shape of $\mathbf{M}$ and $\hat{T}$ is $(2c) \times T \times F$, considering real and imaginary parts of a spectrogram as separate real-valued channels. This approach allows CaC to fully utilize the information in complex-valued spectrograms for both the input and the output. Meanwhile, current SOTA models (e.g., SA-SHN [4] and DGRU-DGConv [12]) decompose a complex-valued spectrogram into magnitude and phase, and only use the magnitude for the input of their networks. Although SA-SHN and DGRU-DGConv yielded impressive results by introducing novel attention method [4] and by adopting dilated 1-D convolutions [12] with Gated Recurrent Units (GRU) [13] respectively, they do not consider phase information. In §4.5, we compare the Source-to-Distirtion (SDR) [14] performance of models based on the CaC framework and that of models based on the Magnitude-only framework.

2.2 U-Net Architecture for Spectrogram Estimation

For spectrogram estimation in CaC, we use a U-Net-based architecture. It consists of an encoder and a decoder: the encoder transforms $\mathbf{M}$ into a downsized spectrogram-like representation, and the decoder takes it and returns the estimated target spectrogram $\hat{T}$. Before we describe them in detail, we introduce two types of main components in the architecture as follows.

- An *intermediate block* transforms an input spectrogram-like tensor into an equally-sized tensor (possibly with a different number of channels).

- A *down/up sampling layer* halves/doubles the scale of an input tensor either in the time, frequency, or Time-Frequency domain.

Figure 2. U-Net Architecture for Spectrogram Estimation

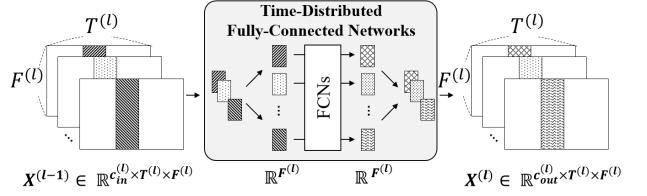
As shown in Figure 2, the number of down-sampling layers and the number of up-sampling layers are the same. Also, it uses the same number of intermediate blocks in the encoding and the decoding phase. It has an additional block in between its encoder and decoder. Thus, the total number of blocks should be an odd integer. It has skip connections that concatenate output feature maps of the same scale between the encoder and the decoder.

Besides basic components, our architecture has two additional convolution layers, as illustrated in Figure 2. We use them to increase or restore the number of channels. Before describing them, let us introduce some notations. We denote the input of the l-th intermediate block by $X^{(l-1)}$, and the output by $X^{(l)}$. The size of $X^{(l-1)}$ is denoted by $c_{in}^{(l)} \times T^{(l)} \times F^{(l)}$, where $c_{in}^{(l)}$ represents the number of channels and and $T^{(l)} \times F^{(l)}$ represents the size of the spectrogram-like tensor. Also, we denote the size of $X^{(l)}$ by $c_{out}^{(l)} \times T^{(l)} \times F^{(l)}$, where $c_{out}^{(l)}$ is the number of channels. Using these notations, we denote the input of the first block by $X^{(0)}$, and its size by $c_{in}^{(1)} \times T^{(1)} \times F^{(1)}$. To increase the number of channels, it applies a 1×2 convolution with $c_{in}^{(1)}$ output channels followed by ReLU [15] activation to the given input $\mathbf{M}$. To adjust the number of channels, it also applies a final 1×2 convolution with $(2c)$ output channels to the output of the final block. Note that the last layer is not followed by any activation function since target TF bins can be negative. We empirically set the parameter $c_{in}^{(1)}$ to be 24 in our experiments. Models with smaller $c_{in}^{(1)}$ (e.g., 12) are trained faster, but usually perform inferior than models with larger size of $c_{in}^{(1)}$.

We can implement various SVS models based on this architecture in the CaC framework because multiple options are available for intermediate blocks. In section 3, we present several neural networks which can be used as intermediate blocks in this paper.

3. INTERMEDIATE BLOCKS

We present several types of intermediate blocks based on different design strategies. We first present time-distributed blocks and then present time-frequency blocks.

3.1 Time-Distributed Blocks


Some existing models use CNNs (e.g., [16]) for intermediate blocks to extract timbre features of the target source. However, the authors of [8] reported that conventional CNN kernels are limited for this task. They found that long-range correlations exist along the frequency axis in the spectrogram of voice signals, which Fully-connected Neural Networks (FCNs) can efficiently capture. They proposed a model named Phasen for speech enhancement, which uses the Frequency Transformation Block (FTB) that has a single-layered FCN without bias. This FCN is applied to each frame of the internal representation in a *time-distributed* manner.

Inspired by TFB, we introduce *time-distributed* blocks, which are applied to a single frame of a spectrogram-like feature map. These blocks try to extract time-independent features that help singing voice separation without using inter-frame operations. We first introduce an FCN-based block and then propose an alternative time-distributed block based on 1-D CNNs.

3.1.1 Time-Distributed Fully-connected networks

We present an FCN-based intermediate block, called Time-Distributed Fully-connected network (TDF). As illustrated

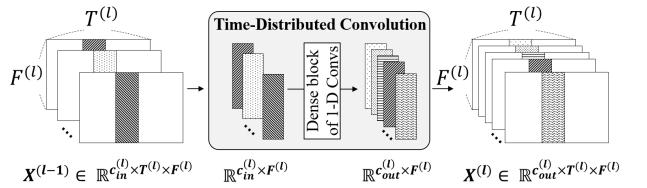
in Figure 3, a TDF block is applied to each channel of each frame separately and identically.


Figure 3. Time-Distributed Fully-connected networks

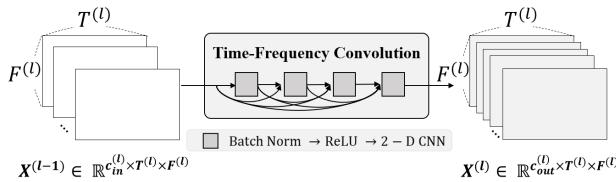
Suppose that the l-th intermediate block in our U-Net structure takes input $X^{(l-1)}$ into an output $X^{(l)}$. As shown in Figure 3, a fully-connected network is applied separately and identically to each frame (i.e., $X^{(l-1)}[i, j, :]$) in order to transform an input tensor in a time-distributed fashion. While an FTB of Phasen [8] is single-layered, a TDF block can be either single- or multi-layered. Each layer is defined as consecutive operations: a fully-connected layer, Batch Norm (BN) [17], and ReLU [15]. If it is multi-layered, then each internal layer maps an input to the hidden feature space, and its final layer maps the internal vector to $\mathbb{R}^{F^{(l)}}$. The number of hidden units is $\lfloor F^{(l)}/bn \rfloor$, where we denote the bottleneck factor by bf. We can reduce parameters if we use two-layered TDFs of $bf > 2$. We investigate the effect of adding additional layers in §4.2.

3.1.2 Time-Distributed Convolutions

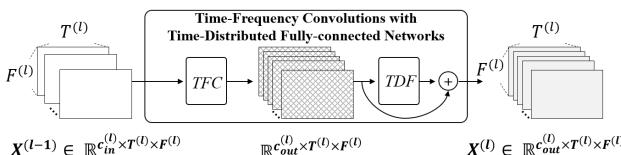
We propose an alternative time-distributed block named Time-Distributed Convolutions (TDC), which is applied separately and identically to each multi-channeled frame. It is a series of 1-D convolution layers. Inspired by [5,6], it takes form of a *dense block* [18] structure. A dense block consists of densely connected composite layers, where each composite layer is defined as three consecutive operations: 1-D convolution, BN, and ReLU. As discussed in [5,6,18] the densely connected structure enables each layer to propagate the gradient directly to all preceding layers, making a deep CNN training more efficient.

Figure 4. Time-Distributed Convolutions


3.2 Time-Frequency Blocks

The performances of U-Nets with time-distributed blocks were above our expectation (see §4.2), but were still inferior considerably to those of current SOTA methods. The reason is that features observed in musical sources include sequential patterns (e.g., vibrato, tremolo, and crescendo) or musical patterns (e.g., rhythm, repetitive structure), which cannot be modeled by time-distributed blocks.

While time-distributed blocks cannot model the temporal context, time-frequency blocks try to extract features considering both the time and the frequency dimensions. We introduce the Time-Frequency Convolutions (TFC) block, which is used in [5]. We also propose two novel blocks that combine two different transformations.

3.2.1 Time-Frequency Convolutions


The Time-Frequency Convolutions (TFC) is a dense block of 2-D CNNs, as shown in Figure 5. The dense block consists of densely connected composite layers, where each layer is defined as three consecutive operations: 2-D convolution, BN, and ReLU. It is applied to the spectrogram-like input representation in the time-frequency domain. Every convolution layer in a dense block has kernels of size (k_F, k_T). Its 2-D filters are trained to jointly capture features along both frequency and temporal axes.

Figure 5. Time-Frequency Convolutions

3.2.2 Time-Frequency Convolutions with TDF

We propose the Time-Frequency Convolutions with Time-Distributed Fully-connected networks (TFC-TDF) block. It utilizes two different blocks inside: a TFC block and a TDF block. Figure 6 describes a TFC-TDF block. It first maps the input $X^{(l-1)}$ to a same-sized representation with $c_{out}^{(l)}$ channels by applying the TFC block. Then the TDF block is applied to the dense block output. A residual connection is also added for efficient gradient flow.

Figure 6. Time-Frequency Convolutions with TDF

Phasen [8] has shown that inserting time-distributed operations into intermediate blocks can improve speech enhancement performance. We validate whether it also works for SVS or not in §4.3.

3.2.3 Time-Distributed Convolutions with RNNs

We propose an alternative way to consider both the time and frequency dimensions. A Time-Distributed Convolutions with Recurrent Neural Networks (TDC-RNN) block uses two different blocks: a TDC block for extracting timbre features and RNNs for capturing temporal patterns. It extracts timbre features and temporal features *separately*, unlike a TFC block. We validate whether this approach can

outperform the 2-D CNN approach by comparing TDC-RNNs with TFCs in §4.3.

The structure of a TDC-RNN block is similar to that of a TFC-TDF block. It applies the TDC block to an input $X^{(l-1)}$, and obtains a same sized hidden representation with $c_{out}^{(l)}$ channels. The RNNs compute the hidden representation and output an equally sized tensor. A residual connection is added, as is a TFC-TDF block.

4. EXPERIMENT

We evaluate U-Nets with different types of blocks introduced in §3. We compare the performance of models in §4.2 and §4.3. Also, we compare our models with SOTA models in §4.4. We compare the spectrogram estimation framework in §4.5. We discuss reusable insights in §4.6.

4.1 Setup

4.1.1 Dataset

Train and test data were obtained from the MUSDB dataset [7]. The train and test sets of MUSDB have 100 and 50 musical tracks each, all stereo and sampled at 44100 Hz. Each track file consists of the mixture and its four source audios: 'vocals,' 'drums,' 'bass' and 'other.' Since we are evaluating on singing voice separation, we only use the 'vocals' source audio as the separation target for each mixture track.

4.1.2 Model Configurations

We implemented U-Nets with different blocks (§3). Each model is based on the U-Net architecture (§2.2) on the CaC framework (§2.1). We set $c_{in}^{(1)}$, the number of internal channels to be 24, as mentioned in §2.2. Each model uses a single type of block for its intermediate blocks. We usually used an FFT window size of 2048 and a hop size of 1024 for STFT. However, we used a larger window size in some models for a fair comparison with SOTA methods.

4.1.3 Training and Evaluation

Weights of each model were optimized with RMSprop [19] with learning rate $lr \in [0.0005, 0.001]$ depending on model depth. Each model is trained to minimize the mean square error between $\hat{T}$ and $\mathbf{T}$ as mentioned in §2.1. We use the default validation set (14 tracks) as defined in the *MUSDB* package, and use the Mean Squared Error (MSE) between target and estimated signal (waveform) as the validation metric for validation. Data augmentation [20] was done on the fly to obtain fixed-length mixture audio clips comprised of the source audio clips from different tracks.

We use the official evaluation tool[2] provided by the organizers of the SiSEC2018 [21] to measure Source-to-Distortion Ratio (SDR) [14]. We use the median SDR value over all the test set tracks to obtain the overall SDR performance for each run, as done in the SiSEC2018. We report the average of 'median SDR values' over three runs for each model.

Table 2. Evaluation results of Time-Frequency Blocks.

4.2 U-Nets with Time-Distributed Blocks

We implemented and trained U-nets with TDC and TDF blocks. We also implemented models with TDC blocks that do not use down/up-sampling to investigate the effect of down/up-sampling in the frequency axis. The other models use 1-D convolution/transposed-convolution layers with stride 2 for down/up-sampling. Every TDC block is a dense block with 5 composite layers with the growth rate 24 (used in dense blocks [18]). The kernel size of each convolution layer in a dense block is 3. Each TDF block is either single-layered or two-layered. The bottleneck factor bf of each TDF block is set to be 4. All models have 17 intermediate blocks except for two shallow models.

We summarize evaluation results in Table 1. The TDC block-based U-Net with sampling achieves an SDR of 4.86, the highest among the three models. Results show that the use of down/up-sampling in TDC-based U-Nets was significant, although the model without sampling can exploit higher resolution of internal representations. It may indicate that enlarging receptive fields via sampling may help the model to capture long-term dependencies better, and long-term dependencies are preferred over local features when distinguishing unique time-independent frequency patterns. (at least for these configurations).

Although FCNs can capture long-ranged patterns along the frequency domain, as mentioned in [8], TDF-based U-Nets did not perform well enough compared to the TDC-based models in a deep architecture. Among TDF-based models, the U-Net equipping single-layered TDFs (the fourth row of Table 1) outperforms the other models. However, it is notable that we can reduce parameters when we use two-layered TDFs. Also, we found that the TDF blocks can outperform TDC blocks in a shallow architecture (the third and sixth row of Table 1). The reason is that the U-Nets with few TDC blocks has a small receptive field, while a single TDF block has a full receptive field in the frequency dimension, which has led us to inject it in a time-frequency block instead of TDC (see §3.2.2).

4.3 U-Nets with Time-Frequency Blocks

We implemented U-Nets with time-frequency blocks. All models are trained on 3 seconds (128 STFT frames) of music. Since the number of frequency bins is much larger than the number of frames, models with more than 7 neural transforms use both 2×2 or 2×1 sized down/up-sampling layers to scale the frequency axis more than 3

times while maintaining the number of scales in the temporal axis to 3. Exceptionally, we use different down/up-sampling layers for one model to investigate the effect of down/up-sampling in the temporal axis.

We set every TFC block to have 5 convolution layers with kernel size 3×3. We set the growth rate to be 24, the same growth rate of §4.2. By using this TFC block configuration, we implemented a TFC-based U-Net (the first row of Table 2). We set the model in the second row to use different down/up-sampling layers to investigate the effect of down/up-sampling in the temporal axis. Every kernel size used in each down/up-sampling layer of this model is 2×1 to preserve the temporal resolution while scaling frequency resolution. The first two rows of Table 2 summarize the experiment results of two TFC-based models. The model that preserves the temporal resolution was slightly inferior to the other model. It is also notable that our U-Nets with TFC blocks achieve comparable results with state-of-the-art methods 4.4, even using lower frequency resolution. Compared to the frequency axis where the TDC-based U-Net with down/up-sampling outperforms the counterpart model, no significant SDR was gained by enlarging the receptive field by down/up-sampling.

We reused the configuration of TDC in of §4.2, for TDCs in TDC-RNN blocks. The RNN layers were implemented with bidirectional GRUs with a single hidden layer, which has $f/16$ hidden units, where f is the number of input frequency bins. Although having more parameters and a better potential for capturing long temporal dependencies than the two fully convolutional models, TDC-RNN performs lower than them. Increasing the number of hidden units or hidden layers could have increased SDR since many other state-of-the-art recurrent models use a hidden size that is at least 512. Increasing the number of STFT frames, thus training on longer clips of music, might have also worked. Although it performs the worst among the time-frequency blocks, it is superior to all the time-distributed blocks. It indicates that inter-frame operations are necessary for higher quality separation.

The fourth and fifth rows of the Table 2 shows promising results regarding the U-Nets with TFC-TDF blocks. We reused the same TFC setting above, and we set bf to be 16 for each TDF. The 7-blocked U-Net with TFC-TDFs outperforms the other 17-blocked models. These results show that inserting FCNs into intermediate blocks can be useful for MSS as well as for Speech Enhancement [8]. Also, results show that it is also achievable with fewer parameters by using FCNs with a bottleneck layer.

model	# parameters	SDR (vocals)
DGRU-DGConv	more than 1.9M	6.99
TAK1	1.22M	6.60
UMX	8.89M	6.32
TFC-TDF (small)	0.99M	**7.07** $\pm.08$
TFC-TDF (large)	2.24M	**7.98** $\pm.07$

Table 3. Comparison: SDR median value on test set.

esimation	n_fft	# blocks	# params	SDR
CaC	2048	7	0.99M	**7.07**
Mag	2048	7	0.99M	6.43
CaC	4096	9	2.24M	**7.98**
Mag	4096	9	2.24M	7.24

Table 4. Comparison of TFC-TDFs: CaC vs Mag

4.4 Comparison with SOTA models

We compare our models with other spectrogram-based models on the MUSDB benchmark. The first three rows of Table 3 shows the SDR performance of SOTA models, namely DGRU-DGConv [12], TAK1 [6], and UMX [22]. Their SDRs can be found in [12], SiSEC2018 repository [3], and UMX repository [4]. We estimated the lower bound of the number of parameters of DGRU-DGConv with 1-D CNN parameters without considering its GRUs.

Comparing with Table 2, we can see that our models perform comparably to or even outperform existing models even with less frequency resolution and fewer parameters. On top of that, our TFC extensions do not use recurrent layers, which is a key factor in the other previous models. It may lead to shorter forward/backward propagation time. Also, it is worth noting that previous models adopt Multi-channel Wiener Filtering as a post-processing method to further enhance SDR. Ours directly use the signal reconstruction output without such post-processing.

For a fair comparison with SOTA models, we trained an additional U-Net with 9 TFC-TDF blocks (notated as 'large' in Table 3) with the same frequency resolution as the other SOTA models (FFT window size = 4096) and achieved outstanding results with a 0.9 dB gain over DGRU-DGConv.

4.5 Spectrogram Estimation: Complex vs Magnitude

For our final experiment, we see how much SDR was gained by extending a magnitude-only model into a CaC model. Our TFC-TDF-based U-Nets in Table 4 are compared to their magnitude-only form (referred to as 'Mag'). They use the same hyperparameter set except for $c_{in}^{(0)}$, the input/output number of channels. Mag also has an additional ReLU after the final 1×1 convolution to obtain non-negative-valued output spectrograms. Results show that training with raw STFT outputs instead of magnitudes

---

[3] https://github.com/sigsep/sigsep-mus-2018
[4] https://github.com/sigsep/open-unmix-pytorch

significantly boosts SDR performance. It is also notable that the Mag model with n_fft of 4096 still outperforms all previous state-of-the-art models in Table 3.

4.6 Discussion: Developing Reusable Insights

Our work provides a practical guideline for choosing fundamental building blocks to develop an SVS or MSS model based on the U-Net architecture as follows.

- TDC-based models are sensitive to the number of blocks, compared to TDF-based models.

- Using down/up-sampling is important for CNN-based blocks, especially in the frequency dimension.

- Stacking 2-D CNNs is a simple but effective way to capture T and F features, compared to TDC-RNNs.

- Injecting a time-distributed block to a time-frequency block can improve SDR.

- A simple extension from a magnitude-only U-Net to a CaC U-Net can improve SDR.

Our work is not limited to the U-Net-architecture nor MSS. Blocks can be used as core components in more complex architectures as well. We can use different types of blocks for a single model, meaning that a lot of space remains for improvement. Also, our observations can be exploited in other MIR tasks such as Automatic Music Transcription (AMT) or Music Generation: for example, we expect that injecting TDFs to intermediate blocks for f_0 estimation model can improve performance since fully-connected layer can efficiently model long-range correlations such as harmonics.

5. CONCLUSION AND FUTURE WORKS

In this paper, we designed several types of blocks based on different design strategies. We implemented U-Net models with these blocks for SVS and evaluated their performance. Our experiments provide abundant material for future works by comparing several U-Nets with different types of blocks. Also, one of our models outperforms SOTA methods. For future work, we would like to extend this model to utilize attention networks for modeling long-term dependencies observed in both the frequency and the temporal axis.

DISCOURSE NOT DUALISM: AN INTERDISCIPLINARY DIALOGUE ON SONATA FORM IN BEETHOVEN'S EARLY PIANO SONATAS

ABSTRACT

The computational analysis of music has traditionally seen a sharp divide between the "audio approach" relying on signal processing and the "symbolic approach" based on scores. Likewise, there has also been an unfortunate gap between any such computational endeavour and more traditional approaches as used in historical musicology. In this paper, we take a step towards ameliorating this situation through the application of a computational method for visualizing local key characteristics in audio recordings. We exploit these visualizations of diatonic scale content by discussing their musicological implications, being aware of methodological limitations as for the case of minor keys. As a proof of concept, we use this method for investigating differences between the traditional sonata-form model and selected Beethoven piano sonatas in the context of sonata theory from the end of the 18$^{\text{th}}$ century. We consider this scenario as an example for a rewarding dialogue between computer science and historical musicology.

1. INTRODUCTION

The analysis of musical works in terms of their compositional style and context is at the core of historical musicology. Scholars engage with a reasonably large body of works over the course of their career and make observations about these works through manual analysis. As valuable as this is, it is a time-consuming and individuated approach that poses difficulties for making meaningful observations at scale. In this paper, we seek to demonstrate how a question of musicological relevance could be complemented by using computational analysis methods. While such methods can never achieve the flexible and interconnected consideration of the human mind nor capture the compositional intricacies of a specific work, we aim to show that suitable visualizations can assist in the process of expert interpretation in a rewarding way.

Numerous computational methods for harmony analysis have been developed over the past decades, centered on global key detection [1–4], local key estimation [5–7], chordal analysis [8–10], and their combination into functional harmony analysis systems [11–13]. Many of these are based on *symbolic* encodings of music notation such as MIDI or MusicXML. However, symbolic music datasets are rarely available, in particular when requiring symbolic encodings of high quality covering an entire corpus of music (not just individual pieces). Optical Music Recognition (OMR) software for automatically converting graphical formats into symbolic data does not yet offer reliable results, meaning that time-consuming manual postprocessing is often required [14, 15].

Beyond such practical problems, we should remember that Western music notation is essentially "prescriptive": a set of instructions for performance that requires reading and interpretation. As an alternative to the processing of sheet music, analyses can be carried out on the basis of audio recordings [4, 7, 10]. In this paper, we make use of an existing audio-based method [16] for visualizing the diatonic scale content of a music recording over time in order to complement and facilitate the close analytical reading by human experts. We address this paper to both musicologists and computer scientists alike and thus explain the relevant background from both domains.

We first set out the musicological context (Section 2), describe the computational method (Section 3), and explain its musical implications through the example of three piano sonatas by L. v. Beethoven (Section 4), which have been subject to automatic analysis [9, 12, 17]. Using our visualizations, we discuss the implications for sonata form theories (Section 5). Finally, we summarize our findings and the rewards of an interdisciplinary dialogue between computer science and musicology (Section 6).

2. MUSICOLOGICAL BACKGROUND

Our focus in this paper is on large-scale tonal structures that are attested to play a crucial role in sonata form. This section provides a short, simplified introduction to sonata form for readers unfamiliar with it and serves to introduce the main musicological question addressed in this paper.

Sonata form is a central model for describing the first movement of most multi-movement works in classical music from about 1770 far into the 19th century. The term is applicable not only to *sonatas* but also to symphonies, string quartets, and other genres, and thus has a wide explanatory potential for the music of the time, with a focus on these works' first movements.

The definition of sonata form widely adopted by musicians and musicologists seems to stem primarily from the writings of A. B. Marx [18], which were driven mainly by an effort to understand the music of then recently deceased Ludwig van Beethoven (1770–1827). According to this model, the sonata is divided into three main sections: a first section, later denoted as *exposition* (in two or more keys, often repeated), a central *development*, and a *recapitulation* of the exposition (set mainly in one key). This is the core structure which may be framed by an introduction at the start, and/or a coda at the end [19]. Automatically detecting these large-scale segments and their tonal relations has been approached both for Mozart's string quartets [20, 21] and Beethoven's piano sonatas [17].

The exposition is tasked with setting out the melodic material (e. g., themes or motives) and the main key relationships. It is usually divided into a first subject area, followed by a transition into a second subject area, and a short cadential passage (*Schlussgruppe*). Crucially, the two focal areas are defined by contrasts both in theme (melody) and key (tonality). The typical tonal pairing is of a major key and its dominant key (the major key one fifth higher, e. g., C major and G major), or of a minor key with its relative major key (e. g., A minor and C major).

Our primary focus will be on key, which we approximate in the broader sense with our visualizations of diatonic pitch class content. With this computational method, we elucidate the tonal relations in specific early Beethoven piano sonatas. In this paper, we focus on works in major keys overall and on the exposition sections of those works.

3. COMPUTATIONAL APPROACH

In this work, we employ a computational method for visualizing local keys or, more precisely, the *diatonic pitch class content* over the course of a piece, closely following the approach proposed in [16]. The method operates on audio recordings, i. e., *performances* of the pieces, thus allowing for scalability to a wide repertoire (see Section 1).

3.1 Chroma-based Scale Estimation

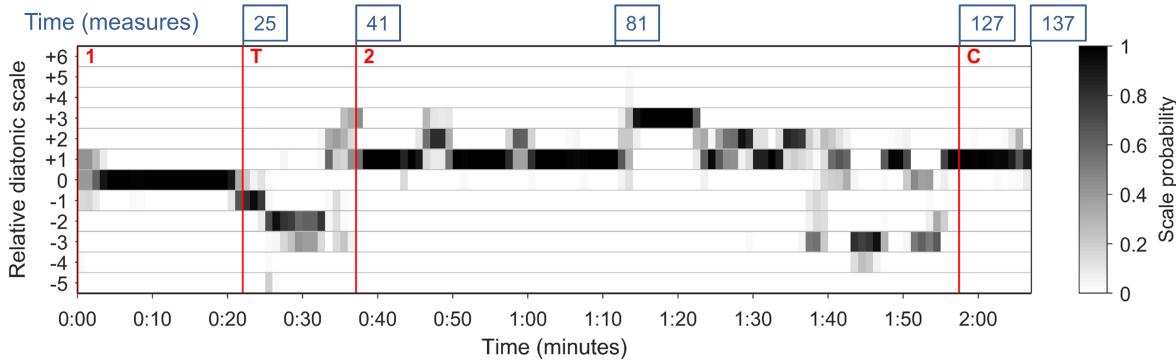
Our method is based on the measurement of spectral energies over time. These energies are summarized into twelve *chroma bands* irrespective of their octave, according to the pitch classes of the twelve-tone equal-tempered scale. The resulting *chroma features* can be represented as twelve-dimensional vectors whose entries refer to the pitch classes C, C♯, ..., B in chromatic order. For chroma extraction, we use the filter-bank approach provided by the chroma toolbox [22] with a feature rate of 10 Hz (i. e., ten chroma vectors per second). For each frame, we match the chroma

vector with binary diatonic scale templates using the inner product (cosine similarity). For instance, the template for the "0 diatonic scale" (corresponding to the pitch classes of the C major and A natural minor scales) is given by

$$\mathbf{t}_0 = (1, 0, 1, 0, 1, 1, 0, 1, 0, 1, 0, 1)^\top . \quad (1)$$

Assuming enharmonic equivalence (C♯=D♭), there are a total of 12 diatonic scales, whose templates are obtained by circularly shifting the template $\mathbf{t}_0$ shown above. Thus, we obtain for each frame an analysis given by a twelve-dimensional vector. We will discuss our choice of using binary diatonic templates in Section 3.4.

3.2 Pre-processing

Before the template matching step described above, we apply several pre-processing steps. Since local keys or scales refer to the pitch class content of larger sections of music, we smooth the chromagrams (with an initial feature rate of 10 Hz) using a window of size $w \in \mathbb{N}$ in frames and a hopsize of 10 frames (one second). The musical implications of the window size parameter will be discussed in Section 4.3. Additionally, we normalize the smoothed chroma features according to the ℓ_2-norm.


3.3 Post-processing and Visualisation

In this interdisciplinary work, we do not aim for a fully automatic "key detection," which locally decides on the most likely key or scale. Instead, following [16], we propose the use of suitable visualization techniques allowing for a direct interpretation of the continuous-valued diatonic scale probabilities in the musicological discussion. For generating this visualization, we obtain re-scaled local analyses by using the *softmax* function, thus suppressing weak components and enhancing large ones. Using a normalization with respect to the ℓ_1-norm, we can interpret the analysis as pseudo-probabilities of diatonic scales, which we then visualize in grayscale, where darker gray corresponds to higher probabilities (see Figure 1 for an example).

We adopt a musical criterion for arranging the order of scales in this visualisation. There are two main options of ordering the scales, either chromatically (C, C♯, ...) or according to the circle of fifths (C, G, ...). Motivated by [23, 24], we prefer the latter arrangement accounting for the similarity of fifth-related scales, which have six out of seven pitch classes in common. We set the diatonic scale corresponding to the piece's global key in the center of the visualization, with upper-fifth-related scales (more sharps) above and lower-fifth-related scales (more flats) below that center scale. This "global key normalization" facilitates the comparison between movements in different keys.

3.4 Scale versus Local Key

Our analytical approach directly maps the locally predominant pitch class content (as measured from the audio recordings) to probabilities for diatonic scales. While there have been many such template-based approaches based on psychological and empirical studies [25, 26], our choice

Figure 1. L. v. Beethoven, piano sonata Op. 7 in E♭ major, 1st mvmt. *Allegro molto e con brio*, exposition. Computational tonal analysis with a window size of $w = 4$ seconds.

of straightforward diatonic templates allows for an interpretable and objective investigation of the tonal content.

There are certainly limitations to this approach. Most importantly, it relates to the notion of local key only in a loose way since there is a methodological gap between "scale" and "key." In particular, pitch class content is not the only determinant of musical key. Furthermore, the pitch class content is rarely exclusively diatonic, which is especially the case for pieces in minor, where scale degrees outside the natural minor scale ($\sharp\hat{6}$ and $\sharp\hat{7}$) play a crucial role. Moreover, our method cannot resolve relative key differences such as C major – A minor, which would be relevant particularly for minor key movements.[1] On the other hand, it provides an easier overview (only 12 scales) and is not susceptible to relative key confusions.

Leaving aside these methodological gaps, even identifying a scale can be problematic. For example, certain chords such as the (relatively rare) augmented triad and the (not at all rare) diminished seventh chord pose challenges because they cannot be unambiguously assigned to a diatonic scale. Moreover, frequent modulations constitute a problem for assigning a single scale to a specified time window. That being said, this computational issue reflects a genuine musical problem: hearing a tonal moment in isolation would leave the allocation of a key highly ambiguous—and composers (Beethoven very much included) exploit this potential for ambiguity. It is only through context that we are able to make clear assertions. We remain mindful of these limitations as we proceed to consider how these visualizations may yet be useful in support of a better understanding of sonata form in general and, more precisely, in Beethoven's early piano sonatas.

4. APPLICATION TO SONATA EXPOSITIONS

Consequently, we apply the method described above to several exposition sections of Beethoven's early sonatas (first movement, respectively). The time stamps are given in MM:SS and refer to Daniel Barenboim's 1984 set of recordings for Deutsche Grammophon.

4.1 Sonata Op. 7 in E♭ major

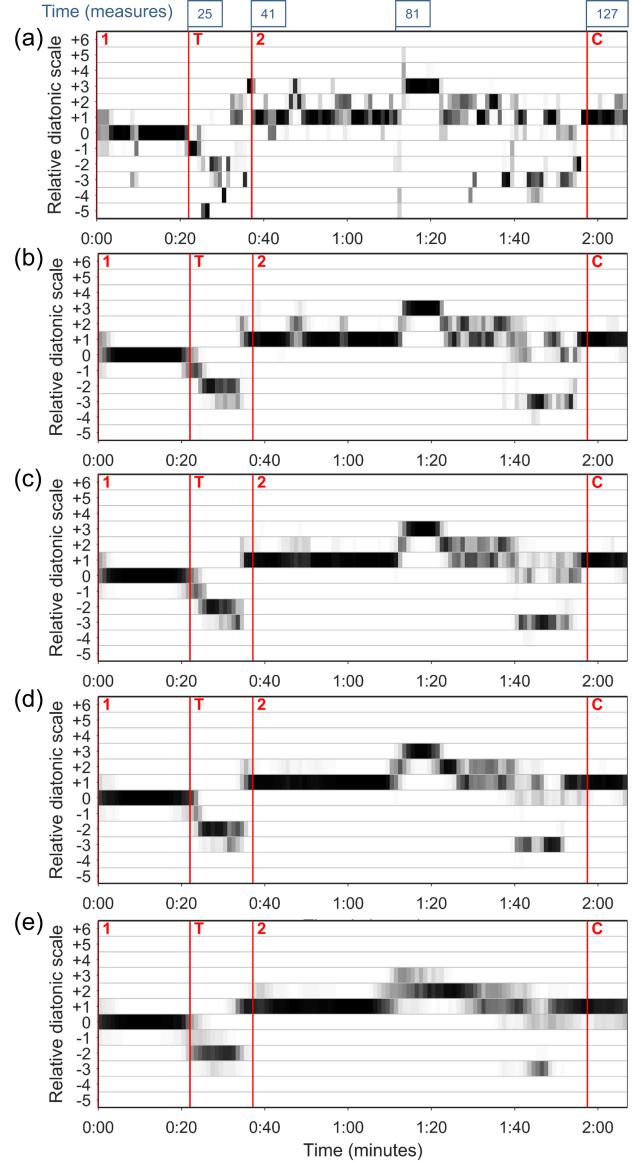
Figure 1 provides an example of our visualization method for the exposition from Beethoven's piano sonata Op. 7 in E♭ major, first movement. As E♭ major is the global key of this movement, the relative diatonic level 0 on the y-axis of this figure refers to an absolute scale of –3, corresponding to the key signature of E♭ major and its relative minor (C minor, both with a key signature of three ♭s). Likewise, +1 refers to the key signature of B♭ major (and G minor), –1 stands for A♭ major (and F minor), and so on.

In addition to the time stamps, the figure (and all subsequent figures) also provide vertical lines (in red) to divide the sections on the basis of Donald F. Tovey's iconic guide to Beethoven's piano sonatas [27]. These lines add additional score-related timestamps given in measure numbers (in blue) and are paired with the formal labels that Tovey used, following the standard terms for the sonata form's main parts discussed above. The vertical lines on Figure 1 use the following abbreviations: "1" stands for the *first group*, "T" for the *transition*, "2" for the *second group*, and "C" for the *cadence group*. The following section takes a closer look at the example with a view to both the visualization method and the implications for understanding sonata form in this specific repertoire.

4.2 A Closer Look

The visualization in Figure 1 provides a straightforward, easily readable overview of the diatonic scale content in the exposition of the first movement. The movement begins with a moment of ambiguity, centered on the central (0) scale (corresponding to E♭ major), and quickly settles much more emphatically into that tonal region for the first 22 seconds (until m. 24). A phase of tonal instability follows, befitting the transition phase of a sonata form exposition, which traverses at least the scales –1 (4♭ or A♭ major / F minor) to –2 (5♭), and then +1 (2♭) to +3 (no accidentals).

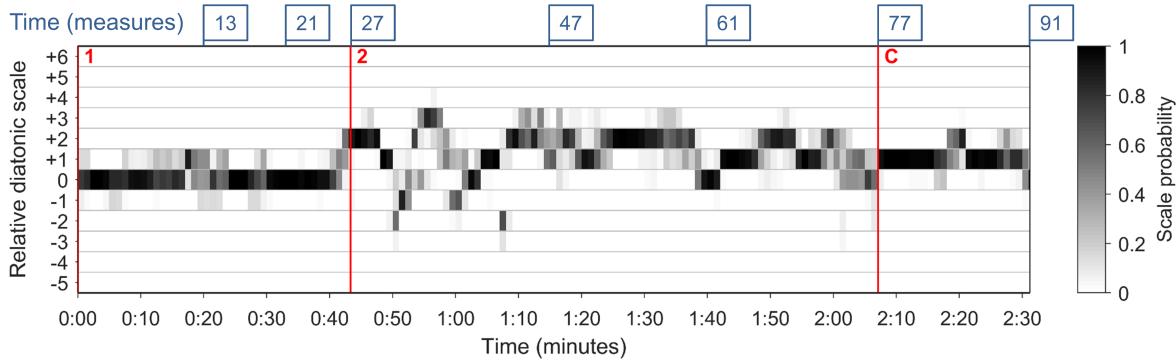
At 0:37 (m. 41), a longer section starts in the +1 area, neatly corresponding to what is traditionally called the "Second Theme" or "Second Group." At 1:11 (m. 79), the proportions (with a second subject equal in length to the first) might lead us to expect the exposition to close. Instead, about a minute more music follows, with only the last approx. 10 seconds being displayed in the anticipated

+1 area (mm. 127–136, largely corresponding to the final group). The course of the movement from 1:11 to 1:57 (mm. 79–127), by contrast, seems to be characterized by greater harmonic mobility, centered on the +1 axis, but not restricted to it. Regardless of any designation of the formal parts, the graphic shows a clear distinction in the course of the exposition from 0:38 (m. 41) into a tonally stable part until 1:11 (mm. 78–79), a more flexible part until 1:57 (m. 127), and again a stable one until the end.


4.3 Effects of the Window Size

As one of the essential properties of our methodology, we have to specify the window size parameter w, which defines the temporal context of the local scale analysis. The use of a window size of four seconds in Figure 1 affects the result we see in that visualization. In order to demonstrate the effect of this parameter, Figure 2a–e shows five different visualizations of the same example with window sizes varying from 2–20 seconds.

Naturally, shorter time windows portray a more "atomized" harmonic course, emphasizing the moment-to-moment details, while longer windows diminish the individual moments in favor of the "bigger picture." Any gain in uniformity and clarity comes at the cost of a corresponding loss in detail. In this respect, a computational analysis does not differ from a manual one, in which the analyst also has to decide whether to focus on fine-grained details or to favour better readability and clarity. This speaks to music theory's attention to the "level" of reductive analysis [28]—an approach to which the variable window size on offer here may be highly suitable. Multi-scale approaches for simultaneously using several window sizes suggest an alternative [29]. However, these visualizations require a third dimension (usually color-coded), which complicates readability in our application scenario. Moreover, interactive visualizations with a flexible adjustment of the window size can be realized with user interfaces or websites.

To better illustrate the behaviour of our method, we now proceed to discuss the effects of the window size at the example of several specific passages. With a window size of four seconds (Figure 1), the dominant seventh chord G-Bb-Db-Eb of Ab major in m. 10 (at 0:08) does not lead to any deviation from the level 0. With a resolution of two seconds (Figure 2a), it causes a much stronger gray coloration, which reaches down to the –3 level (corresponding to Gb major / Eb minor). Similarly, the diminished seventh chord F♯-A-C-Eb in mm. 79–89 (1:11–1:22) triggers a whole range of possible interpretations. First, the chord eludes the assignment to a single diatonic scale, and second, through the pitch class F♯, it does not fit into the previous Bb major context (–2), nor through F♯ and Eb into the subsequent C major context (0). In the case of longer windows, these uncertainties are smoothed out and therefore no longer catch the eye (see Figure 2d–e).


An even larger window size, e. g. of 20 seconds (Figure 2e), shows that only certain resolutions make sense for a specific work. Such large windows neither increase clarity nor do all the gray shadings of ambiguity disappear. In

Figure 2. L. v. Beethoven, piano sonata Op. 7 in Eb major, 1st mvmt. *Allegro molto e con brio*, exposition. Computational tonal analysis with a window size w of (a) 2 sec., (b) 6 sec., (c) 8 sec., (d) 12 sec., (e) 20 sec.

Figure 2e, the C major section in mm. 81ff. (1:12–1:22) is no longer visible as +3 (C major / A minor); instead, it blurs with the +2 level. At the same time, the tonally stable final group (+1), which only lasts about 10 seconds (mm. 127–136), shows considerably more shades of gray on the 0 level than visualizations with shorter windows, which is caused by the previous measures and the subsequent repetition of the exposition. The choice of very large windows not only leads to an increased smoothing of the visualization but also reaches limits beyond which the results are no longer meaningful.

In the present sonata, window sizes of 4–12 seconds have proven to be useful, illuminating most of the relevant phenomena. In particular, these visualizations clearly highlight phases of tonal stability and instability as well as diatonic regions, which are of high importance for the for-

Figure 3. L. v. Beethoven, piano sonata Op. 2 No. 3 in C major, 1st mvmt. *Allegro con brio*, exposition. Computational tonal analysis with a window size of $w = 4$ seconds.

Figure 4. L. v. Beethoven, piano sonata Op. 2 No. 3 in C major, 1st mvmt. *Allegro con brio*, mm. 25–28.

mal organization of expositions. Based on these observations, we now examine two further sonata expositions that have received frequent attention in the literature: sonatas Op. 2 No. 3 in C major and Op. 10 No. 3 in D major.

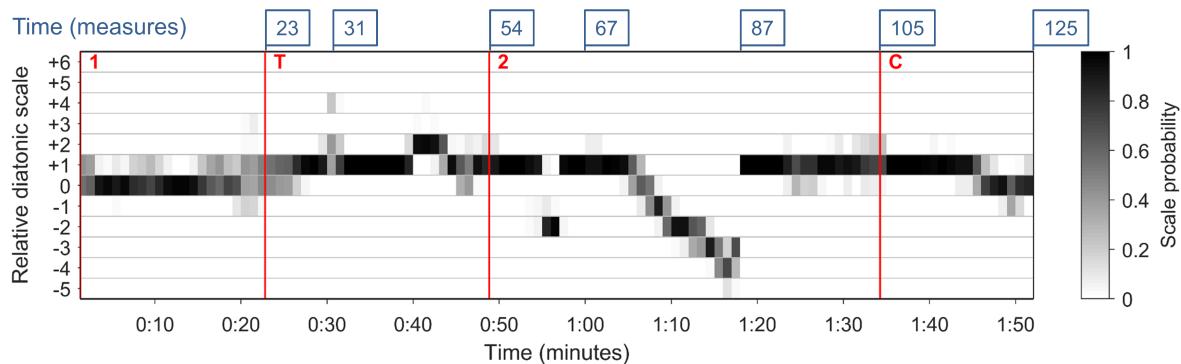
4.4 Sonata Op. 2 No. 3 in C major

Spanning 90 measures, the exposition of the sonata Op. 2 No. 3 in C major is even more extensive than that of Op. 7. The computational analysis (Figure 3) shows that the piece remains in a C major context for an unusually long time. These first 26 measures include the main subject (mm. 1–13) followed by playful figurations, which surprisingly do not modulate (mm. 13–21), and a cadence passage (mm. 21–26), which ends after a G major scale on the single tone G without having modulated (see Figure 4). [2] From m. 27 (0:43) on, this is followed by the melodic motif in G minor mentioned above, which is repeated in D minor (m. 33) and continued towards A minor (m. 39).

The visualization makes it clear that this G minor passage is by no means the beginning of the "Second Group (or Transition and Second Group) in Dominant"—as marked in Figure 3 after Tovey—but the beginning of the modulation to the upper-fifth key, i. e., the "transition." First of all, the abrupt tonal change in m. 27 (0:43) is visible. [3] However, the visualization does not show G minor (–2) but D major (+2), which may be caused by the frequent occurrence of the leading notes F♯ and C♯. In the following modulation, we observe level 0 at 1:03 (mm. 39ff., pointing to in A minor), then again level +2 at 1:09-–1:14 (mm. 43–45, pointing to D major), thereby terminating the transition to the second group (mm. 47–61; 1:15–1:40). The second group starts at level +1, then from m. 53 (1:26) on mainly represented as +2 due to several neighbor notes

C♯ and the secondary dominant chord A major sounding for a whole measure. This is followed by a longer cadence section, initially at the 0 level (C major) from 1:40 (mm. 61ff.) and then confirms level +1 with smaller swings to the levels +2 and 0. The largely stable level +1 in the final group is then clearly visible (mm. 77–90).

4.5 Sonata Op. 10 No. 3 in D major

The visualization of the sonata Op. 10 No. 3 gives a completely different picture (Figure 5). After about 20 seconds (m. 22), the initial tonality (D major, level 0) is left, followed by a longer section on the level +1 (mm. 23–45). In fact, we find here a lyrical motif in B minor, which actually corresponds to level 0. Due to the frequent occurrence of the leading note A♯, however, there seems to be a kind of "statistical averaging" between B minor (0) and B major (+3). The occurrence of C♯ major and F♯ minor in mm. 31–34 leads to a small shade of gray in the +4 level at 0:31. The second group in A major is then reached at 0:48 (m. 54). The repetition of the second subject in –2 (pointing to A minor) is briefly visible at 0:54 (mm. 60–63). It is then striking that the second group again ends more or less in the middle of the movement and is followed by a longer developmental passage at 1:00–1:18 (mm. 67–87).


5. MUSICOLOGICAL DISCUSSION

Section 4 examined the use of this visualization method for illuminating the details of three exemplary cases. We now broaden the scope to consider its potential contribution to the wider question of sonata form itself.

The visualizations discussed above have shown a multifaceted structure within the tonal course of the exposition. The plots point out that the musical course cannot be unproblematically reconciled with the traditional sonata form schema of *first group – transition – second group –*

---

[2] This ending constitutes a clear example of a so-called "bifocal close" [30].

[3] See also [17] for a method to highlight such changes.

Figure 5. L. v. Beethoven, piano sonata Op. 10 No. 3 in D major, 1st mvmt. *Presto*, exposition. Computational tonal analysis with a window size of $w = 4$ seconds.

cadence group [19], a problem raised by Carl Dahlhaus decades ago [31, p. 101–103]. This leads us to reconsider other, earlier theories of sonata form from the late 18th century which emphasize the idea of a musical *discourse* as opposed to a thematic *dualism*.

A detailed description of such an 18th-century form model is given by Francesco Galeazzi in the second volume of his *Elementi teorico-pratici di musica* (Rome 1796) [32]. Galeazzi's model differs from the theory more familiar today in two principal respects: the presence of a contrasting *second motif* before or at the beginning of the transition and a *cadential period* ahead of what he calls the *coda* (i. e., a codetta or final group).

For the section we now denote as *exposition* (which Galeazzi simply calls *prima parte*), Galeazzi sets out an alternative schema of seven elements [32, p. 324]:

1. Prelude (*preludio*)
2. Principal motive (*motivo*)
3. Second motive (*secondo motivo*)
4. Departure to [...] related keys (*uscita di tono*)
5. Characteristic passage / middle passage (*passo caratteristico / passo di mezzo*)
6. Cadential period (*periodo di cadenza*)
7. Codetta (*coda*)

Of these seven parts, according to Galeazzi [32], parts 2, 4, and 6 (in modern terms: *first key subject*, *transition*, and *cadential confirmation of the second key*) are compulsory, the remainder are optional. Accordingly, Galeazzi bases his model on a main motif that dominates the musical discourse like the topic of a speech and that can be followed by a whole series of new, partly related thoughts:

> "The motive [...] must be very conspicuous and perceptible because inasmuch as it is the theme of the discourse, if it is not well understood, neither will the consecutive discourse be understood." [32, pp. 326–327] [4]

If one starts from such a discursive form idea, the occurrence of a new thought before or in the transition (e. g.

Op. 2 No. 3 mm. 27–39, Op. 10 No. 3 mm. 23–30) and of a longer form part after the "middle sentence" (Op. 2 No. 3 mm. 61–77, Op. 7 mm. 81–127, Op. 10 No. 3 mm. 67–105) in no way leads into "insoluble theoretical difficulties" [31]. Even though some detailed structures might differ from a human analysis, the computational visualizations show something that was taken for granted for composers and audiences of the late 18th century: the individual formal parts are not opposed in a *dualistic* tension, but rather formed a series, where uniformity and diversity, tonal stability and modulation are combined into a living, *discursive* whole. Beethoven's early piano sonatas—differing considerably from the traditional model as codified by Marx—fit perfectly in this context [33]. Beethoven as well as Mozart before him [30] seem to have been influenced by Italian music. Galeazzi's account of sonata form—based on Italian composers of the 1770s and 1780s (Mozart and Beethoven were unknown to him)—points towards such an understanding as reflected in our visualizations.

6. CONCLUSIONS AND OUTLOOK

In this paper, we have demonstrated the use of a computational analysis system for shedding new light on a research question at the heart of historical musicology. The method relies on audio recordings and visualizes the diatonic scale content of a piece in an objective and interpretable way, providing an easy, at-a-glance insight into the phases of stability, instability, and tonal transition. Being aware of several alternative analysis strategies, we plan to work on a closer interrogation of the method, its relation to local key analysis, and the comparison of the output to systematic human analyses as provided by [12, 34, 35].

Even though any type of automated approach can never achieve the flexibility of human analysis, we have shown that it can provide an overview of large-scale structures, thus aiding the research process of historical musicology. Since this approach can be scaled up easily without requiring human annotations [36], it allows for corpus studies in a novel order of magnitude, which can enrich musicological research. In future work, we thus intend to apply this method to a wider range of musical contexts involving extensive corpora and individual large-scale works, both of which would benefit from these "at-a-glance" reductions.

---

[4] Galeazzi does not at all favor a monothematic structure as found sometimes in the works of Joseph Haydn. The model described by him is open to new motives in any part of the exposition, not just in the sense of two contrasting themes as modelled by Marx [18].

ABSTRACT

Grammatical models which represent the hierarchical structure of chord sequences have proven very useful in recent analyses of Jazz harmony. A critical resource for building and evaluating such models is a ground-truth database of syntax trees that encode hierarchical analyses of chord sequences. In this paper, we introduce the Jazz Harmony Treebank (JHT), a dataset of hierarchical analyses of complete Jazz standards. The analyses were created and checked by experts, based on lead sheets from the open iRealPro collection. The JHT is publicly available in JavaScript Object Notation (JSON), a human-understandable and machine-readable format for structured data. We additionally discuss statistical properties of the corpus and present a simple open-source web application for the graphical creation and editing of trees which was developed during the creation of the dataset.

1. INTRODUCTION

Jazz music exhibits hierarchical relations between chords. This is particularly apparent in the fact that virtually any chord of a Jazz standard can be prepared by an applied dominant or subdominant. In fact, many chord sequences can be explained as the recursive application of such preparations [41]. Chords that are far apart in time can therefore be directly related, establishing long-range dependencies that can span whole formal sections of pieces. Such hierarchical structures also correlate with empirical findings from music perception research [25]. This is by no means to say that hierarchies are the only relevant relations between chords. Hierarchical chord relations are, however, underrepresented in computational models of harmony to date; the here presented dataset is intended to ease the development of hierarchical models.

Inspired by Schenkerian theory [3, 45] and generative syntax formalisms for natural language, generative theories of harmonic syntax model the hierarchical relations in chord sequences based on formal grammatical

devices such as context-free grammars. Recent research uses formal grammars to represent hierarchical relations in melodies [1, 10, 13, 16, 24, 34], chord sequences [15, 19, 43], and rhythms [18, 29]. The fields of application include music theory [37, 40], music psychology [25, 42], automatic harmonic analysis [7, 8], and automatic music transcription [11, 30, 35].

The aim of this article is to present the Jazz Harmony Treebank (JHT), a dataset of hierarchical harmonic analyses of Jazz standards by music experts in a human-understandable and machine-readable format. We report on the creation of the treebank, describe the musical interpretation of the syntax trees, and explain the decisions that were made to meet the challenges of the annotation procedure. The dataset is available on GitHub. [1]

Treebanks are of particular importance for the study of hierarchical models and their applications. In linguistics, they have been and remain instrumental for many natural language processing tasks. The well-known Penn Treebank [28], first published in the early nineties, is an instructive example since it has been used as an object of study in and of itself [12], as a basis for publishing additional treebanks with different paradigms [21] and for different languages [27], and–most prominently–as a dataset for training and evaluating machine-learning methods [22, 31, 44].

The present article describes the creation process of the JHT. We take this as an opportunity to study the details of harmonic syntax using several concrete examples of Jazz standards. The major challenge of this application lies in the many individual decisions analysts have to take to address the ambiguity of music. Importantly, our goal is not to create uniform syntax trees of Jazz chord sequences, but to describe individual and subjective listening experiences in an unambiguous formal representation. Harmonic relations in sufficiently long chord sequences can be perceived in several ways, without one interpretation being clearly preferable. Therefore, the syntax trees of the JHT are best understood as proposals with a clear interpretation. The trees provide a basis for further analytical discussions, sophisticated computational models, and for education.

1.1 Related Symbolic Datasets

Many existing collections of symbolic data about chord sequences concentrate on providing chord labels for harmonic entities. Two prominent datasets of time-aligned

---

[1] https://github.com/DCMLab/JazzHarmonyTreebank

chord symbols were created by Harte et al. [20] and Burgoyne et al. [2] to study automatic chord transcription from audio. Neuwirth et al. [36] take a more music-theoretically motivated approach by proposing a chord-symbol representation for Western classical music and apply it to scale degree analyses of Beethoven's string quartets. Chen and Su [5] and Devaney et al. [9] similarly label excerpts from common-practice tonality. Micchi et al. [32] combine existing Roman numeral analyses into a meta-dataset.

The datasets just mentioned use chord labels to analyze music given as audio data or in a symbolic representation. Since we analyze the relations between the chords of such sequences, this study is located at a higher level of abstraction. Only a few datasets of hierarchical analyses of sequential musical data are available in divergent formats [39]. Hamanaka et al. [17] and Kirlin [23] created two datasets of tree analyses of melodies of Western Classical Music. Gotham and Ireland [14] study musical form by the creation of datasets in a hierarchical representation. Moss et al. [33] study Brazilian Choro using a dataset with hierarchical form encoding. Granroth-Wilding and Steedman [15] provide a dataset of 76 sub-sequences of Jazz standards with partial harmonic grouping labels. In contrast to previous research that analyzed snippets of musical pieces, the JHT consists of 150 full chord sequences of Jazz standards with complete harmonic syntax trees.

2. HARMONIC SYNTAX

A harmonic syntax tree, as shown in Figure 1a, denotes a mental representation of a musical piece as a whole. Unlike sequential models that describe how, for instance, a sequence of chord symbols is generated chord by chord from the start to the end, hierarchical models describe how the skeleton of a piece is generated and recursively elaborated [43]. In Jazz, the most prominent of those elaboration operations are the duplication of chords and the preparation of a chord by an applied dominant. Each application of an operation establishes a direct relation between two chords. A syntax tree consists exactly of the sum of all those relations. It is therefore not directly a model for first-time listening of a musical piece, but rather for the abstract representation of musicians or listeners who are (implicitly or explicitly) aware of a piece's harmonic relations. This usage of the word *syntax* is closely related to generative syntax formalisms of natural language that address the question of which relations between words a listener must notice to understand the meaning of a sentence [6].

The scope of this paper is limited to tonal Jazz, including Swing, Bossa Nova, Jazz Blues, Bebop, Cool Jazz, and Hard Bop, and excluding parts of traditional Blues, Modal Jazz, Free Jazz, and Modern Jazz. We furthermore excluded tunes such as *Groovin' High* whose harmonic structure requires even more expressive representations than trees. [2] The general idea of harmonic syntax is, however, also applicable to other musical styles such as Western classical music.

2.1 Prolongation and Preparation as Fundamental Principles

In the following, we present the syntactic formalism with a particular emphasis on its musical interpretation. The concept of functional harmony describes an expectation-realization structure between musical objects such as notes, chords, and keys. Consider for example the chords of the final cadence of the Jazz standard *Birk's Works*, Fm6 Abm7 Db7 G%7 C7 Fm6, where G%7 denotes a half-diminished seventh chord with root G. Figure 1b shows the expectation-realization structure of this chord sequence. The first Fm6 establishes the tonic and as such creates the expectation that the progression ends with Fm6. The chords Abm7 and Db7 function as the tritone-substituted subdominant and dominant of C7, respectively. They therefore create expectation that resolves in the (temporally distant) chord C7. The chord G%7 functions as a subdominant chord in F minor. It therefore creates expectation that resolves with the dominant chord C7 which itself resolves into the last tonic chord Fm6. We say that the tonic chords constitute a *prolongation*. The subdominant chords *prepare* the dominant chords and the dominant chords *prepare* the tonic chord. Abstractly, we say that a chord X *refers* to a chord Y if X either prolongs or prepares Y. [3]

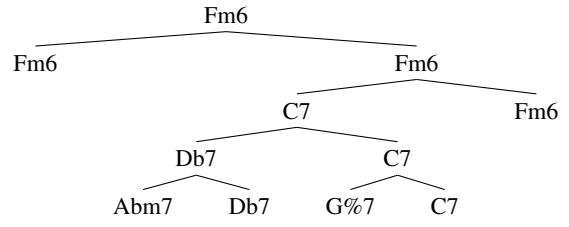
Prolongation and preparation are the two fundamental principles of functional harmonic syntax [41]. They can be formalized as rules of a context-free grammar with chord symbols both as terminals and nonterminals. In the formalization, *strong prolongations* that prolong chords of the same root and chord form are distinguished from *weak prolongations* that prolong a chord with a functionally equivalent chord (e.g., prolongation of C with Am). Note that this concept of weak prolongation is more general than in the GTTM where prolonging chords are for instance required to have the same root [26]. Strong prolongation is represented by rules of the form $X \longrightarrow X\ X$ for chord symbols X (e.g., Fm6 $\longrightarrow$ Fm6 Fm6). For chord symbols X and Y, rules of the form $X \longrightarrow Y\ X$ and $X \longrightarrow X\ Y$ represent weak prolongations if X and Y are functionally equivalent (e.g., Fm6 $\longrightarrow$ Ab Fm6). If otherwise X and Y are not functionally equivalent, $X \longrightarrow Y\ X$ represents a preparation (e.g., Fm6 $\longrightarrow$ C7 Fm6).

The practise of having no separate alphabet of nonterminal symbols, and requiring each binary rule to have a left-hand side symbol also on the right-hand side, is related to dependency grammars [38] and categorical grammars [47] which are well-known in computational linguistics and natural language processing. The symbol that appears both on the left-hand side and the right-hand side is called the *head* of the rule. In our setting of prolongation and preparation, the prolonged (resp. prepared) chord is the head. Therefore, weak prolongation rules may be left- or right-headed, while preparation rules are always right-headed. In sum, our harmony grammar consists of the following rules which model strong prolongation, weak pro-

---

[2] *Groovin' High* exhibits crossing harmonic dependencies between a tonic prolongation from m1 to m5 and a dominant preparation from m4 to m7. A similar tune is *Out of Nowhere*.

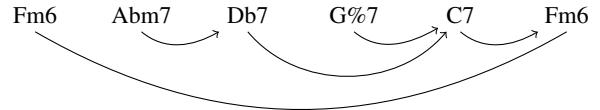
[3] In contrast to models based on the *Generative Theory of Tonal Music* [26], we exclude the concept of departure as a primitive relation, because it is not consistent with our formalization of the expectation-realization structure.

longation, and preparation, respectively,


$X \longrightarrow X\ X$ for any chord X (strong prol.)

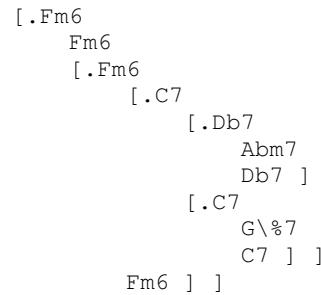
$X \longrightarrow Y\ X \mid X\ Y$ for any chord X and a   (weak prol.)
functionally equivalent
chord Y

$X \longrightarrow Y\ X$ for any chord X and a   (preparation)
chord Y that prepares X

The tree in Figure 1a is a parse tree of the chord sequence Fm6 Abm7 Db7 G%7 C7 Fm6 under such a grammar of harmonic structure. Those parse trees represent exactly the same information as expectation-realization structures such as shown in Figure 1b: Undirected edges correspond to strong prolongations and directed edges correspond to either weak prolongations or preparations. This short example is unambiguous–it has only one plausible syntactic structure. In general, however, there are many syntax trees possible for a chord sequence. Grammar rules and syntax trees can then be weighted by probabilities that capture the plausibility of an analysis [1, 19, 24]. To identify the syntax tree that most accurately describes one's perception of the harmonic structure, other dimensions such as rhythm, form, and melody must also be taken into account. Even the artistic interpretation of a musical performance and the individual musical background of listeners have the potential to influence the perceived harmonic structure of a piece. A formal grammar that purely models chord symbols can therefore only answer the question "Is this a plausible syntax tree for a Jazz standard?", but not the question "Is this tree a good analysis of that particular tune in a particular context?". Until more complete models of musical structure are developed that integrate all relevant musical dimensions, the second question can only be answered by humans.


2.2 Complete Constituents and Open Constituents

Constituents formalize the notion of a musical unit such as a chord or a phrase. In the syntax tree shown in Figure 1a, the complete constituents are exactly the subsequences that are leafs of single subtrees, such as the subsequence Abm7 Db7 G%7 C7. Formally, we call a subsequence a *complete constituent* if it contains a chord, called the *head*, that is transitively referred to by all other chords of the sequence.[4] For instance, the chord C7 is the head of the phrase Abm7 Db7 G%7 C7 and Fm6 is the head of the whole sequence Fm6 Abm7 Db7 G%7 C7 Fm6. In cases in which a constituent is constituted by a strong prolongation (e.g., for the whole sequence of this example), we use the convention that the head is the right chord symbol. Since only the head of a complete constituent is allowed to refer to a chord outside the constituent, the concept of expectation-realization references is generalizable to complete constituents: we say that a complete constituent refers to a chord X if its head refers to X.

---


[4] Note that the word head is used both for rules and constituents. This is not a problem since the head of a constituent is always the head of the top-most rule of its (sub-)tree analysis.

Figure 2: Hierarchical analysis of the initial chords of the Jazz standard *Why Don't You Do Right?* using open constituents (marked with asterisks).

In addition to complete constituents, one other constituent type is used in the JHT analyses. Consider for example the first four measures of the Jazz standard *Why Don't You Do Right?*,

| Dm7 B%7/C | Bb7 A7 | Dm7 B%7/C | Bb7 A7 |,

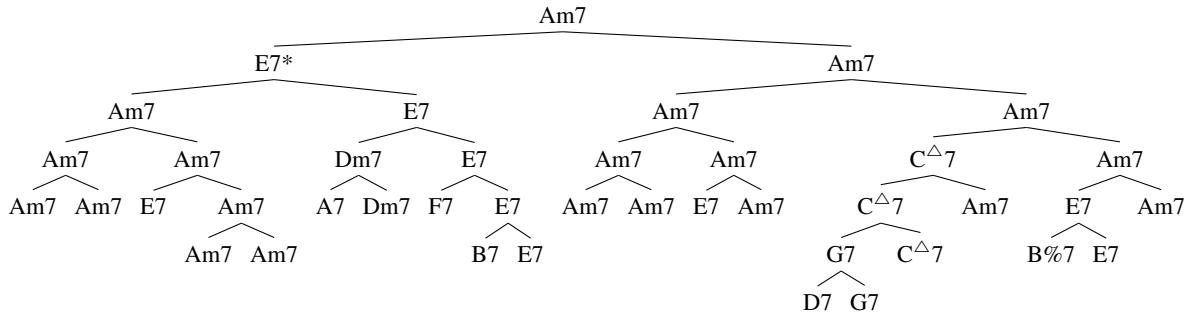
where B%7/C denotes a half-diminished seventh chord with root B and a C in the bass. The first two measures constitute a phrase following the *Lamento* schema (a stepwise descending movement of the bass from scale degree I to scale degree V [4]) that is repeated multiple times in the song. Since the transition from A7 to Dm7 does not sound like a resolution but more like a jump or an interruption (partly because of the repetition of the first two measures), we assume that A7 does not resolve into the following tonic Dm7, but into a tonic later in the song. Therefore, the phrase Dm7 B%7/C Bb7 A7 does constitute some kind of unit as shown in Figure 2a.

Since Dm7 and A7 both refer to a chord outside the phrase (see Figure 2b), the phrase does not have a head. It is therefore not a complete constituent. We call such constituents, in which multiple chords refer to a chord outside of the phrase, *open constituents*. The chords of an open constituent that refer to a chord outside of the constituent are called *chords with open references*. In the example of

Why Don't You Do Right?, the chords Dm7 and A7 are the chords with open references of the open constituent Dm7 B%7/C Bb7 A7. Both chords Dm7 and A7 refer to the same tonic chord Dm7.

The JHT allows a single type of open constituent, called *restricted* open constituent, which consists of two adjacent constituents that refer to the same chord later in the piece. Since all constituents considered in the JHT are restricted in that way, we simple refer to them as open constituents. The restriction enables a further generalization of expectation-realization references to open constituents: We say that an open constituent refers to the chord to which all of its chords with open references refer. As shown in Figure 2a, the topmost node of an open constituent is labeled by the chord symbol of the right child of the node and additionally marked with an asterisk.

Other examples of open constituents are (i) I-VI-II-V-like phrases in *I Got Rhythm* and *I Can't Give You Anything But Love* and, in particular, (ii) tunes of form ABAC in which the B-part ends in a half cadence such as *All of Me*, *How High the Moon*, and *A Fine Romance*. *Summertime*, shown in Figure 3, is a prototypical example of a song with a ABAC form and a half cadence at the end of the B section. The interruption after the half cadence is supported by the movement from scale degree 3 to scale degree 2 in the melody and denoted using an open constituent.

2.3 Interpretation of Open Constituents as Prolongation-Preparation Structures


Syntax trees containing open constituents are interpretable as expectation-realization structures as shown in Figure 2. The interpretation procedure transforms a syntax tree that contains open constituents (e.g., Figure 2a) in to a tree that only represents prolongation and preparation operations (e.g., Figure 2c). This transformed tree then characterizes the expectation-realization structure (e.g., Figure 2b). Since open constituents are explicitly marked with asterisks, their interpretation is unambiguous.

To formalize the interpretation of open constituents, let Y^* be the chord symbol labeling an open constituent consisting of two constituents labeled with chord symbols X and Y. Let further be Z the chord symbol that is referenced by both X and Y. The reference is expressed by Z being the right sibling of the open constituent. The conversion then transforms

Z
Y^*
Z
X
Y
into
Z
X
Z
Y
Z

In the more general case of nested open constituents, the conversion is recursively applied from the root to the leaves of the tree (i.e., top-down).

The JHT contains trees for both representations, with open subtrees and in pure preparation-prolongation form. A python script was used to automatically transform the former into the letter. The script and additional utilities such as for tree traversal and drawing are provided with the treebank.

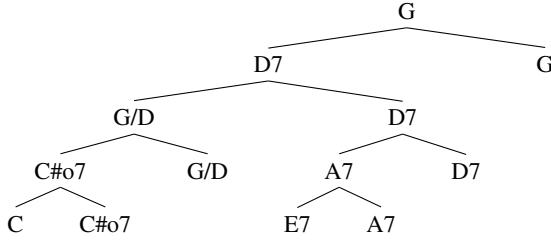
Figure 3: Complete syntax tree of the Jazz standard *Summertime* (turnaround omitted). The top levels of the tree reflect the ABAC form the song using an open constituent.

3. TREE ANNOTATION TOOL

The trees of the JHT are created using a graphical interface implemented as a simple web application, which was developed during the creation of the treebank. The source code of the application is written in ClojureScript (which compiles to JavaScript) and publicly available on GitHub. The application itself is hosted on GitHub pages and can be used independently of this dataset.[5] A screenshot of the application is shown in Figure 1d. The main part of the user interface displays a syntax tree that is represented by a hierarchical button layout. The user interface also contains an input-output section and buttons for creating, deleting, and deselecting tree nodes.

To create a syntax tree, the user inputs a sequence of space-separated strings such as chord symbols. To create an inner node of the tree, the nodes that become the child nodes of the new inner node are selected and combined by pressing a button or a key shortcut. Since the trees are mostly right-headed, the label of the rightmost child is used for the new node by default, but the label of a node can be changed arbitrarily. The output of the application is given as a string representation of the tree in tikz-qtree format as shown in Figure 1c and in JSON format as shown in Figure 1e.[6] Existing trees can be edited by loading them in any of these two formats. Since the application is designed to be agnostic to annotation conventions, it allows arbitrary labels and rule arities.

4. ANNOTATION PROCEDURE

All analyses in the dataset begin from chord sequences drawn from the iRealPro collection of Jazz standards. This collection was created by the user community of the iReal-Pro app[7] and transferred into kern format by Shanahan et al. [46].[8] We transformed the data into a JSON-like format and occasionally corrected individual chord symbols when we noticed serious differences between the iRealPro data and publicly available *Real Books* (i.e., collections of lead sheets.). Annotations of bass notes and optional chord


tones such as ninths and elevenths were excluded from the chord symbols. Chord symbols with a duration of more than one measure were split into multiple chord symbols. 150 Jazz standards were selected for analysis (i) by filtering pieces that are within the scope of the theory of harmonic syntax described in Section 2 and (ii) by preferring shorter pieces. If applicable, turnarounds at the end of a lead sheet were deleted or a final tonic chord not contained in the lead sheet was added. All repetitions were unfolded and codas were appended at the positions indicated in the lead sheet. The selected Jazz standards were initially analyzed by the first author and a student assistant. The analyses were then reviewed by the second and the third author and discussed in the group. To ensure consistent analyses across all 150 Jazz standards, all final tree editing was performed by the first author.

Every hierarchical analysis denotes at least one author's mental representation of the harmonic structure of a Jazz standard. Each analysis is therefore also influenced by other musical features such as harmonic rhythm, phrasing, musical form, and melody. In ambiguous cases, the analyst chose the option that he seemed most important. These choices were necessary, because a single syntax tree can only encode one harmonic function for each chord. For example in the key C major, a C major triad can act as a tonic or as a preparation of a following F major chord. For five particularly ambiguous tunes, we provide alternative analyses in the treebank.

Since the iRealPro lead sheets were created and collected by the community of the application, the chord symbol usage is not fully consistent across the pieces. For instance, a Fm6 chord symbol can denote a tonic chord in F minor over a Dorian scale or a Bb9 chord with omitted root and fifth in the bass. Another example is that fourth-voicings are commonly denoted as suspension chords while actual suspensions of the scale degree V (e.g., suspension of C and E by B and D in a G major triad) are sometimes denoted as chords over the scale degree I (with or without explicitly mentioning the second inversion).

Furthermore, some chords do not have a proper harmonic function, but are better explained as voice-leading connections between two chords. The chords C C#o7 G/D at the beginning of the final 8 measures of *Bill Bailey* are an example of such a voice-leading connection (see Figure 4). Moreover, these final measures are an example of

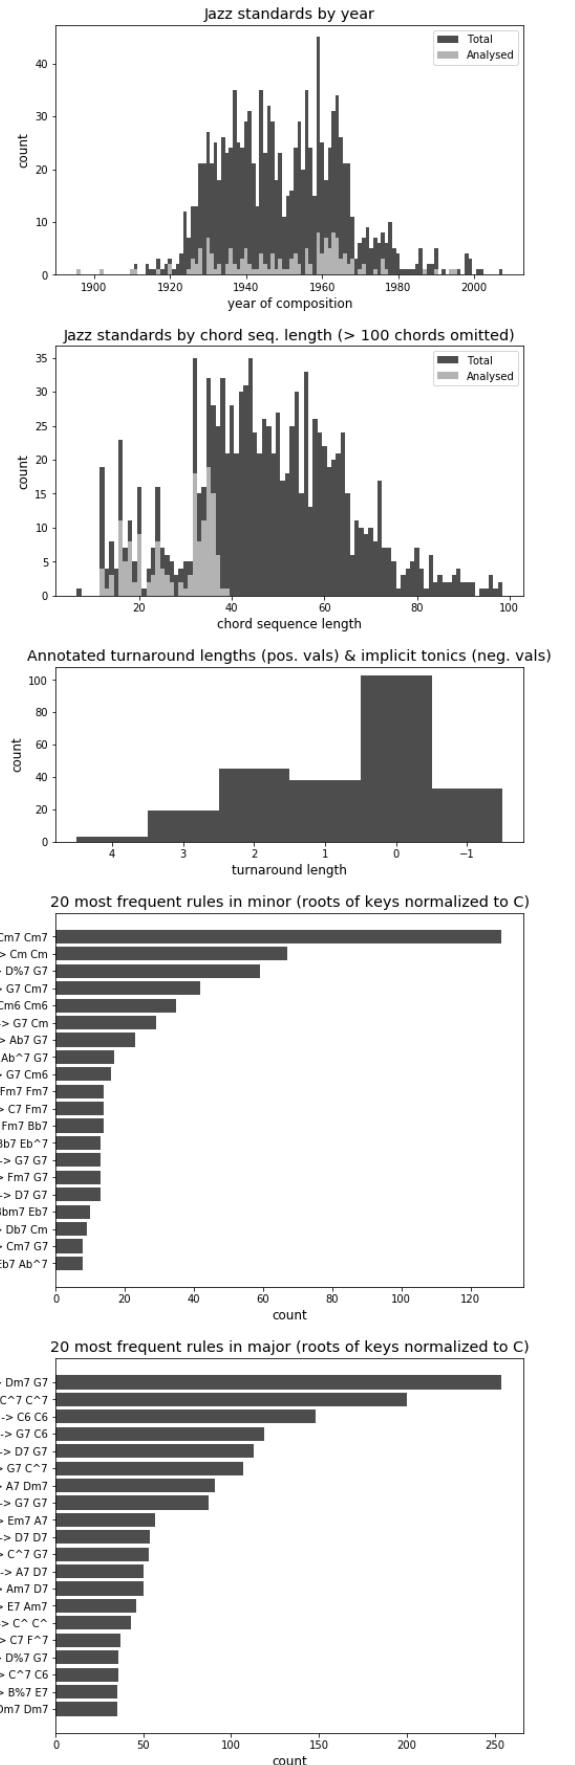
Figure 4: Syntax tree of the final 8 measures of *Bill Bailey* (turnaround omitted).

a common closing pattern. This pattern starts on the scale degree IV in its first measure, then transitions to a suspension of the scale degree V in measure 3, jumps away, and finally approaches the tonic through the cycle of fifths.

5. DATASET SUMMARY


The JHT is provided as a single file in JavaScript Object Notation (JSON) format. For each Jazz standard, this file contains the chord sequence with rhythmical information (measures and beats), metadata about title, composer(s), year of composition, time signature, and key (root & major/minor) as well as the tree analyses. [9]

In addition to the hierarchical analyses, some pieces contain a turnaround annotation represented as an integer. A value of zero means that the Jazz standard ends with a tonic chord. A positive value n means that the lead sheet of the piece ends with a turnaround of length n. For example, the chord sequence of *I love Paris* (in C major) has a turnaround length of $n = 2$, because it ends with the chords Dm7 G7 C6 D%7 G7. A negative turnaround annotation means that the tonic of the piece is not at the end of the piece, but at the beginning. A value of -1 indicates, for example, that the first chord of the chord sequence is the tonic of the piece, like in *Solar*. In rare cases, the tonic is not the first chord but the n-th chord which is represented by a turnaround annotation of $-n$.

The 150 chord sequences analysed in the treebank have an average length of 27.75 and consist of 11697 chords in total with 92 unique chord symbols. The syntax trees consist in total of 3899 binary rule applications with 512 unique rules and 268 open constituents. The average tree height is 7.57.

Further descriptive statistics of the JHT are visualized in Figure 5. The first plot shows that the subset of the analyzed pieces is chosen relatively independently from the year of composition. The second plot shows the bias for short pieces in this subset. The third plot shows that the length of turnarounds, if present, usually ranges between 1 and 3. The two last plots show separately for major and minor keys how often a context-free grammar rule is used in the hierarchical analyses. For these plots, all chord sequences were transposed to C major or to C minor, respectively. Prolongations of the tonic, preparations of the tonic by the fifth scale degree, and preparations of the fifth scale degree by the second are by far the most common rules.

---

[9] The metadata was copied from the iRealPro dataset without detailed validity checking. It is provided for convenience.

ABSTRACT

The human ability to track musical downbeats is robust to changes in tempo, and it extends to tempi never previously encountered. We propose a deterministic time-warping operation that enables this skill in a convolutional neural network (CNN) by allowing the network to learn rhythmic patterns independently of tempo. Unlike conventional deep learning approaches, which learn rhythmic patterns at the tempi present in the training dataset, the patterns learned in our model are tempo-invariant, leading to better tempo generalisation and more efficient usage of the network capacity.

We test the generalisation property on a synthetic dataset created by rendering the Groove MIDI Dataset using FluidSynth, split into a training set containing the original performances and a test set containing tempo-scaled versions rendered with different SoundFonts (test-time augmentation). The proposed model generalises nearly perfectly to unseen tempi (F-measure of 0.89 on both training and test sets), whereas a comparable conventional CNN achieves similar accuracy only for the training set (0.89) and drops to 0.54 on the test set. The generalisation advantage of the proposed model extends to real music, as shown by results on the GTZAN and Ballroom datasets.

1. INTRODUCTION

Human musicians easily identify the downbeat (the first beat of each bar) in a piece of music and will effortlessly adjust to a variety of tempi, even ones never before encountered. This ability is the likely result of patterns and tempi being processed at distinct locations in the human brain [1].

We argue that factorising rhythm into tempo and tempo-invariant rhythmic patterns is desirable for a machine-learned downbeat detection system as much as it is for the human brain. First, factorised representations generally reduce the number of parameters that need to be learned. Second, having disentangled tempo from pattern we can

transfer information learned for one tempo to all others, eliminating the need for training datasets to cover all combinations of tempo and pattern.

Identifying invariances to disentangle representations has proven useful in other domains [2]: translation invariance was the main motivation behind CNNs [3] — the identity of a face should not depend on its position in an image. Similarly, voices retain many of their characteristics as pitch and level change, which can be exploited to predict pitch [4] and vocal activity [5]. Crucially, methods exploiting such invariances don't only generalise better than non-invariant models, they also perform better overall.

Some beat and downbeat trackers first estimate tempo (or make use of a tempo oracle) and use the pre-calculated tempo information in the final tracking step [6–15]. Doing so disentangles tempo and tempo-independent representations at the cost of propagating errors from the tempo estimation step to the final result. It is therefore desirable to estimate tempo and phase simultaneously [16–20], which however leads to a much larger parameter space. Factorising this space to make it amenable for machine learning is the core aim of this paper.

In recent years, many beat and downbeat tracking methods changed their front-end audio processing from hand-engineered onset detection functions towards beat-activation signals generated by neural networks [21–23]. Deep learning architectures such as convolutional and recurrent neural networks are trained to directly classify the beat and downbeat frames, and therefore the resulting signal is usually cleaner.

By extending the receptive field to several seconds, such architectures are able to identify rhythmic patterns at longer time scales, a prerequisite for predicting the downbeat. But conventional CNN implementations learn rhythmic patterns separately for each tempo, which introduces two problems. First, since datasets are biased towards mid-tempo songs, it introduces a tempo-bias that no post-processing stage can correct. Second, it stores similar rhythms redundantly, once for every relevant tempo, i.e. it makes inefficient use of network capacity. Our proposed approach resolves these issues by learning rhythmic patterns that apply to all tempi.

The two technical contributions are as follows:

1. the introduction of a scale-invariant convolutional layer that learns temporal patterns irrespective of their scale.

2. the application of the scale-invariant convolutional layer to CNN-based downbeat tracking to explicitly learn tempo-invariant rhythmic patterns.

Similar approaches to achieve scale-invariant CNNs, have been developed in the field of computer vision [24, 25], while no previous application exists for musical signal analysis, to the best of our knowledge.

We demonstrate that the proposed method generalises better over unseen tempi and requires lower capacity with respect to a standard CNN-based downbeat tracker. The method also achieves good results against academic test sets.

2. MODEL

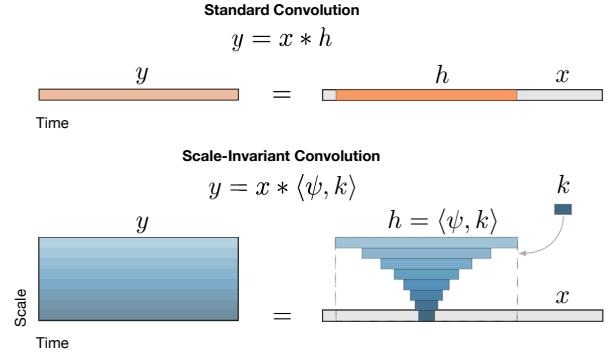
The proposed downbeat tracking model has two components: a neural network to estimate the joint probability of downbeat presence and tempo for each time frame, using tempo-invariant convolution, and a hidden Markov model (HMM) to infer a globally optimal sequence of downbeat locations from the probability estimate.

We discuss the proposed scale-invariant convolution in Sec. 2.1 and its tempo-invariant application in Sec. 2.2. The entire neural network is described in Sec. 2.3 and the post-processing HMM in Sec. 2.4.

2.1 Scale-invariant convolutional layer

In order to achieve scale invariance we generalise the conventional convolutional neural network layer.

2.1.1 Single-channel

We explain this first in terms of a one-dimensional input tensor $x \in \mathbb{R}^N$ and only one kernel $h \in \mathbb{R}^{N^*}$, and later generalise the explanation to multiple channels in Sec. 2.1.2. Conventional convolutional layers convolve x with h to obtain the output tensor $y \in \mathbb{R}^{N-N^*+1}$


$$y = x * h, \tag{1}$$

where $*$ refers to the discrete convolution operation. Here, the kernel h is updated directly during back-propagation, and there is no concept of scale. Any two patterns that are identical in all but scale (e.g. one is a "stretched" version of the other) cannot be represented by the same kernel.

To address this shortcoming, we factorise the kernel representation into scale and pattern by parametrising the kernel as the dot product $h_j = \langle \psi_j, k \rangle$ between a fixed scaling tensor $\psi_j \in \mathbb{R}^{N^* \times M}$ and a scale-invariant pattern $k \in \mathbb{R}^M$. Only the pattern is updated during network training, and the scaling tensor, corresponding to S scaling matrices, is pre-calculated (Sec. 2.1.3). The operation adds an explicit scale dimension to the convolution output

$$y_j = x * h_j = x * \langle \psi_j, k \rangle. \tag{2}$$

The convolution kernel is thus factorised into a constant scaling tensor ψ and trainable weights k that learn a scale-invariant pattern. A representation of a scale-invariant convolution is shown in Figure 1.

Figure 1. The figure shows a representation of the standard and scale-invariant convolution operations with input/output channel dimensions removed for simplicity. In order to achieve scale invariance, we parametrise the kernel as the dot product of two tensors ψ and k, where ψ is a deterministic scaling tensor and k is the trained part that will learn scale-invariant patterns. The resulting kernel h contains multiple scaled versions of k.

	layer input	
variable	**single-channel**	**multi-channel**
# frames	N	
# pattern frames	M	
# scales	S	
# input channels	1	C_x
# kernels	1	H
signal x	$\mathbb{R}^N$	$\mathbb{R}^{N \times C_x}$
patterns k	$\mathbb{R}^M$	$\mathbb{R}^{M \times C_x \times H}$
kernel h	$\mathbb{R}^{N^* \times S}$	$\mathbb{R}^{N^* \times C_x \times S \times H}$
output y	$\mathbb{R}^{(N-N^*+1) \times S}$	$\mathbb{R}^{(N-N^*+1) \times S \times H}$
scaling tensor ψ	$\mathbb{R}^{N^* \times M \times S}$	
scale indices	$j = 0, \ldots, S-1$	

Table 1. Variables and dimensions.

2.1.2 Multi-channel

Usually the input to the convolutional layer has $C_x > 1$ input channels and there are $H > 1$ kernels. The formulas in Section 2.1 can easily be extended by the channel dimension, as illustrated in Table 1.

2.1.3 Scaling tensor

The scaling tensor ψ contains S scaling matrices from size M to $s_j M$ where s_j are the scale factors.

$$\psi_{n,m,j} = \int_{\tilde{s}} \int_{\tilde{n}} \delta(\tilde{n} - \tilde{s}m)\kappa_n(n - \tilde{n})\kappa_s(s_j - \tilde{s}) d\tilde{n} d\tilde{s}, \tag{3}$$

where δ is the Dirac delta function and κ_n, κ_s are defined as follows:

$$\kappa_n(d) = \sin(\pi d)/(\pi d)$$
$$\kappa_s(d) = \alpha \cos^2(\alpha d\pi/2)\mathcal{H}(1 - \alpha|d|),$$

where $\mathcal{H}$ is the Heaviside step function. The inner integral can be interpreted as computing a resampling matrix for a given scale factor and the outer integral as smoothing along the scale dimension, with the parameter α of the function κ_s controlling the amount of smoothing applied. The size N^* of the scaling tensor ψ (and the resulting convolutional kernel h) is derived from the most stretched version of k:

$$N^* = \max_j s_j M. \tag{4}$$

2.1.4 Stacking scale-invariant layers

After the first scale-invariant layer, the tensor has an additional dimension representing scale. In order to add further scale invariant convolutional layers without losing scale invariance, subsequent operations are applied scale-wise:

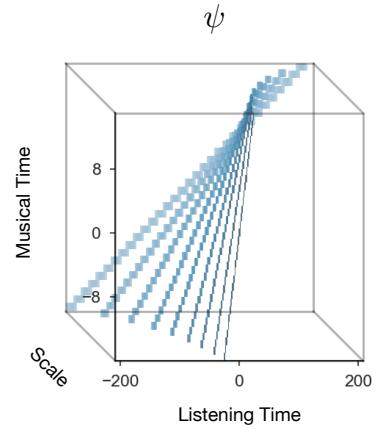
$$y_j = x_j * \langle \psi_j, k \rangle. \tag{5}$$

The only difference with Eq. (2) is that the input tensor x of Eq. (5) already contains S scales, hence the added subscript j.

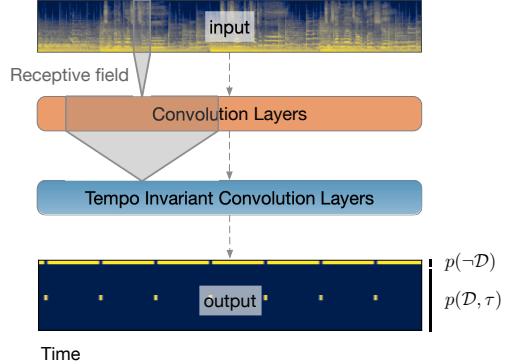
2.2 Tempo invariance

In the context of the downbeat tracking task, tempo behaves as a scale factor and the tempo-invariant patterns are rhythmic patterns. We construct the sequence of scale factors s as

$$s_j = \frac{r\tau_j B}{M}, \quad \tau_j = \tau_0 2^{\frac{j}{T}} \tag{6}$$

where τ_j are the beat periods, r is the frame rate of the input feature, B is the number of beats spanned by the convolution kernel factor k, τ_0 is the shortest beat period, and T is the desired number of tempo samples per octave. The matrix k has a simple interpretation as a set of rhythm fragments in musical time with M samples spanning B beats.


To mimic our perception of tempo, the scale factors in Eq. (6) are log-spaced, therefore the integral in Eq. (3) becomes:

$$\psi_{n,m,j} = \int_{\tilde{j}} \int_{\tilde{n}} \delta(\tilde{n} - s_{\tilde{j}} m) \kappa_n(n - \tilde{n}) \kappa_s(j - \tilde{j}) d\tilde{n} d\tilde{j}, \tag{7}$$


where the parameter α of the function κ_s has been set to 1. A representation of the scaling tensor used in the tempo-invariant convolution is shown in Figure 2.

2.3 Network

The tempo-invariant network (Fig. 3) is a fully convolutional deep neural network, where the layers are conceptually divided into two groups. The first group of layers are regular one-dimensional convolutional layers and act as onset detectors. The receptive field is constrained in order to preserve the tempo-invariance property of the model: if even short rhythmic fragments are learned at a specific tempo, the invariance assumption would be violated. We limit the maximum size of the receptive field to 0.25 seconds, i.e. the period of a beat at 240 BPM.

Figure 2. The scaling tensor ψ is a sparse 3-dimensional constant tensor. In the figure ψ is represented as a cube where the 0 bins are rendered transparent. ψ transforms the rhythm patterns contained in the kernel k from musical time (e.g. 16th notes) to listening time (e.g. frames) over multiple scales.

Figure 3. A global view of the neural network. The first group of layers are regular convolutional layers and act as onset detectors. They have a small receptive field, in order to focus on acoustic features and avoid learning rhythmic patterns, which will be learned by the successive tempo-invariant layers. The output tensor represents joint probabilities of downbeat presence $\mathcal{D}$ and tempo τ.

The second group is a stack of tempo-invariant convolutional layers (as described in Sec. 2.1, 2.2). The receptive field is measured in musical-time, with each layer spanning $B = 4$ beats. The last layer outputs only one channel, producing a 2-dimensional (frame and tempo) output tensor.

The activations of the last layer represent the scores (logits) of having a downbeat at a specific tempo. An additional constant zero bin [1] is concatenated to these activations for each frame to model the score of having no downbeat. After applying the softmax, the output o represents the joint probability of the downbeat presence $\mathcal{D}$ at a specific tempo τ

$$o_j = \begin{cases} p(\mathcal{D}, \tau_j) & j = 0, \ldots, S-1 \\ p(\neg\mathcal{D}) & j = S \end{cases} \tag{8}$$

---

[1] We can keep this constant because the other output values will adapt automatically.

The categorical cross-entropy loss is then applied frame-wise, with a weighting scheme that balances the loss contribution on downbeat versus non-downbeat frames. [2]

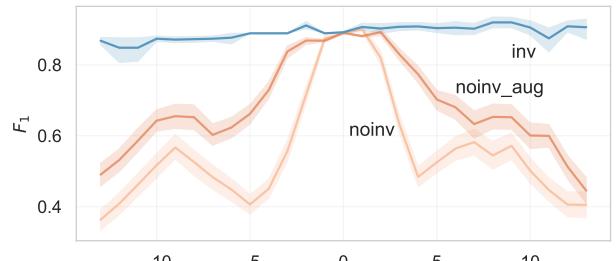
The target tensors are generated from the downbeat annotations by spreading the downbeat locations to the neighbouring time frames and tempi using a rectangular window (0.1 seconds wide) for time and a raised cosine window ($2/T$ octaves wide) for tempo. The network is trained with stochastic gradient descent using RMSprop, early stopping and learning rate reduction when the validation loss reaches a plateau.

2.4 Post-processing

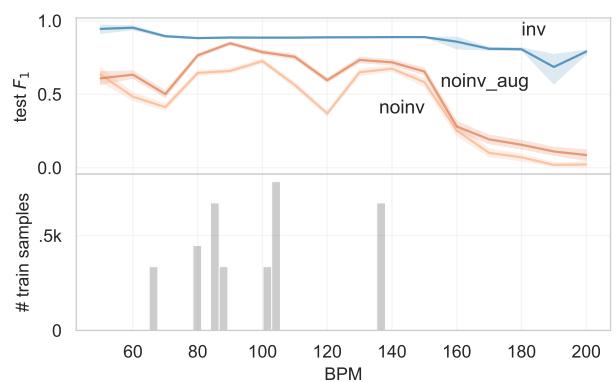
In order to transform the output activations of the network into a sequence of downbeat locations, we use a frame-wise HMM with the state-space [26].

In its original form, this post-processing method uses a network activation that only encodes beat probability at each position. In the proposed tempo-invariant neural network the output activation models the joint probability of downbeat presence *and tempo*, enabling a more explicit connection to the post-processing HMM, via a slightly modified observation model:

$$
P(o_j | q) = \begin{cases} c(\tau_j, \tau_q) o_j & q \in \mathcal{D}, \quad j < S \\ o_S / (\sigma S) & q \in \neg \mathcal{D} \end{cases} \quad (9)
$$

where q is the state variable having tempo τ_q, $\mathcal{D}$ is the set of downbeat states, $c(\tau_j, \tau_q)$ is the interpolation coefficient from the tempi modeled by the network τ_j to the tempi modeled by the HMM τ_q and σ approximates the proportion of non-downbeat and downbeat states ($|\neg\mathcal{D}|/|\mathcal{D}|$).


3. EXPERIMENTS

In this section we describe the two experiments conducted in order to test the tempo-invariance property of the proposed architecture with respect to a regular CNN. The first experiment, described in Sec. 3.1, uses a synthetic dataset of drum MIDI recordings. The second experiment, outlined in Sec. 3.2, evaluates the potential of the proposed algorithm on real music.


3.1 Tempo-invariance

We test the robustness of our model by training a regular CNN and a tempo-invariant CNN on a tempo-biased training dataset and evaluating on a tempo-unbiased test set. In order to control the tempo distribution of the dataset, we start with a set of MIDI drum patterns from the magenta-groove dataset [27], randomly selecting 4 bars from each of the 40 `eval-sessions`, resulting in 160 patterns. These rhythms were then synthesised at 27 scaled tempi, with scale factors $\varepsilon_i = 2^{i/26}$ ($-13 \leq i \leq 13$) with respect to the original tempo of the recording. Each track starts with a short silence, the duration of which is randomly chosen within a bar length, after which the rhythm is repeated

(a) accuracy with respect to relative tempo change

(b) accuracy with respect to absolute tempo

Figure 4. Tempo invariance experiment using a dataset of 27 time scaled versions of a set of drum patterns. The scale factors $\varepsilon_i = 2^{i/26}$ range from 0.707 to 1.414. A tempo-invariant CNN (`inv`) and a standard CNN (`noinv`) are trained on the non scaled versions (scale=0) and tested on all others. A standard CNN trained on scales $[-1, 1]$ (`noinv_aug`) simulates the effect of data augmentation. Figure (a) shows that the invariant model is able to generalise on seen patterns at unseen tempi. Figure (b) shows that the effect of the tempo-biased training set: for non-invariant models the benefit is localised, while the invariant model distributes the rhythmic information across the entire tempo spectrum.

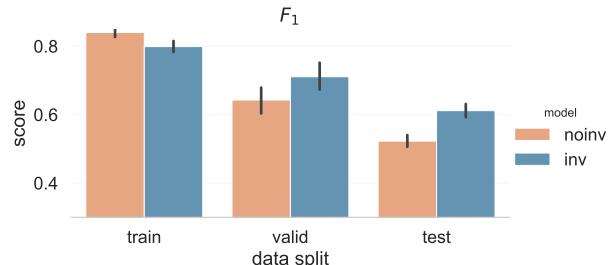
4 times. Audio samples are rendered using FluidSynth [3] with a set of 40 combinations of SoundFonts [4] and instruments, resulting in 172800 audio files. The synthesised audio is pre-processed to obtain a log-amplitude mel-spectrogram with 64 frequency bins and $r = 50$ frames per second.

The tempo-biased training set contains the original tempi (scale factor: $\varepsilon_0 = 1$), while the tempo-unbiased test set contains all scaled versions. The two sets were rendered with different SoundFonts.

We compared a tempo-invariant architecture (`inv`) with a regular CNN (`noinv`). The hyper-parameter configurations are shown in Table 2 and were selected maximising the accuracy on the validation set.

The results of the experiment are shown in Fig. 4 in terms of F_1 score, using the standard distance threshold

group	architecture	
	inv	noinv
1	CNN 3×32	CNN 3×32
2	TI-CNN 2×16 1×1	dil-CNN 3×64 1×1
#params	60k	80k

Table 2. Architectures used in the experiment. Groups of layers are expressed as (number of layers × output channels). All layers in group 1 have kernel size equal to 3 frames. dil-CNN is a stack of dilated convolution layers with kernel size equal to 7 frames and exponentially increasing dilation factors: $2, 4, 8, 16$. The specific hyperparameters of the tempo-invariant network TI-CNN are configured as follows: $T = 8, \tau_0 = 0.25, S = 25, M = 64, B = 4$. ReLU non-linearities are used on both architectures.


of 70 ms on both sides of the annotated downbeats [28]. Despite the tempo bias of the training set, the accuracy of the proposed tempo-invariant architecture is approximately constant across the tempo spectrum. Conversely, the non-invariant CNN performs better on the tempi that are present in the training and validation set. Specifically, Fig. 4a shows that the two architectures perform equally well on the training set containing the rhythms at their original tempo (scale equal to 0 in the figure), while the accuracy of the non-invariant network drops for the scaled versions. A different view of the same results on Fig. 4b highlights how the test set accuracy depends on the scaled tempo. The accuracy of the regular CNN peaks around the tempi that are present in the training set, showing that the contribution of the training samples is localised in tempo. The proposed architecture performs better (even at the tempi that are present in the training set) because it efficiently distributes the benefit of all training samples over all tempi.

In order to simulate the effect of data augmentation on the non-invariant model, we also trained an instance of the non-invariant model (`noinv_aug`) including two scaled versions (ε_i with $|i| \leq 1$) in the training set. As shown in the figure, data-augmentation improves generalisation, but has similar tempo dependency effects.

3.2 Music data

In this experiment we used real music recordings. We trained on an internal dataset (1368 excerpts from a variety of genres, summing up to 10 hours of music) and the RWC dataset [29] (Popular, Genre and Jazz subsets) and tested on Ballroom [30,31] and GTZAN [32] datasets. With respect to the previous experiment we used the same input features, but larger networks [5] because of the higher amount of information contained in fully arranged record-

---

[5] In terms of number of channels, layers and convolution kernel sizes, optimized on the validation set.

Figure 5. Results of the experiment on music data in terms of F-measure. Track scores are used to compute the average and the confidence intervals at 95% (using bootstrapping). The proposed tempo-invariant architecture is able to better generalise over unseen data with respect to its standard CNN counterpart.

ings, with `inv` having 170k trainable parameters and `noinv` 340k.

The results in Fig. 5 show that the proposed tempo-invariant architecture is performing worse on the training set, but better on the validation and test set, with the comparisons on train and test set being statistically significant ($p < 0.001$). Here the tempo-invariant architecture seems to act as a regularisation, allocating the network capacity to learning patterns that better generalise on unseen data, instead of fitting to the training set.

4. DISCUSSION

Since musicians are relentlessly creative, previously unseen rhythmic patterns keep being invented, much like "out-of-vocabulary" words in natural language processing [33]. As a result, the generalisation power of tempo-invariant approaches is likely to remain useful. Once tuned for optimal input representation and network capacity we expect tempo-invariant models to have an edge particularly on new, non-public test datasets.

Disentangling timbral pattern and tempo may also be useful to tasks such as auto-tagging: models can learn that some classes have a single precise tempo (e.g. ballroom dances [30]), some have varying tempos within a range (e.g. broader genres or moods), and others still are completely invariant to tempo (e.g. instrumentation).

5. CONCLUSIONS

We introduced a scale-invariant convolution layer and used it as the main component of our tempo-invariant neural network architecture for downbeat tracking. We experimented on drum grooves and real music data, showing that the proposed architecture generalises to unseen tempi by design and achieves higher accuracy with lower capacity compared to a standard CNN.

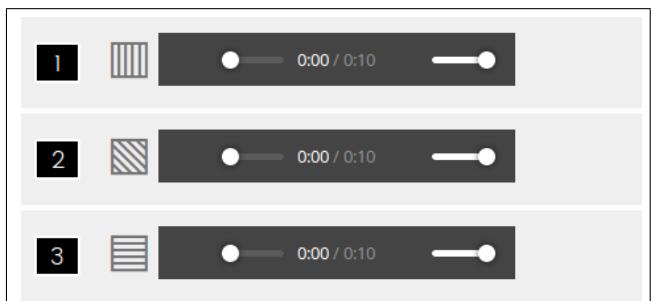
ABSTRACT

More and more music is becoming available digitally, increasing the need to navigate through large numbers of audio tracks easily. One approach for improving the browsing experience is *music thumbnailing*: the procedure of finding a continuous fragment that can represent the whole musical piece. This paper proposes a human-centred approach to creating thumbnails based on listeners' perception, directly asking listeners to identify the most characteristic fragment. We carried out a user study to assign representativeness scores to multiple fragments from a selection of popular music tracks. To strengthen the results, we performed a replication of the same user study with new participants and a different set of music. Thereafter, we used audio features, a segmentation algorithm, and participants' overall familiarity with the songs to predict representativeness scores. The results suggest that neither segmentation nor familiarity have a significant impact on users' thumbnail preferences: even segments with starting points that pay no regard to song structure can be suitable thumbnails. Three high-level audio characteristics, however, do impact the perceived representativeness of a fragment: Raw Intensity, Melodic Conventionality, and Conventionality of Intensity. Based on these findings, we propose a new, easy-to-apply method for music thumbnailing.

1. INTRODUCTION

With the rise of the digital age, more and more music is becoming available; streaming services and websites make music readily accessible to the public. The availability of so much music increases the need to navigate through large numbers of audio tracks easily, e.g., the results of search queries or long playlists. One approach to improve the browsing experience is to create music thumbnails. Music *thumbnailing*, or audio thumbnailing, is the procedure of finding a continuous segment within a musical piece which represents the whole piece [1–4]. By using these shorter fragments of audio, music thumbnails allow users to explore large quantities of music without spending too


much time listening to or seeking within complete musical pieces [2, 5]. Audio thumbnailing should not be confused with music *summarisation*, which combines snippets of different parts of the song [2, 6], or audio *fingerprinting*, which creates a simpler representation of musical piece in the form of a vector or sequence [7, 8].

One practical example of music thumbnails even outside the major streaming services is Muziekweb, a Dutch music library that aims to make music and information about music available to everyone. [1] On their website, excerpts can be played to get a sense of the musical pieces on offer. To be able to assess the musical pieces, representative music thumbnails are a must. Currently, however, Muziekweb simply chooses its thumbnails randomly, which makes it likely that these excerpts do not represent the musical pieces very well.

There is no consensus about what approach works best to create good music thumbnails, and even the concept of music thumbnails is ambiguous [3–5, 9–11]. Approaches in previous studies include identification of the most repeated part [1, 4], finding the segment which is the most similar to the average sound [2], chorus detection [3–5, 9, 11], and structural identification of the "main part" [10]. Nonetheless, there is overlap between these approaches as the chorus is often the most repeated part in pop music [4] and is also likely to be the most memorable [3].

This paper proposes a user-driven approach by using the listeners' perception to improve upon Muziekweb's current thumbnailing method. Previous research has dis-

Figure 1. Example of three playable audio fragments of the same tune as displayed in the user study. To be able to distinguish the fragments, the players are displayed with differently filled squares. The numbers show the ranking chosen by the participant.

cussed that the best thumbnail could be the segment containing the most memorable and distinguishable part of the musical piece [1, 3]. This aligns with the cognitive definition of *hooks*: hooks are the most salient segments in a musical piece, making them the most recognisable part of a song [12]. Suggestions have already been made about the potential of hooks and catchiness for music search engines [13]. Therefore, the method here is inspired by previous studies on catchiness to identify the most representative part as a music thumbnail.

To use listeners' perception for thumbnailing, we set up a user study to gain information on the representativeness of different fragments of the same tunes. The main task in this user study asked participants to rank three segments of the same song with respect to how well they conveyed a general idea of the song (see Figure 1). Thereafter, features were extracted from the audio fragments with the CATCHY toolbox [14]. To increase the interpretability of these features, we conducted an exploratory factor analysis for dimensionality reduction. These factors, the segmentation method, and the participant's familiarity with the songs were used to create an approximation of the scores from the user study with a linear model. Finally, we combined the feature loadings of the factors and the parameters of the linear model to create a function that can rate the relative representativeness of fragments within a song. The best-rated fragment in any set of candidates would be chosen as the audio thumbnail. To confirm our findings, we repeated the user study with new participants and a different music set and found a very similar result. Based on the findings, we propose a new user-driven method for music thumbnailing. Although we are certainly not the first researchers to test a thumbnailing algorithm on users, to our knowledge, this is the first published study to derive an algorithm for music thumbnailing algorithm directly from user preferences.

2. METHOD

2.1 Music Selection

Consistent with previous studies on catchiness [12, 14, 15], our study focused on popular music. The music came from lists of the 100 most-played songs on Muziekweb's website in 2017 and 2018, to ensure the data consisted of well-known music. Where the lists contained more than one song in languages other than English or Dutch (the two languages that would be most familiar to Muziekweb users), we retained only the most-played song. The resulting list was further reduced by removing songs with low play counts from artists or albums that appeared multiple times on the lists, in order to keep the music as diverse as possible. This resulted in a set of 60 songs, which Muziekweb provided to us as FLAC files. [2]

---

[2] The song list, segment start times, computed features, and analysis code can be found at `https://github.com/arianne-n/ISMIR-2020-User-Driven-Music-Thumbnailing`

2.2 Segmentation

Because hooks mostly occur at the start of structural sections [12, 13], we used a boundary detection algorithm to identify the start of these structural sections. Specifically, we used an algorithm that identifies boundaries based on structural features and time series similarity [16], as implemented in the Python package MSAF [17]. [3] We used Pitch Class Profiles (PCPs) as the underlying time series for segmentation, as the audio features we use to analyse the results are also mostly harmonic. The other harmonic time series available in MSAF were either too slow or resulted in too few boundaries to be feasible. Moreover, using PCPs aligns with previous thumbnailing studies that describe the importance of chroma [1, 11].

Thumbnails are by their nature short, and as such, our user study used only short excerpts from the original audio: 9.95 seconds, starting from one of the detected boundaries. Muziekweb is only allowed to make 29.9 seconds of music per song available on their site due to copyright, and excerpts of this length allow users to compare three segments from each song without causing copyright violations. Previous studies have assumed the middle of the song to be the most characteristic [3, 5], while others have noted the intro can also serve as a hook [18, 19]; given the conflicting opinions in the literature, we simply chose four segments at random among all the detected boundaries.

To check whether the segmentation method impacts the representativeness of fragments, we also created two extra baseline segments per song. The first is based on Muziekweb's current method: it picks any random point in a song as the start of the segment. The second baseline segment starts at the 1-minute mark in the song, skipping the intro, but staying away from the end. This resulted in six segments for each of the 60 songs.

2.3 User Study Design

The aim of the user study was to provide scores of the representative power for each of the six segments of the 60 songs. The study was carried out as a web-based survey, accessible between 3 April 2019 and 27 May 2019. Participants were recruited via social media and the Muziekweb website. Consent from the institutional ethics committee was acquired prior to collecting any data.

The main task in the survey was similar to the prediction task in the Hooked on Music study of catchiness [12], but rather than asking participants to make a binary choice, participants needed to provide an ordered ranking. Each question would display the title and artist of a song along with three audio fragments (see Figure 1). The participants were asked to rank the fragments on how well they helped them to get a sense of what the song is about (*"een idee van het nummer"*). This phrasing was intended to trigger participants to follow their gut feeling about the song, without thinking too much; asking for a ranking was intended to encourage participants to provide finer-grained distinctions than we might have obtained from a traditional rating

---

[3] `https://msaf.readthedocs.io/`

scale. The participants were also asked whether they were familiar with the song with a simple yes–no question.

The survey was implemented in the online survey platform Qualtrics. [4] Qualtrics offers a built-in drag-and-drop option whereby users can drag alternatives and place them in their preferred order. To help users distinguish among the different options visually, we gave each fragment one of six differently filled squares as a drag handle. These fill patterns have no apparent ordering in and of themselves, so as to avoid any bias during the ranking.

The survey started with a short explanation of the task, an informed consent form, and two practice songs. Then, the 60 songs were presented to each participant in random order, with a random selection of three of its segments also initially presented in random order. We elected for three segments instead of all six in order to keep the task manageable for participants. Participants were allowed to participate only once to reduce chances of bias. Participants were not required to complete all 60 songs and could end the survey whenever they wished.

2.4 Measures

Based on the data from the user study, we compute a representativeness score for each fragment. The data are in the form of partial rankings: for each song, we know each participant's relative ordering of three segments, but we have no information about their perception of the other three segments. The easiest way to model data in this form is to use a type of discrete-choice model known as the *Plackett–Luce* or *exploded logit model* [20]. We used the variant of the model implemented in the R package **PlackettLuce** [21]. The model is similar to a softmax function or a sort of logistic regression for rankings: specifically, it estimates the probability that, were participants given a choice among *all* six segments of a song, they would choose a particular segment as the most representative thumbnail. This probability is called the segment's *worth*.

In the user study, participants were also asked whether they were familiar with the songs they ranked. We convert these ratings to a continuous familiarity score by dividing the number of responses that indicated that a participant was familiar with the song by the number of responses where a participant was not familiar. As a continuity correction, we add one extra count to the numerator and to the denominator. Finally, we take the log of this ratio, and the standard score (z) of the result:

$$\text{familiarity} = z\left\{\log\frac{\text{known} + 1}{\text{unknown} + 1}\right\}. \tag{1}$$

2.5 Audio Features

We evaluate the core measures from the user study with the help of audio features from the CATCHY toolbox [14]. This toolbox can compute psychoacoustic features such as loudness, roughness, and sharpness as well as more common MIR features such as MFCCs, melodic pitch height estimates, and chroma based on HPCPs. Additionally,

---

[4] https://www.qualtrics.com

the CATCHY toolbox introduces three higher-dimensional harmonic and melodic features that attempt to bring some of the concepts available in symbolic music processing to audio. The first is the *Harmonic Interval Co-occurrence* (HIC), which describes the distribution of triads based on their interval representation. The *Melodic Interval Bigram* (MIB) indicates how often triples of successive melodic pitches occur in the melody. Lastly, the *Harmonic Interval* (HI) measures how often pitches in the melody are accompanied by harmonic pitches measured in the chroma.

The last feature of the toolbox is the implementation of *first-order* and *second-order* features for audio. First-order features are computed using the intrinsic content of the music or audio itself, such as the average note duration within the melody [14, 15, 22]. Second-order features reflect the characteristics of the music in context of a corpus. This means that corpus-based second-order features describe the *commonality* of a segment as it describes the segment in the context of the complete corpus. Song-based second-order features outline the *recurrence* of the segment within the song as it measures characteristics of a segment in relation to the whole song.

Like most MIR toolboxes, CATCHY creates a larger set of features than desirable for interpretability, and there is substantial overlap among some subsets of features. We conducted an Exploratory Factor Analysis (EFA) on all the features as a means of dimensionality reduction similar to [14]. Closely related to PCA, EFA looks for shared variance to identify a smaller underlying latent structure responsible for a larger set of observed features [23]. We used Spearman rank correlations instead of Pearson correlations as the basis for our EFA to avoid problems with the non-normality of some CATCHY features. Given a correlation matrix, several algorithms for EFA are in wide use; we chose the standard minimum residual method, which is commonly used for exploratory and descriptive analyses [24]. In order to maximise interpretability, we then rotated the latent factor space using Varimax, a common orthogonal rotation that pushes as many loadings as possible either toward 0 or toward the extremes (correlation of −1 or 1 with a latent factor) [23].

2.6 Regression

The last step is to combine the features to obtain insights into what contributes to the representativeness of segments. We model a segment's representativeness with a log-linear regression implemented as a generalised linear model (GLM) [25, 26]. In this case, the independent variables are the features derived from the audio, the familiarity score, and the segmentation method; the non-linear dependent variable is the Plackett–Luce worth. Although more complex models would be possible, given the applied nature of this research, we are aiming for simplicity as much as accuracy: linear relations among independent variables make the models both easy to interpret and easy to implement for non-experts. By using the resulting model to assign a worth to an unseen fragment, new fragments can be evaluated and the fragment of a song with the

highest value can thereafter be used as a music thumbnail.

2.7 Replication Study

As a final check, we ran a bilingual replication study with a new set of data from Muziekweb. The data set for this study consisted of an arbitrary list of 32 songs derived from the Dutch "Top 2000" of 2019. Although it is less directly connected to Muziekweb users, it should nonetheless also represent music that would be well known to its users. The only substantial difference in the replication was that we did not ask participants explicitly whether they were familiar with the songs. Results of the original study indicated that familiarity had no impact on how segments were perceived, and we hoped to encourage participants to rate more songs by reducing the number of extraneous questions. Ethical consent was also acquired for the replication study and the survey was available from 24 March 2020 until 30 April 2020.

3. RESULTS

3.1 Number of Responses

The original survey received 148 responses, of which 76 participants quit without completing more than the example questions, 14 participants completed the survey completely (i.e., all 60 songs), and 58 partially. The mean number of songs ranked per participant was 25 ($SD = 21$). This resulted in each segment being ranked by a mean of 15 participants ($SD = 3$). Segments in the replication study were ranked 17 times on average ($SD = 3$).

3.2 Dimensionality Reduction

To aid interpretability, we conducted an EFA based on all the CATCHY features computed for the two studies combined. As there is much disagreement in the literature about how to choose the optimal number of factors in EFA, we used a simple heuristic that each factor had to have at least three features with high loadings (correlation higher in magnitude than 0.4) to facilitate easier interpretation of factors [27]. This led to a maximum of five factors. Underfactoring is more harmful than overfactoring, and as four factors started to have more overlap between factors, we retained all five factors to improve identifiability.

Table 1 shows the CATCHY features which had loadings of magnitude greater than 0.4 for one of the five latent factors. To get a sense of what these factors are measuring, we consider the features with the highest loadings per factor.

3.2.1 Harmonic and Melodic Entropy

The first factor consists of second-order features describing harmony and melody. High absolute entropy is combined with high cross-entropy with respect to segments' own songs and with respect to the entire corpus of songs we considered. Sharpness also positively influences the factor, but does so with a far lower loading. This factor

Feature	Factors				
	1	2	3	4	5
HI Entropy	**0.90**	0.20	0.05	-0.01	0.05
MIB Entropy	**0.90**	0.35	-0.03	0.00	0.04

Table 1. Factor loadings for Minimum Residual EFA for the features with loadings above 0.4 for one of the factors. The factors group features together that explain the same variance. 1. Harmonic and Melodic Entropy; 2. Harmonic Conventionality; 3. Raw Intensity; 4. Melodic Conventionality; 5. Conventionality of Intensity.

thus describes unpredictability or lack of motivic repetition in the harmony and melody; we call it Harmonic and Melodic Entropy.

3.2.2 Harmonic Conventionality

The second factor also consists of second-order features for harmony and melody. For this factor, however, the loadings prefer higher values for the commonality and recurrence of these features rather than entropy calculations. Note that the commonality of HIC and HI is of high importance both with within songs and across the entire corpus, whereas the melody-based MIB loads only against the full corpus. There is, of course, a high correlation between melody and harmony, and so we call this factor Harmonic Conventionality, while acknowledging that it may also have some melodic aspects. This factor can indicate repetition within a song itself, as well as tonal language that does not stray too far from our corpus norm.

3.2.3 Raw Intensity

The third factor mostly relies on high positive values for loudness (mean and standard deviation) and roughness. It also prefers a lower MFCC variance, which means a fragment is more consistent, a high MFCC mean in comparison to the complete corpus, which could be caused due to

Feature	Overall Result			Original – Replication		
	b	SE	p	b	SE	p
Intercept	0.15	0.06	0.006	−0.22	0.11	0.044
Audio Factors						
Harmonic and Melodic Entropy	0.03	0.04	0.448	−0.32	0.09	<0.001
Harmonic Conventionality	0.11	0.05	0.014	0.01	0.09	0.912
Raw Intensity	0.20	0.04	<0.001	−0.12	0.09	0.149
Melodic Conventionality	0.19	0.04	<0.001	0.19	0.09	0.036

Segmentation Strategies						
MSAF	−0.21	0.06	<0.001	0.14	0.13	0.249
Random	0.13	0.11	0.238	0.06	0.15	0.585
1-minute	0.10	0.08	0.205	−0.43	0.16	0.009

Table 2. GLM results showing how features contribute to perceived representativeness of thumbnails ($R^2 = 0.09$). The left-most part shows estimates using the data from both the original and replication study. The right-most results shows the differences in estimates between the two studies. For each of these results, the estimate or coefficient (b), the standard error (SE), and p-value are given.

MFCCs also measuring loudness, and a high melodic pitch height. We call this factor the Raw Intensity of a fragment, as fragments that score high on this factor sound noticeably more "aggressive" than those that do not.

3.2.4 Melodic Conventionality

The fourth factor is heavily based on corpus as well as song-based second-order features for the MIB and HI entropy. This means that the values for this factor rise when the dispersion of MIB and HI is typical for a song or the corpus. Remember also that HI is a measure that explicitly incorporates melodic information. Thus, this factor primarily describes the commonality and recurrence of the dispersion of melodic bigrams and the melody aligning with the harmony. We call it Melodic Conventionality, although it is somewhat less directly linked to conventionality than the Harmonic Conventionality factor.

3.2.5 Conventionality of Intensity

The last factor comprises corpus- and song-based second-order features for the most important components of Raw Intensity. It is easy to understand but hard to name; we call it Conventionality of Intensity.

3.3 Log-Linear Model

A GLM based solely on the data of the original user study showed that familiarity had no significant impact on how participants ranked the segments ($b = -0.08$, $SE = 0.07$, $p = .27$). As mentioned above, we excluded familiarity from the replication study in order to lessen the burden on our participants. We also exclude it from further analysis.

Table 2 showcases the results of a larger GLM with both the original and replication studies combined ($R^2 = .09$). The left part shows how each variable contributes to the representative worth of a fragment overall. The right side shows the differences in these parameter estimates between the original and replication studies. The results indicate that the Raw Intensity, Melodic Conventionality, and Conventionality of Intensity are the most important factors to approximate a segment's worth, each having a positive effect. Although there is a statistically significant difference between the two studies with respect to the *size* of the effect of Melodic Conventionality, the *direction* of the effect is the same in both studies. The role of Harmonic and Melodic Entropy is less clear: its effect on worth goes in opposite directions between the original study and the replication. Harmonic Conventionality has a small positive effect in each study. The effects of segmentation are less consistent (there is a significant Segmentation × Experiment interaction, $\chi^2(2) = 6.80$, $p = .03$) but with one surprising finding: in both studies, choosing thumbnails that line up with (estimated) structural boundaries seems to make users' opinions *worse*.

4. DISCUSSION

The results show that the most significant features that could contribute to the representative worth of a fragment are the Raw Intensity, Melodic Conventionality, and Conventionality of Intensity. Conventionality of Intensity has the highest impact on the representative worth: users prefer typical levels of intensity, neither too "hard" nor too "soft", for thumbnails. In addition to Conventionality of Intensity, higher-intensity thumbnails are preferred, as well as thumbnails with typical, familiar melodic patterns. The effect of Harmonic Conventionality is statistically significant, but its effect size is quite small; if anything, it may have a small positive effect on the perceived quality of a thumbnail.

Our results also show that the effect of Harmonic and Melodic Entropy seems to differ between the original and replication study. As both data sets had the same data format and were used to create the factors, the difference is most likely caused by the songs themselves. The replica-

tion study contained primarily pop-rock songs, whereas the original study also contained a broader of popular styles, e.g., rap and trance. Harmonic and melodic entropy are fundamental and sometimes genre-defining musical characteristics, and as such, it is not surprising that the effect of this factor would differ. This possibly genre-dependent aspect of thumbnails could be an interesting area for future work.

The impact of the segmentation method on the representative worth shows that in contrast to our hypothesis, segments chosen by a segmentation method do not outperform the base cases: in fact, boundary-aligned thumbnails seem to perform worse. While a thumbnail may benefit from containing the most memorable and recognisable part of a song, it does not necessarily need to start at that point. In practice, an algorithm for selecting thumbnails is going to be more successful if it simply has many candidate thumbnails to choose from, without worrying about where they start.

Altogether, users most prefer music thumbnails with high intensity and conventional, frequently recurring intensities and melodic patterns. This aligns with previous automatic thumbnailing studies, which have mostly focused on detecting the most repeated section or chorus [1,3–5,9,11]. Moreover, previous research shows that the chorus is generally louder, has a higher and more salient pitch, and has less dynamic diversity [28], which overlaps with the factor for Raw Intensity in this study.

A similarity can also be found with research on catchiness, which shows that the most memorable parts of a song have a more typical sound, more conventional melodies, more recurrence in the timbral aspects, as well as a prominent vocal line [14]. Earworms, which are related to catchiness, also seem to appear more in often recurring fragments with a faster tempo and a common melodic contour [22, 29]. In short, our findings about listeners' thumbnail preferences are consistent with previous studies on thumbnails, choruses, and catchiness.

4.1 Proposed Thumbnailing Method

Based on these results, we propose a new method for music thumbnailing. First, several fragments should be obtained from the song. The results of this study show that there is no preferred segmentation method and therefore that any method that results in a reasonable amount of fragments suffices. Then, the CATCHY features for each of these fragments need to be computed. An approximation of the factors in this study can be computed by multiplying standardised feature values by the highest factor loadings for the Raw Intensity, Melodic Conventionality, and Intensity Conventionality. Thereafter, these approximations are multiplied by the estimates of the GLM of the combined results to gain a representative score. The fragment of a song with the highest score can be selected as the music thumbnail.

4.2 Limitations

Like any user study, our research has some limitations. First, this study only focuses on pop music; the results cannot necessarily be transferred to other musical genres [11]. Apart from the musical genre, the choice of a linear model might also have been too simplistic to grasp fully how audio features are related to perceived representativeness. More insights might be gained by also considering nonlinear models that could pick up more intricate relationships. While this study does consider features for psychoacoustics and harmony, rhythm is not considered. Further research might look into the effects of rhythm features on representativeness. Lastly, the segmentation method used here had a negative impact on the representativeness score; perhaps a different algorithm might have yielded better results. Nonetheless, it is clear from our findings that simple heuristics like starting at a fixed time point or even a fully random starting point can also yield effective thumbnails.

5. CONCLUSION

This study aimed to create a user-driven music thumbnailing method based on easily computable audio features and an easy-to-implement scoring strategy. Segments of well-known pop songs were obtained and audio features of these segments were derived with the CATCHY toolbox. Thereafter, the segments were presented in two user studies where participants could rank segments on their representativeness. Using the data from the user studies, we used a log-linear model to understand how audio features might explain the perceived worth of a potential thumbnail. The results were significant: representativeness seems to be positively influenced by a higher intensity, and a higher commonality and recurrence of intensity and melodic dispersion. Based on these findings, we propose a new, easy-to-apply method for music thumbnailing.

ABSTRACT

Choral music recordings are a particularly challenging target for source separation due to the choral blend and the inherent acoustical complexity of the 'choral timbre'. Due to the scarcity of publicly available multi-track choir recordings, we create a dataset of synthesized Bach chorales. We apply data augmentation to alter the chorales so that they more faithfully represent music from a broader range of choral genres. For separation we employ Wave-U-Net, a time-domain convolutional neural network (CNN) originally proposed for vocals and accompaniment separation. We show that Wave-U-Net outperforms a baseline implemented using score-informed NMF (non-negative matrix factorization). We introduce *score-informed Wave-U-Net* to incorporate the musical score into the separation process. We experiment with different score conditioning methods and show that conditioning on the score leads to improved separation results. We propose a 'score-guided' model variant in which separation is guided by the score alone, bypassing the need to specify the identity of the extracted source. Finally, we evaluate our models (trained on synthetic data only) on real choir recordings and find that in the absence of a large training set of real recordings, NMF still performs better than Wave-U-Net in this setting. To our knowledge, this paper is the first to study source separation of choral music.

1. INTRODUCTION

In this paper, we set out to investigate the application of source separation to choral music. We aim to take a recording of choral music and extract from it individual recordings for each of the choir sections (normally soprano, alto, tenor, and bass).

Audio source separation refers to extracting one or more sound sources of interest from a recording that involves multiple sound sources [1]. The musical applications of audio source separation include separating instruments in a recording and generating 'karaoke' tracks of songs by separating the accompaniment and the lead vocals [2]. To the best of our knowledge, this paper is the first to attempt separation of choral music. Separation of choral music en-

ables applications such as fine-grained editing, analysis, and automatic creation of practice tracks (recordings of individual choir parts used by singers as an aid for learning new music) from professional choir recordings.

At the outset, choral music separation would seem a challenging task. Every choir section is composed of multiple singers singing simultaneously with slight variations in pitch and in timing, and every singer has a unique voice timbre. It follows that the resulting 'choral timbre' has extremely varied acoustical characteristics. Furthermore, an important goal in choral performance is achieving *blend* between singers, so that the choir is perceived by listeners as one coherent sound source [3]. This blend can naturally hinder the operation of an algorithm wishing to separate the choir. Choral music is often recorded in highly reverberant spaces such as churches, and the reverberations constitute yet another hurdle for separation. Finally, choirs are seldom recorded in a 'one voice per track' setting [4], and this lack of multi-track recordings makes it harder to design and validate source separation systems.

The rest of this paper is structured as follows. In Section 2 we review related work. In Section 3, we present a dataset of synthesized Bach chorale harmonizations. In Section 4, we establish baseline separation performance for choral music using NMF [5]. In Section 5, we apply a deep learning separation technique called Wave-U-Net [6] to choral music and in Section 6 we extend it to incorporate musical scores into the separation process. In Section 7, we present the results of several experiments conducted to determine the effectiveness of the proposed techniques.

2. RELATED WORK

Recently, the state of the art in source separation has advanced considerably, with some applications in speech even surpassing ideal time-frequency magnitude masking [7]. In music, one of the most common applications is vocals and accompaniment separation [8]. In this task, deep learning methods show the best performance among separation techniques [9]. Some state-of-the-art techniques operate on spectrograms [10, 11] while others operate directly on the signal [6, 7, 12–14]. The reader is referred to [15] for a review of deep learning for speech separation and to [2, 8] for overviews of music separation.

U-Net [16] is a prominent deep learning separation technique. Originally used for semantic segmentation of biomedical images [17], U-Net employs an encoder-decoder CNN architecture with skip connections to process the input on multiple scales. Wave-U-Net [6] extends

U-Net but instead of processing spectrograms it is applied directly to the signal. Demucs [12] is also based on a U-Net architecture and operates on the time-domain signal, with added features such as gated linear units and a recurrent layer between the encoder and the decoder.

2.1 Score-Informed Source Separation

The musical score, when available, is an invaluable source of detailed information on the mixture, such as instrumentation, pitch, and timing. Score-informed separation techniques use this information to guide the separation process [18]. One of the earliest techniques is synthesizing a signal from the target source's score and then using this signal as a reference [19–21]. Another technique is creating harmonicity-based masks or constraints driven by the note pitches and timings specified in the score [22–24]. Scores have also been used extensively as factorization constraints in the framework of NMF and its extensions [25–30].

More recently, scores have also been integrated into deep learning-based separation techniques. In [31], an autoencoder network was trained while imposing score-based constraints on the latent representation so that each latent unit represents a single note. Separation was then performed on a note-by-note basis. A technique for orchestral music separation [32] used a CNN that operates on 'score-filtered' spectrograms.

3. SYNTHESIZED BACH CHORALES DATASET

For training source separation techniques based on supervised learning, a large dataset of multi-track recordings is required. For example, the MUSDB18 dataset [9] for vocals and accompaniment separation contains 150 songs with a total duration of about 10 hours. Unfortunately, such a dataset of choir recordings does not currently exist. The Mixing Secrets dataset [1] contains some multi-microphone choral recordings, but there is significant leakage between the microphones. Choral Singing Dataset [33] is a good multi-track dataset, but it consists of only three songs.

In the absence of a large choral music dataset, we opt to use a synthesized dataset. Recently, a method for choir synthesis was proposed based on voice cloning [34], but unfortunately the implementation and the dataset are not publicly available. Choir audio tracks are often produced using commercial sample libraries [2] that contain thousands of professionally recorded choir samples. Unfortunately, these sample libraries are prohibitively expensive.

Previous work has shown that synthetic training data does not have to sound realistic for a model to generalize well [35, 36]. In light of this, we choose a relatively simple and cheap approach. We use the FluidSynth software synthesizer [37], which converts MIDI messages to audio by using audio samples and synthesis rules stored in a SoundFont file. We use the 'Choir Aahs' preset from the `MuseScore_General` SoundFont [3]. Each sample

in this preset is a short recording of a single choir section singing a sustained note on an 'aah' vowel with a single pitch. To synthesize a pitch that does not have an associated sample, FluidSynth pitch-shifts the sample that has the closest pitch. To synthesize a note that is longer than the corresponding sample, a predefined segment of the sample is looped.

3.1 Bach Chorale Harmonizations

We construct our dataset from a well-known corpus of chorale harmonizations by J. S. Bach. A chorale is a Lutheran church hymn [38]. Bach harmonized around 400 chorales as part of large-scale vocal compositions as well as shorter works [39]. Bach's chorales are highly structured and this makes them good candidates to serve as a coherent dataset for source separation. They are written for four voices in homorhythmic texture [39]. The rhythm consists mainly of quarter notes and eighth notes. Structurally, the chorales are built as a sequence of short phrases, each ending with a fermata (musical pause).

3.2 Data Augmentation

Real-world choir recordings possess many sources of variability that are absent from Bach chorales. In order to make our dataset more closely resemble real-world recordings, we augment it with three added features: simulated breaths, random omitted notes, and tempo variations.

To simulate breaths between phrases, we insert a one-beat-long rest in all voices simultaneously every eight beats. To simulate sections in which one or more voices are silent while the other voices continue to sing, we randomly choose 10% of the notes in each voice and change them into rests. To add tempo variation, we synthesize each chorale at a random tempo between 70 and 100 BPM.

3.3 Synthesis Procedure

To synthesize our dataset we read the corpus of Bach chorales in MusicXML format using the music21 library [40]. From the 371 chorales in the Riemenschneider edition we exclude 20 chorales that contain instrumental parts or more than four vocal parts. The 351 remaining chorales are split into three partitions: training (270 chorales), validation (50), and test (31). For each chorale we export four MIDI files, one file per voice, and synthesize them using FluidSynth. [4] The total duration of the dataset is 3h 48m.

4. BASELINE: SCORE-INFORMED NMF

We establish a baseline for separation performance on our dataset using a classic separation technique: non-negative matrix factorization (NMF) [5, 41]. NMF factorizes a mixture spectrogram into two matrices: basis signals and temporal activations. To constrain the NMF separation process we use a score-based initialization scheme for the basis

---

signals and activations matrices [25]. We dub this technique SI-NMF. Our implementation is available online.[5] We use the variant dubbed I_{WH} in the original paper, which imposes constraints on both basis signals and activations. For the STFT we use a Hann window with a size of 2,048 samples (the dataset sampling rate is 22,050 Hz). The SI-NMF score-based constraints allow some tolerance to account for slight pitch and timing variations in the mixture. Since in our dataset the scores are perfectly aligned to the mixture, we use onset tolerance of 0 and offset tolerance of 0.2 seconds (to account for note decay). We use pitch tolerance of 1 semitone. These parameters were found to give the best results after comparing several alternatives.

5. WAVE-U-NET FOR CHORAL MUSIC

To improve on the SI-NMF baseline, we propose to apply Wave-U-Net (described in Section 2). Wave-U-Net attained good results in the SiSEC 2018 evaluation campaign [9] and its code is publicly available. Since Wave-U-Net operates in the time domain, it may be well suited for separating sources with overlapping partials, which are ubiquitous in choral music and may pose a challenge for methods that rely on spectrogram masking [12].

We follow the training procedure used in the original Wave-U-Net paper. Every training batch consists of 16 short (6-second) segments extracted from the training set at random positions. The Adam optimizer [42] is used with the mean squared error loss and an initial learning rate of 0.0001. The validation set is used for early stopping.

In the original implementation of Wave-U-Net, a single model is trained to extract all sources at the same time. This is economical in terms of model weights and training time, but it forces the latent representations to be generic enough to fit all sources. Instead, we propose to train a separate model for each extracted source. This way the model can be specifically geared to extract each of the sources.

6. SCORE-INFORMED WAVE-U-NET

We propose to condition Wave-U-Net on the musical score of the separated sources to improve separation quality.[6] The pitch and timing information contained in the score can help overcome the challenges of separating choral music. Timbre is generally a useful differentiating factor for separation, but the timbres of the women's voices (soprano and alto) are similar to each other, and so are the men's (tenor and bass). Relying on the pitch range of each choir part is also not sufficient for separation because the ranges have considerable overlap. For example, an F4 note (F above middle C) could easily be sung by the soprano, alto, or tenor, and in rare cases also by the bass [3, p. 234]. The standard SATB (soprano-alto-tenor-bass) ordering of the voices could sometimes be used for separation, but this ordering is not always kept, and in any case it could only be used in sections where all voices sing at the same time.

Hence, in many cases the musical score may be the only way to associate notes to a specific voice in choral music.

6.1 Score Representations

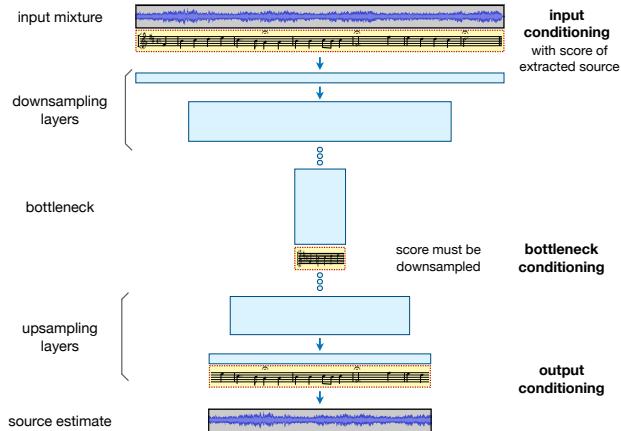
Our dataset provides the score for each part as a monophonic MIDI file indicating each note's onset time, offset time, and pitch. We transform the MIDI note sequence into a representation that can be efficiently processed by Wave-U-Net. In choral music, every part sings at most one note at a time. (In the case of *divisi*, such as when soprano is split into soprano 1 and soprano 2, we can treat every divisi section as a distinct source.) Therefore, we represent a part's score as a time series that indicates the active pitch (if any) at every time point. To keep the score aligned with the network's audio input, we use the same sampling rate for the audio and the score representation. We investigate four different score representations [43].

normalized pitch. A part's score is represented as a vector in which every element indicates the active pitch at the corresponding time instant. Since the range of MIDI note numbers (0 to 127) is radically different from the range of the audio input (-1 to 1), we normalize the note number to the range $[0, 1]$, and use the special value -1 to indicate no note is active. Given a MIDI note number M, the normalized pitch S_{n} is computed as:

$$S_{\text{n}}(M) = \frac{M - M_{\text{min}}}{M_{\text{max}} - M_{\text{min}}}, \qquad (1)$$

where M_{min} and M_{max} are the minimum and maximum expected note pitches, respectively. We set $M_{\text{min}} = 36$ and $M_{\text{max}} = 84$, based on the normal choral voice ranges: from C2 (very low bass note) to C6 (very high soprano note).

pitch and amplitude. In order to better encode the difference between sung notes and silence, we introduce a two-channel representation, in which one channel represents pitch and the other represents amplitude. The pitch channel S_{p} is normalized to the range $[-1, 1]$, as given by: $S_{\text{p}}(M) = 2S_{\text{n}}(M) - 1$. The amplitude channel is boolean: its value is 1 when a note is active and 0 otherwise. When no note is active the pitch channel is set to -1.

piano roll. The score is represented as a one-hot matrix of size $p \times n$ where p is the number of available pitches ($p = M_{\text{max}} - M_{\text{min}} + 1$) and n is the length of the network's audio input. The matrix element at row p_i and column n_j is set to 1 if a note with pitch p_i is active at time n_j. Otherwise, the element is set to 0.


pure tone. Since the model inputs are audio, we propose to represent the score in a simplistic audio-like form. We use a pure tone signal constructed as a piecewise sine function where the frequency is controlled by the active note's pitch. For simplicity, we do not create smooth note transitions, so any note onset will result in a discontinuity. The pure tone frequency f is determined by the standard MIDI note number to frequency mapping:

$$f(M) = 440 \cdot 2^{\frac{M-69}{12}}. \qquad (2)$$

When there is no active note, f is set to 0. The score vector

---

[6] https://git.io/si-Wave-U-Net

Figure 1. Conditioning locations for Wave-U-Net (showing a model that extracts a single source, see Section 5)

then receives the following value at each sample index i:

$$S_\text{t}(M, i) = \sin\left(2\pi f(M) * \frac{i}{F_s}\right), \qquad (3)$$

where F_s is the sample rate of the model's audio input.

All four score representations do not differentiate between a sustained note and a repeated note: consecutive notes with the same pitch are represented the same as one note with a longer duration. Devising a score representation that does encode this difference is left to future work.

6.2 Conditioning Method

Common methods for conditioning neural networks include *concatenation*, in which a conditioning tensor is concatenated to the input tensor; *biasing*, in which a conditioning tensor is added to the input tensor; and *scaling*, in which the input tensor is multiplied element-wise by a conditioning tensor [44]. In this work we use concatenation, which is equivalent to biasing with a linear transformation applied to the conditioning [44].

We investigate three conditioning locations in the Wave-U-Net architecture (see Figure 1): *input conditioning* (score is concatenated to the input audio before the decoder), *output conditioning* (score is concatenated to the decoder's output before the output layer), and *input-output conditioning* (a combination of both). Other conditioning locations are also possible, but they would require a transformed score representation. Conditioning at the bottleneck, for example, would necessitate resampling the score information to the bottleneck's much lower temporal resolution, thus discarding important timing information contained in the score. Conditioning at the bottleneck could work well when the conditioning has no temporal dimension, such as instrument labels [45].

6.3 Multi-Source Training

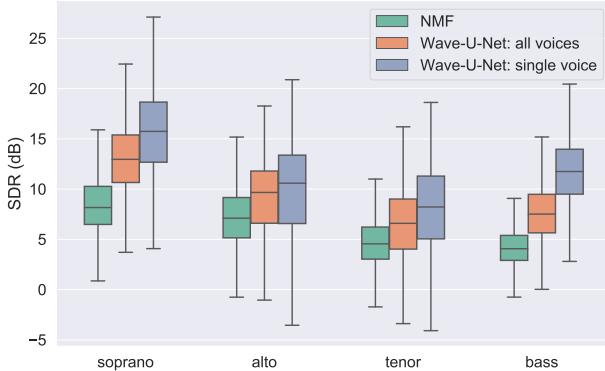
In addition to the standard method of training the network to extract specific voices, we propose a *multi-source* model variant which can separate any one of the four voices given only that voice's score. To achieve this, we train a model

to extract a single voice from the mixture, where every training example consists of a mixture segment (used as input to the model), the score of one random voice out of the four voices (used to condition the model), and the corresponding audio for that voice as the target to extract (used to compute the loss). Since training examples do not explicitly specify which voice they correspond to, the model learns to extract the desired voice based on its score alone. Whereas a normal score-informed model *could* use the score to improve separation results, the multi-source model *must* make use of the score. In this sense, the separation is not only score-informed, it is *score-guided*. A multi-source model also gives greater flexibility by allowing users to choose individual notes to extract, possibly alternating between voices. Furthermore, multi-source training can enable a model trained only on four-voice mixtures to be used on recordings with any number of voices.

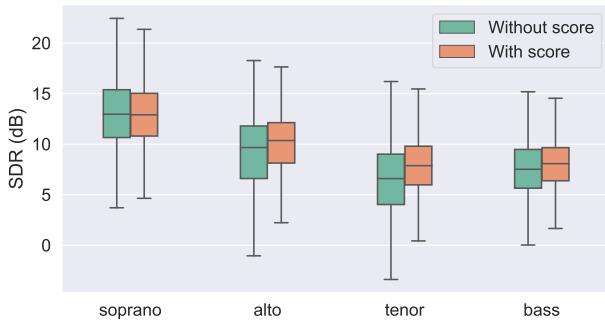
7. EXPERIMENTS AND RESULTS

To evaluate model performance, we use the SDR metric [46] provided by the BSS Eval library (version 4) [9] with its default settings [7]. Like SiSEC 2018 and subsequent works, we report median SDR rather than mean in order to reduce the effect of outliers. We compare all proposed model variants in 6 experiments, listed in Table 1. Audio examples are available online. [8] We assess whether certain methods perform better than others by reporting p-values from pairwise Conover–Iman tests [47] (also used by [9]; we adjust for multiple comparisons using the Bonferroni method [48]), always after rejecting the Kruskal–Wallis [49] null hypothesis with $P < 0.001$.

Experiment	Method	Score-Informed	Model Type
1	SI-NMF	yes	-
2	Wave-U-Net	no	one model for all voices
3	Wave-U-Net	no	one model per voice
4	Wave-U-Net	yes	one model for all voices
5	Wave-U-Net	yes	one model per voice
6	Wave-U-Net	yes	one model: multi-source

Table 1. List of experiments


7.1 Experiments 1–3: SI-NMF and Wave-U-Net

A comparison of separation performance of SI-NMF and Wave-U-Net on the test set is shown in Figure 2. While SI-NMF achieves decent results, Wave-U-Net consistently outperforms it in all voices by a large margin ($P < 0.001$).


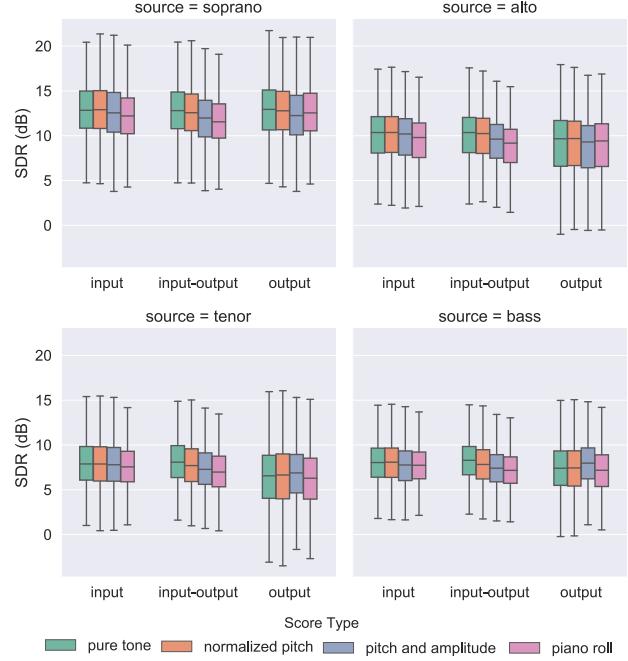
In SI-NMF, interferences between estimated sources are very low due to the hard constraints imposed using the score. However, estimated sources contain noticeable amplitude modulation artifacts. These are likely caused by the use of static spectral templates, which cannot effectively model the continuous evolution of spectral parameters in choral music. Source-filter signal models can be integrated into NMF to improve its performance in such cases [50–52]. The effectiveness of such models for choral

---

[7] We also provide supplementary SIR, SAR, and ISR evaluations. [8]
[8] https://www.matangover.com/choirsep-ismir

Figure 2. Results for SI-NMF and Wave-U-Net

Figure 3. Results from Experiment 4 (with score; score type: normalized pitch, conditioning location: input) compared to Experiment 2 (without score)

Figure 4. Results from Experiment 4 by voice, score type, and conditioning location


music may be limited, however, as a choir section is actually composed of multiple sound sources (singers). Figure 2 further shows that single-voice Wave-U-Net (Experiment 3) is superior to all-voice Wave-U-Net (Experiment 2) ($P < 0.001$).

Examination of segments in which the model achieved a particularly low SDR reveals that the most common source of errors is misclassified notes (that is, when the model assigns notes to the wrong voice) [43]. One cause for misclassified notes is voice crossings, which occur when the normal voice ordering is violated. The fact that voice crossings cause misclassification shows that the model has learned to rely on the standard ordering of the voices. Misclassified notes also occur in segments in which one voice is silent while the other voices continue to sing. In such segments the model cannot always infer which voice is silent due to the overlap between voice ranges.

7.2 Experiment 4: Score-Informed, Extract All Voices

In Experiment 4 we examine the effect of adding score conditioning to the model from Experiment 2. We train 12 score-informed model variants: all combinations of 4 score representations and 3 conditioning locations. Figure 3 shows that adding the score improves median SDR in all voices ($P < 0.001$) except for soprano ($P > 0.05$).

Figure 4 compares all score conditioning methods. Conditioning location has no consistent effect on soprano

and bass separation. For alto and tenor, however, output conditioning is overall worse than both input and input-output conditioning ($P < 0.001$). We suspect that output conditioning performs poorly because the Wave-U-Net output layer is a simple sample by sample dot-product (convolutional layer with kernel of size 1).

7.3 Experiment 5: Score-Informed, Extract Single

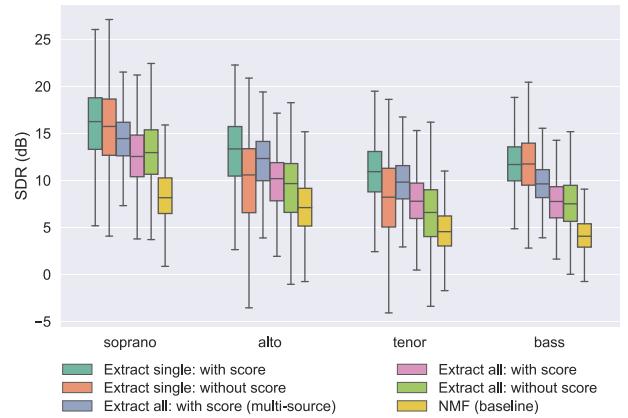
Figure 5 compares the performance of score conditioning methods for tenor extraction in Experiment 5. We compare results for tenor specifically because it is the most challenging to separate (it achieved the lowest median SDR in most experiments). Output conditioning gives the worst performance and has no significant effect compared to no score at all ($P > 0.05$). It appears the models conditioned at the output have learned to simply ignore the score. For input and input-output conditioning, the choice of score type has no effect, and all score types perform considerably better than no score at all ($P < 0.001$), with an improvement of up to 2.7 dB in median SDR.

7.4 Experiment 6: Score-Informed, Multi-Source

This experiment tested the effect of score conditioning method on multi-source training (described in Section 6.3). We do not include a figure due to limited space, see website [8] for results. Models using output conditioning perform very poorly, confirming the results of Experiments 4 and 5. Other than that, conditioning method does not have an effect in this experiment. The difference in median SDR between the best method (pitch and amplitude, input) and the worst method (piano roll, input-output) is only 0.4 dB.

Figure 5. Comparison of score conditioning methods in Experiment 5 (on tenor only), with the non-score-informed counterpart (Experiment 3) shown for reference

7.5 Overall Comparison

In Figure 6 we compare results from all experiments. For the score-informed models we use the conditioning method that performed best, taking into account all experiments and all voices (score type: pitch and amplitude, conditioning location: input). As expected, using the score improves performance mainly for the inner voices (alto and tenor), as they are more prone to induce misclassified notes due to voice crossings and vocal range overlap (see Section 7.1). Examination of frames with misclassified notes confirms that using the score eliminates this problem [43, p. 95].


The score-informed single-source model has the best performance overall. For alto and tenor, this model achieves a 2.7 dB improvement in median SDR compared to the best non-score-informed model ($P < 0.001$). For soprano, the improvement is only 0.5 dB ($P < 0.001$) and for bass performance is degraded by 0.06 SDR ($P < 0.01$). Compared to the NMF baseline, score-informed Wave-U-Net improves median SDR by 6.2 to 8.1 dB ($P < 0.001$).

Interestingly, for tenor and alto, the multi-source model outperforms the non-score-informed single-source model ($P < 0.001$), even though the multi-source model uses only a quarter of the parameters (because it uses a single model for all four voices).

Listening to audio results of score-informed models,[8] we notice that most score conditioning methods result in audible clicks at note boundaries. This is likely caused by the discontinuity of the score representations at these locations. These clicks hardly affect the SDR evaluations because they are highly localized. Using the pure tone score representation eliminates these clicks almost completely.

7.6 Evaluation on Real-World Recordings

Although our models have only been trained on synthesized data, we also evaluate using real choir recordings from the Choral Singing Dataset [33]. In this evaluation, non-score-informed Wave-U-Net (Experiment 3 model) performs poorly with a median SDR of 0 dB (for all voices

Figure 6. Comparison of results from all experiments

combined). Score-informed Wave-U-Net performs better with SDR of 1.4 and 1.5 dB (models from Experiments 5 and 6, respectively). SI-NMF outperforms Wave-U-Net by a large margin with SDR of 5.6 dB ($P < 0.001$).

Listening to estimated sources we notice that score-informed Wave-U-Net predicts all the right notes, but cannot faithfully generate the lyrics and unique timbre of the specific choir, likely due to it being trained on a dataset containing only a single choir without any lyrics. SI-NMF predictions also omit many of the lyrics and timbre variations, but are nonetheless better than Wave-U-Net in this case. This shows that to be effective on real-world recordings, Wave-U-Net needs to be trained on a more representative dataset. We postulate that if score-informed Wave-U-Net (or similar methods) could be trained on a diverse dataset of choral recordings, it would achieve an improvement over SI-NMF that is comparable to the improvement that it has achieved on the synthesized dataset.

8. CONCLUSIONS

In this paper we investigated source separation of choral music. Due to the lack of publicly available datasets, we developed a dataset of synthesized Bach chorales. We established baseline separation performance using a score-informed NMF method. We then showed that NMF is outperformed by Wave-U-Net, a deep learning separation technique. We further proposed to condition Wave-U-Net on musical scores. Our experiments with several conditioning methods showed that using the score improves separation quality. We introduced multi-source training, in which a single model separates any of the four choir voices using only the score as a guide. We found that multi-source training performs comparably to single-source training, even though it requires much less resources.

When evaluated on real choir recordings, SI-NMF still outperforms Wave-U-Net. Hence, a major challenge that remains is compiling a multi-track choir recording dataset to be used for training. Until such a dataset is available, better choir synthesis methods could be used. Another avenue for improvement would be to consider more versatile conditioning methods, such as FiLM layers [53, 54].

CAN'T TRUST THE FEELING? HOW OPEN DATA REVEALS UNEXPECTED BEHAVIOR OF HIGH-LEVEL MUSIC DESCRIPTORS

ABSTRACT

Copyright restrictions prevent the widespread sharing of commercial music audio. Therefore, the availability of resharable pre-computed music audio features has become critical. In line with this, the AcousticBrainz platform offers a dynamically growing, open and community-contributed large-scale resource of locally computed low-level and high-level music descriptors. Beyond enabling research reuse, the availability of such an open resource allows for renewed reflection on the music descriptors we have at hand: while they were validated to perform successfully under lab conditions, they now are being run 'in the wild'. Their response to these more ecological conditions can shed light on the degree to which they truly had construct validity. In this work, we seek to gain further understanding into this, by analyzing high-level classifier-based music descriptor output in AcousticBrainz. While no hard ground truth is available on what the true value of these descriptors should be, some oracle information can still be derived, relying on semantic redundancies between several descriptors, and multiple feature submissions being available for the same recording. We report on multiple unexpected patterns found in the data, indicating that the descriptor values should not be taken as absolute truth, and hinting at directions for more comprehensive descriptor testing that are overlooked in common machine learning evaluation and quality assurance setups.

1. INTRODUCTION

In many music information retrieval (MIR) applications, it is useful to include information related to music content. However, many large-scale music audio collections of interest cannot legally be shared as-is. As a compromise, efforts have been undertaken to locally pre-compute music audio descriptors and make these available through APIs or as part of research datasets. Parties without in-house access to large audio corpora need to rely on such data for

subsequent use. Indeed, large-scale pre-computed descriptor corpora have been feeding into further machine learning pipelines, empowering music applications, facilitating benchmarking initiatives [1, 2], and leading to inferences and statements about the nature of music preferences and listening behavior at an unprecedented scale [3–6].

Audio-based music descriptors are commonly divided into low- and high-level descriptors. Low-level descriptors can closely be related to the audio signal, while high-level descriptors are more semantically understandable to humans. This does not make high-level descriptors easier to extract; many of them cannot objectively and directly be measured in the physical world, and thus consider *constructs* rather than physically measurable phenomena.

The performance of automated music descriptor extraction procedures is reported according to the common evaluation methodologies in the field. For descriptors based on supervised machine learning, this normally includes a performance report on a test set that was partitioned out of the original dataset and not seen during training, or on cross-validation outcomes. However, descriptors that are reported and assumed to be successful may still be prone to sensitivities not explicitly accounted for in their design and evaluation. In lower-level music descriptors, implementations of MFCC and chroma descriptors showed sensitivities to different audio encoding formats [7], while common textual descriptions of audio extractor pipelines turned out insufficiently specific to yield reproducible results [8]. For higher-level descriptors, seemingly well-performing trained music genre classifiers turned out to be unexpectedly sensitive to subtle, humanly interpretable audio transformations [9]. Such sensitivities are not restricted to music genre classification; for example, trade-offs between accuracy and semantic robustness have also been observed in deep music representations [10]. Generally, in many MIR tasks, ground truth relies on human judgement and labeling. This may be imprecise and subjective, leading to low inter-rater agreement. In its turn, this leads to questions on whether a clear-cut ground truth exists at all, while this often is fundamental to machine learning techniques and their evaluation [11–14].

Can we tell whether automated descriptors are as trustable as initially assumed? Do they truly measure what they are intended to measure? Do they match broader, less explicitly encoded assumptions we have on them? These are important questions to ask: in case of negative an-

swers, the descriptors may not provide a valid basis for subsequent work to build upon. However, finding sensitivities that were unnoticed in original evaluation contexts is non-trivial, requiring a broader, more meta-analytic perspective. In this work, we focus on this, by providing an analysis of music descriptor values obtained through the AcousticBrainz [15] platform. By soliciting community-contributed submissions of locally run, but largely standardized music feature extractors, the platform offers a large-scale perspective on music that 'people felt worth the upload'. As such, it offers a more ecological 'in-the-wild' data perspective than what was studied in the lab, when the descriptors were originally designed. Indeed, through cross-collection evaluation procedures employing independent ground truth validation sets, several well-known genre classification models were shown not to generalize well beyond their original evaluation datasets [16].

The AcousticBrainz data is unusually transparent and rich: more so than e.g. the popular Million Song Dataset [17]. Many descriptor fields are available for each submission, multiple submissions can be added for the same MusicBrainz recording, each submission is encoded with additional metadata on characteristics of the input audio and the extractor software, and the extractor software is open source [18]. We use this richness to comprehensively analyze existing computed descriptor values in AcousticBrainz. Rather than relying on explicit and clear-cut ground truth, we look at the data through a meta-scientific lens, and impose more general assumptions on descriptor behavior, inspired by psychological and software testing techniques. This way, we will reveal several unexpected patterns in the descriptor values. As original music audio is not attached to the descriptor entries, we will not (yet) be able to fully replicate how descriptors were computed, nor will we be able to recreate experimental conditions on this data, in which possible reasons for unexpected behavior can cleanly be statistically controlled. Still, our analysis will help in pinpointing concrete directions towards future controlled studies.

In the remainder of this paper, we will discuss related work in Section 2. Then, we will introduce the data used for our analyses in Section 3, after which we will present analyses into intra-dataset correlations (Section 4), descriptor stability (Section 5), and descriptor value distributions (Section 6), followed by the conclusion and an outlook towards future work.

2. RELATED WORK

In conducting science, it is non-trivial to assess whether the outcomes we are observing, the inferences we are making and the conclusions we are drawing are truly correct. These questions of *validity* were first acknowledged in the domain of psychological testing, where the focus was on measuring psychological constructs: abstracted human characteristics (e.g. 'conscientiousness') that are not directly and physically observable, but that can still be measured (e.g. through well-designed surveys). Various subcategories of validity exist [19]. Among these, one of the

most intuitive to understand, yet hardest to pinpoint, is the notion of *construct validity*: the question whether a measurement procedure can indeed be considered to yield a *"measure of some attribute or quality which is not "operationally defined""* [20].

The traditional viewpoint on ways to assess construct validity, is to consider a measure procedure as part of a *nomological network*, and relate its outcomes to those of other procedures, that have previously been shown to be valid [20]; in practice, in much of psychological research, this is done by assessing correlations between construct measurements that are theorized to have an interpretable relation to one another. This does create dependencies under uncertainty, still boiling down to a philosophical question of 'what the first truth is to start with'—something that may be disproven during the research process, as more evidence will come in and further comparisons are being made. It has therefore been argued that comprehensive inquiry into construct validity will not only lead to better assessments, but also leads to fundamental questionings and improvements of the complete scientific process [21].

Within MIR, while comprehensive meta-scientific questions on this have not been asked, criticisms of current evaluation practices, referring to the notions of both validity and reliability and the way in which they have been used in the Information Retrieval field, have been presented by Urbano et al. [22]. In addition, Sturm's criticisms of 'horse systems' in MIR [9] (machine learning-based systems that performance-wise appear to make humanly intelligent decisions, but that turn out to pick up on irrelevant confounds in data) can again be related to construct validity.

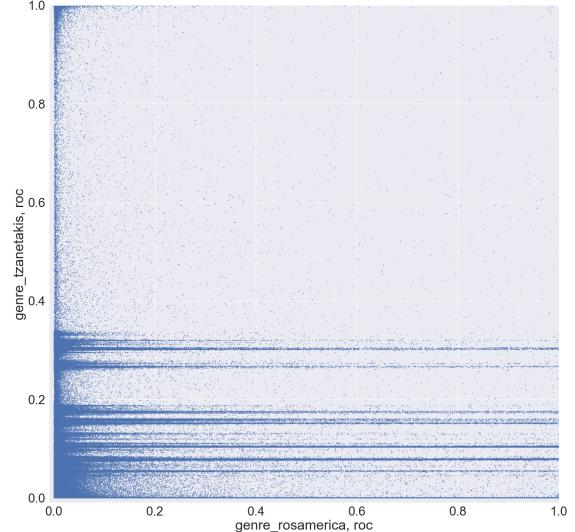
As a method to assess whether a system is a 'horse system', Sturm proposes to investigate how systems react to input data transformations that are considered 'irrelevant' (i.e. imperceptible) to humans. Interestingly, this technique has been used in another research field focused on 'testing': the field of software testing, in which it would be called *metamorphic testing* [23]. While software testing appears to be a much more objective and precise procedure than psychological testing, from a formal, logical perspective, many real-life programs may actually be considered non-testable, and the problem of determining whether a software artefact is bug-free is undecidable [24]. While one cannot pinpoint one exact oracle truth, it still may be possible to *derive* partial oracle truth through transformations based on known data relationships [25], e.g. by applying input transformations that should not change a system's output, which is done in metamorphic testing.

3. ACOUSTICBRAINZ

In our studies, we study descriptor values as found through the AcousticBrainz platform. More specifically, we will depart from the most recent high-level descriptor data dump obtained through the AcousticBrainz website [1]. We are interested in the high-level descriptors, as they should

mimic humanly understandable semantic concepts, which should be relatable in humanly interpretable ways.

The data dump considers 1,805,912 entries of community-contributed high-level descriptor values, that can be broken down into genres, moods, and other categories (e.g. danceability); a full overview can be found in ([15], Table 4). Unless indicated otherwise, our analyses will consider this full data dump. In all cases, descriptor values consider classification outputs, obtained through machine learning; for each possible class label within a descriptor (e.g., `jazz` in the genre_dortmund classifier), the classifier confidence for that class label is given as a float value. The performance of each of the classifiers is documented on the AcousticBrainz website; where possible, performance is reported on publicly available datasets [2].

4. INTRA-DATASET CORRELATIONS


Following the psychological concept of the nomological network, one way to assess validity is to assess how the outcomes of related measurement procedures correlate with each other. For this, we take advantage of *semantic redundancy* within the AcousticBrainz high-level descriptors. For example, several musical genres literally re-occur as class labels within the various genre classifiers. Then, it is not unrealistic to assume that, given the same audio input, the output of alternative jazz classifiers should positively correlate. Furthermore, some 'softer' assumptions on meaningful relationships can be made: e.g., aggressive music is likely not relaxed, and happy music is likely not sad. We defined multiple of these relationships for which we would expect to observe (strong) positive correlations between classifier label predictions, and computed their Pearson correlations. The results are displayed in Table 1.

The found correlations were unexpected; we were especially surprised by the very low correlations found for the genre classifiers, while they should target the same concepts. A scatter plot of `rock` classifier confidences in genre_rosamerica and genre_tzanetakis (which yielded a negative correlation) is given in Figure 1. It appears that confidences outcomes do not uniformly distribute over the full [0.0, 1.0] confidence range; we will investigate this further in the following sections.

Out of all 'softer' assumptions that were compared, the lowest correlation (.13) is between `happy` and `not sad`, implying that music classified as happy could be sad at the same time. The classifiers used in AcousticBrainz indeed allow for this, as separate binary classifiers exist for happy and sad moods; however, this contradicts Russell's 2D circumplex model of affect [26], in which happiness and sadness would have opposite scores on the valence dimension.

5. STABILITY

Our correlation analyses showed unexpected results. However, as different classifiers were trained on different datasets, they may have considered different characteristics of the input data. Inspired by the idea of derived oracles,

---

[2] https://AcousticBrainz.org/datasets/accuracy

Figure 1: Scatter plot of classifier confidences. Each point indicates an AcousticBrainz submission, with confidences for genre_rosamerica, `roc` and genre_tzanetakis, `roc`.

we can however also consider relationships that should be closer to the identity, and thus should lead to (nearly) identical outcomes.

In AcousticBrainz, multiple submissions can be made for the same MusicBrainz recording ID (MBID). Semantically, a MusicBrainz recording really references one and the same recording. So while users may have encoded the recording audio in different ways, and may be using different versions of the feature extractor, we should intuitively be able to assume that re-submissions of one and the same recording should yield descriptor values that are very close to one another. In other words, we wish for re-submissions for the same MBID to display *stability*.

For this, we need to consider the MBIDs in our data dump that have more than one associated submission. Filtering for this led to a corpus of 941,018 submissions for 299,097 different MBIDs. If n submissions are available for a given MBID, a given classifier c and a given classifier label l, the corresponding classifier confidences for these submissions can now be grouped into a population $(MBID, c, l)$ of size n. Considering we have k unique MBIDs in our dataset (in our case, $k = 299,097$), we can then enumerate the populations as $[(MBID_1, c, l), (MBID_2, c, l), ..., (MBID_k, c, l)]$, and operate within and/or across them when calculating instability metrics.

We consider two alternative ways to quantify instability. First, for each of the submission populations, we can compute the variance observed for classifier confidences, for each label l in classifier c. As there may be a varying amount of submissions within a population, we normalize for this by computing the *pooled variance* $\overline{var}(c, l)$ over our filtered corpus as follows:

$$\overline{var}(c, l) = \frac{\Sigma_{i=1}^{k}(n_i \times var((MBID_i, c, l)))}{\Sigma_{i=1}^{k} n_i} \quad (1)$$

Classifier, label A	Classifier, label B	Pearson's r	p
genre_rosamerica, `cla`	genre_tzanetakis, `cla`	.29	<.001
genre_dortmund, `rock`	genre_rosamerica, `roc`	.24	<.001
genre_dortmund, `jazz`	genre_rosamerica, `jaz`	.22	<.001
genre_dortmund, `pop`	genre_rosamerica, `pop`	.11	<.001
genre_dortmund, `jazz`	genre_tzanetakis, `jaz`	.08	<.001
genre_rosamerica, `pop`	genre_tzanetakis, `pop`	.06	<.001
genre_rosamerica, `hip`	genre_tzanetakis, `hip`	.05	<.001
genre_rosamerica, `jaz`	genre_tzanetakis, `jaz`	.02	<.001
genre_dortmund, `blues`	genre_tzanetakis, `blu`	.01	<.001
genre_dortmund, `pop`	genre_tzanetakis, `pop`	-.05	<.001
genre_dortmund, `rock`	genre_tzanetakis, `roc`	-.06	<.001
genre_rosamerica, `roc`	genre_tzanetakis, `roc`	-.07	<.001
mood_aggressive, `aggressive`	mood_relaxed, `not_relaxed`	.59	<.001
mood_acoustic, `acoustic`	mood_electronic, `not_electronic`	.58	<.001
danceability, `danceable`	mood_party, `party`	.53	<.001
mood_electronic, `electronic`	genre_dortmund, `electronic`	.48	<.001
danceability, `danceable`	genre_rosamerica, `dan`	.33	<.001
mood_happy, `happy`	mood_party, `party`	.20	<.001
mood_happy, `happy`	mood_sad, `not_sad`	.13	<.001

Table 1: Pearson correlations between high-level classifier outcomes, theorized to positively correlate with another.

where n_i is the sample size of the ith population in our enumeration.

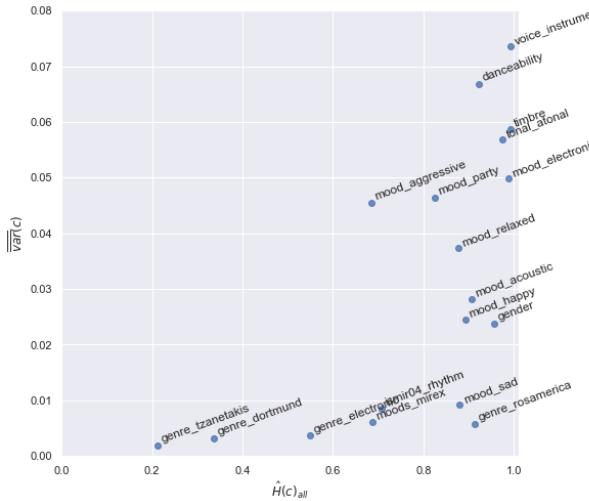
As there are multiple possible labels within the same classifier, but we want to discuss outcomes at the classifier level, we then take the mean pooled variance, $\overline{\overline{\mathrm{var}(c)}}$, over all possible labels $l \in L_c$ for classifier c.

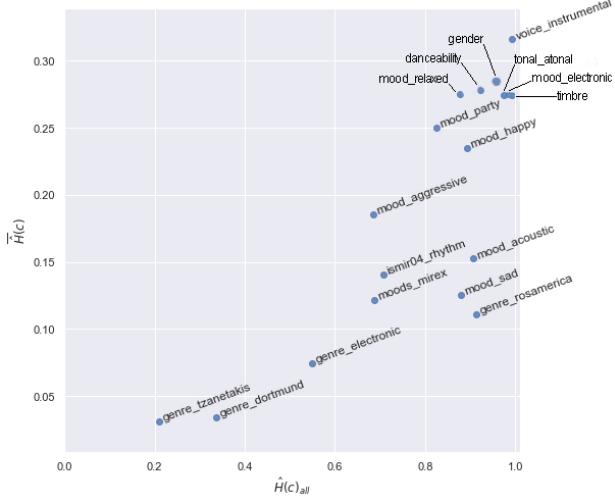
When using variances, classifier confidences are considered to be informative. Alternatively, one could choose to rather consider each classifier label as a binary label. To reflect this perspective, for each population and for each classifier, we can compute the normalized information entropy $\hat{H}(\mathrm{MBID}_i, c)$, which uses the Shannon entropy [27], but normalizes by the amount of possible labels $|L_c|$ for c:

$$
\begin{aligned}
&\hat{H}(\mathrm{MBID}_i, c) \\
&= -\Sigma_{l \in L_c} \frac{P((\mathrm{MBID}_i, c, l)) \log_2 P((\mathrm{MBID}_i, c, l))}{\log_2 |L_c|} \\
&= -\Sigma_{l \in L_c} P((\mathrm{MBID}_i, c, l)) log_{|L_c|} P((\mathrm{MBID}_i, c, l))
\end{aligned}
$$
(2)

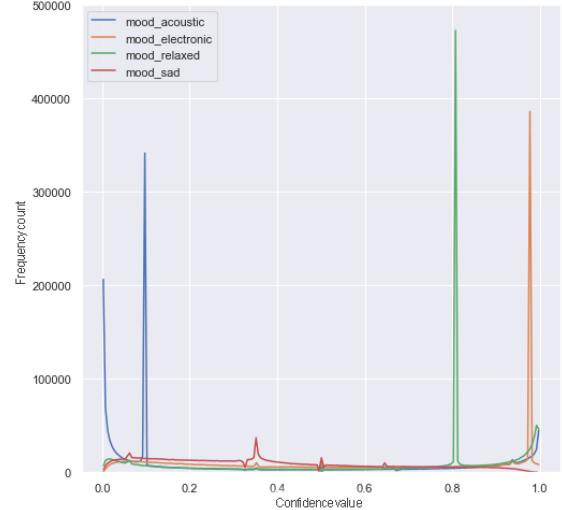
where $P((\mathrm{MBID}_i, c, l))$ is the probability of label l in classifier c, following the observed empirical distribution within the population corresponding to MBID_i. Then, to have a weighted measure per classifier over the whole filtered corpus, we calculate the pooled normalized entropy $\overline{\hat{H}}(c)$, similarly to how we computed the pooled variance.

While we want for descriptor values to be stable within a submission, it is usually not the intention that for a given descriptor, the classifier would be so stable that it always predicts a single l throughout the whole corpus. This e.g. happens for the genre_dortmund classifier, which unrightfully classifies many AcousticBrainz submissions as electronic music, as also noticed in [16]. To quantify the unbiasedness of a classifier, we compute the normalized entropy for each classifier over our complete (unfiltered) corpus, denoted as $\hat{H}(c)_{all}$. A higher $\hat{H}(c)_{all}$ denotes a more uniform distribution over the different possible class labels for c across the corpus, and thus lower classifier bias.

Plots in which we illustrate $\overline{\overline{\mathrm{var}(c)}}$ and $\overline{\hat{H}}(c)$ (pooled with regard to recordings with multiple submissions) vs. $\hat{H}(c)_{all}$ (taken across the whole, unfiltered corpus) are shown in Figure 2. As we can see, indeed, the genre classifiers turn out stable but highly biased. While in most cases, observed trends are comparable for the two possible instability measures, some exceptions are found, most notably on the gender classifier, which is considered stable when using $\overline{\overline{\mathrm{var}(c)}}$, but unstable when using $\overline{\hat{H}}(c)$. Seemingly, confidences for this classifier are close to 0.5, meaning that male/female classifications easily flip within a submission.




6. VALUE DISTRIBUTIONS

From Figure 1, it was observed that descriptor values clustered together in small bands. This behavior occurs for several genre and mood classifiers. To illustrate this, Figure 3 displays a histogram of descriptor values for the mood_acoustic, mood_relaxed, mood_electronic and mood_sad classifiers, as observed across the complete AcousticBrainz corpus. Some confidence values seem disproportionally represented: in the histogram, sharp spikes occur for mood_acoustic, mood_relaxed, mood_electronic, and a minor spike for mood_sad.


There are various reasons why this may be the case. Possibly, the community may have fed skewed data to the classifier. Alternatively, the feature extractor may have shown anomalous responses to specific inputs. For each submission, we have rich metadata, which e.g. includes information about audio codecs, bit rates, song lengths, and software library versions that were used when the submission was created. While, in the absence of a conscious experimental design underlying the data, we cannot cleanly test for contributions of individual facets, we still can examine *whether major distributional differences occur for submissions with scores within the anomalous-looking spikes, when comparing these to submissions with scores outside of these.*

For this, for each of the classifiers, we manually define range intervals for the classifier confidences, within which

(a) Instability based on mean pooled variance $\overline{\overline{\mathrm{var}}}(c)$.

(b) Instability based on pooled normalized entropy $\overline{\overline{\hat{H}}}(c)$.

Figure 2: Submission instability vs. corpus-wide unbiasedness ($\hat{H}(c)_{all}$).

we consider a submission to belong to an anomalous classifier confidence value spike. We then compare the metadata value distributions of submissions within each classifier spike to those of submissions that do not occur in any of the four anomalous spikes (1,239,882 submissions for 855,266 unique MBID recordings).

To investigate whether the observed anomalies may have been skewed towards any particular genre, we also study a subset of our corpus, which was cross-matched against the AcousticBrainz genre dataset [28]. More specifically, we only kept MBIDs which also occurred in all three publicly available ground truth sets (Discogs, last.fm and tagtraum) of the AcousticBrainz genre dataset, reducing the corpus to 402,279 submissions for 164,826 unique MBID recordings. Examining confidence value distributions for this filtered dataset, we still observed the same anomalous spikes for the same range intervals. Therefore, we will apply the same range intervals as before to select values associated to anomaly spikes, and will

Figure 3: Histogram of descriptor values for several classifiers, considered across the whole corpus.

again compare distributional differences between these and non-anomalous submissions (now amounting to 267,394 submissions for 128,687 unique MBID recordings), in this case to see whether certain genres are overrepresented in the anomalous spikes. For each classifier of interest, an overview of anomalous spike interval ranges and counts of corresponding unique recording MBIDs and submissions is given in Table 2.

To quantify distributional differences, we use the Jensen-Shannon (JS) distance metric:

$$JS\_distance(p,q) = \sqrt{\frac{D(p\|m) + D(q\|m)}{2}} \quad (3)$$

where m is the pointwise mean of p and q and D is the Kullback-Leibler (KL) divergence [29]. The JS distance is based on the JS divergence [30]; as advantages over the KL divergence, the JS divergence is symmetric and always has a finite value within the [0, 1] range [31].

For each metadata category in our overall corpus, and for each genre category in our genre-filtered corpus, we calculate the JS distance between the frequency occurrence profiles of category values, counted over all submissions within an anomalous spike, vs. all submissions without any anomalous spike. As some categories can assume many different values (e.g. replay_gain), we only do comparisons for values that occur at least 10 times in both frequency profiles. JS distance values for the metadata comparisons are listed in Table 3, while JS distance for the genre comparisons are listed in Table 4.

As can be observed in Table 3, comparing submissions within and outside of the anomalous spikes, major distributional differences are found for used extractor software versions. These go up to the level of Essentia Git commit and build versions that were used for low-level feature extraction. In addition, we also observe distributional differences for bit_rate and codec, likely confirming earlier observations [7] that low-level feature extractors may display sensitivities with regard to different audio codecs and

Classifier	Anomalous range	Full		Genre	
		#MBIDs	#submissions	#MBIDs	#submissions
mood_acoustic, `acoustic`	[0.09, 0.10]	282,605	358,747	60,261	94,268
mood_relaxed, `relaxed`	[0.805, 0.815]	373,555	485,184	72,739	119,050
mood_electronic, `electronic`	[0.972, 0.982]	315,626	401,151	64,944	101,915
mood_sad, `sad`	[0.346, 0.362]	57,697	75,688	8,854	14,242

Table 2: Details of anomalous spike data slices used for distributional comparisons. For each classifier of interest, we indicate the classifier confidence range for which a submission was considered to be anomalous. We also list the counts of unique MBID recordings and overall submissions, both for the full corpus and our genre-filtered corpus.

	`acoustic`	`relaxed`	`electronic`	`sad`
bit_rate	.42	.32	.39	.17
codec	.34	.26	.32	.06
length	.15	.15	.15	.32
lossless	.28	.21	.27	.02
essentia_low	.61	.52	.59	.15
essentia_git_sha_low	.67	.58	.66	.23
essentia_build_sha_low	.70	.62	.69	.24

Table 3: JS distances between frequency profiles over metadata categories, for anomalous vs. non-anomalous submissions considering the four classifiers of interest. For metadata categories that are not listed, found JS distances were always 0.

	`acoustic`	`relaxed`	`electronic`	`sad`
Discogs	.12	.09	.11	.11
last.fm	.14	.12	.13	.14
tagtraum	.14	.11	.13	.14

Table 4: JS distances between frequency profiles over genre categories, for anomalous vs. non-anomalous submissions considering the four classifiers of interest.

compression rates. In contrast, Table 4 shows that JS distances are equivalent and low across genre taxonomies and types of anomalies: from this, it seems more likely that the anomalies were caused by submission extraction contexts, rather than the inclusion of anomalous data.

7. CONCLUSIONS AND FUTURE WORK

In this work, we analyzed patterns in high-level descriptor values in AcousticBrainz. As we showed, while the descriptors were successfully validated under lab conditions, they show unexpected behavior in the wild, raising questions on the extent to which they have construct validity.

The unexpected behavior could have two potential causes. First of all, **the construct underlying several high-level descriptors may be conceptually problematic by itself**. For example, the concept of genre [32], as well as its use in machine learning classification tasks [33] has been criticized by musicologists and musicians. Furthermore, within music psychology, there have been findings that sad music does not necessarily elicit sad emotions [34, 35]. Further interdisciplinary research will be needed to better understand these phenomena.

Our current analyses also accumulated evidence that **the AcousticBrainz community confronted the descriptors with audio and extraction contexts that were too different from the contexts on which classifiers originally were trained**. It should be noted that original training datasets for the classifiers were far smaller in size (several hundreds to thousands of data points) than the current scale of AcousticBrainz, and that this logically may not have managed capturing all intricacies of larger-scale, ecologically valid data. However, our analyses suggest that anomalous behavior may also be due to audio codecs, compression rates and different versions of software implementations and builds that were used during extraction, which are rarely explicitly considered and reported in evaluation setups. As for the software versions, it should further be noted that, while we focused on high-level descriptors, all found differences occurred in the extraction procedures of low-level descriptors (feature representations), while the high-level machine learning models stayed constant. Thus, low-level descriptor performance should explicitly stay in scope when studying high-level descriptors.

With this work, we wished to shed light on current challenges regarding the reproducibility and generalizability of research outcomes, and on elements of processing pipelines that are under-represented in applied machine learning and signal processing literature, yet play a critical role for the pipeline's performance [8, 36]. Inspired by literature in both psychological and software testing, we also offered several possible strategies to assess descriptor validity, even in the absence of a clear ground truth.

While we exposed several potentially problematic patterns, we explicitly do not wish for this work to be seen as a criticism of AcousticBrainz and/or Essentia. No other MIR resource or API currently offers similar levels of transparency that allow for analyses like we performed here, and we would like to explicitly thank the teams behind these initiatives for their openness. It also is this openness that will allow for us to perform further research in the near future—with more systematic testing strategies and experimental designs—towards more holistic quality assurance procedures for applied machine learning procedures in the context of humanly-interpretable signal data.

ABSTRACT

This study examines gender representation in current music streaming, utilizing one of the world's largest streaming services. First, we found listeners generally stream fewer female or mixed-gender creator groups than male artists, with differences per genre. Second, while still relatively low, we found that recommendation-based streaming has a slightly higher proportion of female creators than "organic" listening (i.e., tracks that are not recommended by editors or algorithms). Third, we examined streaming data from 200,000 US users to determine the proportion of female artists in organic and recommended streams over a 28-day period and the relationship between recommended streams and users' future organic listening. The proportion of female artists in recommended streaming appears predictive of the proportion of female artists in organic streaming; these effects are moderated by gender and age. Fourth, this study also samples creators across different popularity levels, seeing more female and multi-gender groups at lower levels than in the middle tiers. However, (solo) female artists are better represented again in the superstars category, suggesting influence of selected superstars and genres. We conclude by discussing potential avenues in algorithmic auditing.

1. INTRODUCTION

Music has long presented barriers to success for underrepresented groups, including female artists [4, 22]. While gender inequities existed before the advent of streaming, the 7.4 billion dollar streaming industry [1] operates at a scale that merits critical examination. In particular, we examine whether music streaming presents similar imbalances or instead presents opportunities for greater gender parity. Music streaming services recommend tracks using a combination of human editorial and algorithmic decisions. Services learn users' musical taste and make predictions on tracks that may suit a given users' current activity, mood, or curiosity for new artists. Such recommendations

---

[1] http://wwwriaa.com/wp-content/uploads/2019/02/RIAA-2018-Year-End-Music-Industry-Revenue-Report.pdf

may amplify or counter existing inequities. Research on music consumption suggests that online consumers of music tend to have more diverse listening than consumers who primarily discover their music through radio and TV [10] and personalized recommendations can introduce users to new and potentially more diverse content [17]. However, prior research has also indicated that personalized recommendations may funnel consumers into narrower content [7, 18]. Such conflicting results suggest that the impact of algorithmic recommendation may depend on specific data, models used, and the context in which they are applied. This study seeks to understand how one streaming service's recommendations reflect existing gender representation in the music industry as well as different approaches to making such assessments.

2. BACKGROUND & LITERATURE

2.1 Gender Representation in the Music Industry

Women have historically been underrepresented in the music industry relative to society as a whole. This is reflected in industry charts and awards. Smith et al, [22] found that 10.4% of Grammy nominees between 2013 and 2019 were female. In 2018's Hot 100 year-end Billboard Chart, 17.1% were female; a m:f ratio of 4.8 to one, lowest of the 7 years prior evaluated.

Women throughout history have been music role models and artists [11, 20], but barriers have limited their proportional representation in industry. Historically, women for example were not always allowed to be hired as musicians, or to play certain instruments at all [4]. Contemporary barriers reported by female artists include discounting of their abilities, lack of connections, unwanted stereotyping or sexualization, uncomfortable studio cultures, financial instability and lack of female role models [22].

Artists have to contend with expectations of genres and subcultures, including gendered trends and themes. In a content analysis of US music videos, Emerson [9] describes how black female artists appear to navigate both empowerment themes and aesthetic and social expectations. More specific genre (sub)cultures can play a role as well. In country music, Watson [24] found a decline between 1996 and 2016 in individual female artists played on country radio, and cites explicitly asserted beliefs by decision makers that playing more female artists would lead to less advertising revenue. In electronic dance music, Gavanas & Reitsamer [12] report female DJs navigating an environment where male entrepreneurs and DJs are much more visible and networked. In rock, the "groupie"

description is a distinctly lower status label almost exclusively applied to women, even sometimes to those working in the industry, reinforcing a consumer rather than creative or production role [16].

Many music scenes however also explicitly provide space to explore non-conforming identities and roles [2, 13, 25]. Previous research has hypothesized that increased access to music afforded by the Internet disrupts barriers. For example, Epps & Dixon's [10] study on the consumption of hip hop music suggests that listeners who find the majority of their rap online consume more diverse tracks than listeners who consume most of their rap music on traditional media outlets. The same study also found that hip hop music on the Billboard charts (before streaming was included in these rankings) was less diverse on measures of lyrical themes, artist gender, and artist race than hip hop music shared online. While this work suggests that an increase in choice afforded by the internet is related to an increase in diversity of music consumption, few studies have been extended to evaluate the impact of music recommendation systems.

2.2 Bias in Algorithmic Recommendation Systems

A growing body of research examines biases in algorithmic systems. Often, these biases are extensions of biases that exist in broader society [6,23]. We might expect to see biases in algorithmic systems that mirror those in the music industry. However, impact also depends on objectives set, which can include a variety of metrics designed to broaden content consumption and diversity [15]. Choices within algorithmic models, which features to include, types of models used, also influence their output [5]. For gender and book recommendations, Ekstrand et al. [8], for example, found that when using skewed input, most collaborative filtering algorithms reflected user's profile tendencies, but that this effect was substantially stronger for implicit feedback recommendations (behavioral, e.g. clicks or reading) than explicit feedback (e.g. ratings).

In industry practice, a multitude of models build on top of each other. Algorithms designed to recommend music on streaming platforms utilize predetermined content and meta-data traits (e.g., tempo, genre, artist, historical period, etc.), as well as collaborative filtering techniques based on listening behavior by similar users. Some 'biases' are by design, such as when recommending only new releases on a new artists playlist, a playlist focused on women in rock only featuring women, or playlists focused on mood that may not include genres less suitable to that context. Other biases may be unintended, but can still be examined. For music, Aguiar et al. [1] examined gender imbalances on Spotify. They had insufficient evidence to conclude that female underrepresentation in streams was due to platform bias, they found pro-female bias in some playlists, and asserted a potential supply imbalance.

However, their work raises questions on the availability of baselines of streaming as a whole, the comparison at scale of programmed vs. non-programmed streams, and the influence of both streaming services and artist supply into these services. In this article, we build on their work by analyzing a larger data set of streams, providing insight into streaming behavior, as well as a hand-labeled sample of 'supply' in the hopes to provides the research community with baselines for further research.

We show that recommendation-based streaming has a slightly higher proportion of female artists than "organic", non-programmed listening. However, listeners generally stream fewer female or mixed-gender creator groups than male artists, making the proportion as a whole much lower than representation of women in society. We identify differences per genre that merit further investigation. Third, we find that indeed there is a relationship between recommended streams and users' future organic listening, moderated by gender and age. Fourth, we find that while supply of starting female artists plays a role, differing patterns of female representation at different popularity levels suggest differing investment patterns and again differences between genres. We conclude by discussing potential avenues in algorithmic auditing.

3. ORGANIC VS. PROGRAMMED STREAMS

Streams can be either programmed or non-programmed. Programmed streams originate from recommendations such as in algorithmic or editorial playlists, whereas non-programmed, 'organic' streams are explicitly asked-for through user-initiated actions such as search, or picking a playlist from a user's personal library.

Programmed streams include editorial playlists (curated by professional editors), and algorithmic playlists (those that are primarily created by machine learning models). Note that in practice, the latter distinction can be hard to make; editors manually selecting tracks for playlists still have algorithmic tools at their disposal. Similarly, algorithmic playlists are still human-designed with a specific purpose in mind (e.g. to discover new music), or may combine approaches using both editorial pools and algorithmic ranking, as discussed in Bonini & Gandini [3].

4. RESEARCH QUESTIONS

This study addresses the following questions through an analysis of data from a global music streaming service:

- RQ1: What is the current distribution of artist gender in music streaming, and how do recommended and user-initiated streams differ?

- RQ2: Does the proportion of female artist streams in recommended playlists predict the proportion of organic streams?

- RQ3: How do these results relate to gender distribution in creator 'supply' at different popularity levels?

For the first, we analyze a sample of a month of streams from a popular streaming service, and existing commercially available gender metadata. For the second, we take a sample of users, and investigate the relationship between their programmed and non-programmed (self-selected) streams, and the impact of listener characteristics. For the third, to counter the inherent popularity

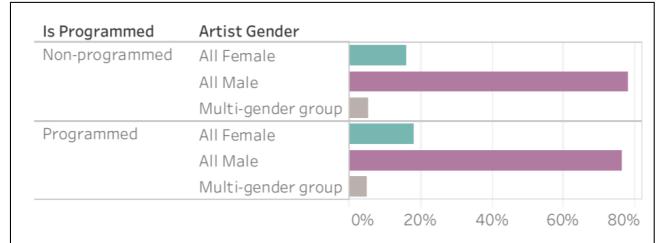
biases in our large-scale (meta)data, we take a random sample of creators at different levels of popularity, hand-label these creators and investigate the 'supply' proportion of female, male, non-binary and multi-gender artists and groups. Each of these will be discussed in their own section below.

5. REPRESENTATION IN STREAMING PATTERNS (RQ1)

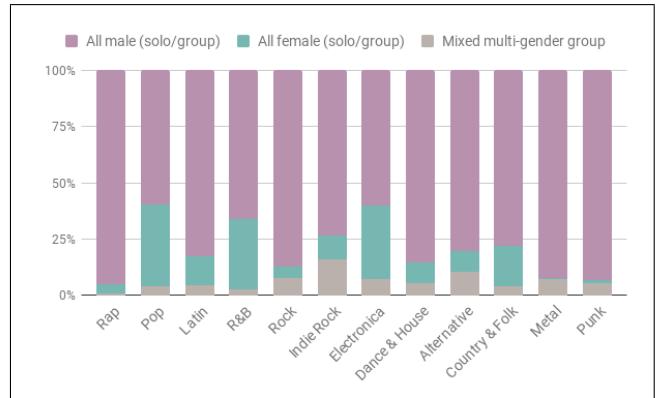
We start this study by comparing programmed and non-programmed streams, and understanding the proportion of female-artist streams within this setting.

5.1 Methods

To obtain a baseline understanding of the artist-gender makeup of streaming, we present a sample containing 30 days of streams starting in early April 2020, from Spotify, a music streaming service with Millions of worldwide users [2] .

For purposes of this study, a *stream* is defined as a 30 second or longer play of a *track recording*. This time threshold minimizes the impact of skipped songs on our analysis. Note that some tracks may be streamed never, while others may get millions of streams. This means that popular artists and their streams will have a large impact on the analysis presented here, which is why we investigate representation at different levels of popularity in the section addressing RQ3.


For our analyses of streams, artist characteristics are supplied from commercially available metadata. Our focus here is on the main performing artist, not potential featured artists, songwriters, composers or producers. This data set has coverage on gender for around 86% of all streams sampled. For each artist entity in the data set, a gender entry states whether they are female, male, a mixed multi-gender creator group (e.g. a band, duo), or unknown/other. The latter covers both non-binary as well as unknown gender artists, meaning that we cannot distinguish between other gender identities in our at-scale analysis than male, female and multi-gender groups. This means this analysis is not inclusive to non-binary gender artists, even though binary conceptualization of gender is an inaccurate conceptualization [14, 21].

5.2 Results


In the 30 days analyzed, for all streams where gender information is available, around 1 in 5 have a female performing artist associated with them, see Fig 1. Of particular relevance to RQ1 was the comparison between programmed and organic streams. Female artists receive slightly more streams in programmed content than in organic streams (Pearson's $\chi^2 = 8e07, df = 2, p < 2.2e - 16$, see Fig 1).

Streams with either a female artist or multi-gender group comprised respectively 21.75% of non-programmed (e.g. user search or library) streams, and 23.55% for programmed (recommended) streams.

Figure 1. 'Programmed' vs. 'organic' streams, stream %. As discussed in section 5.1, non-binary gender not included due to data limitations.

Figure 2. Proportions of streams for most popular genre groupings (cut-off for inclusion: 2% of streaming). Combined programmed and non-programmed streams.

We found considerable differences between genre streams (Fig 2), suggesting that subcultures can impact representation. For example, 95% of rap/hip hop streams were associated with male-only performing artists. For pop, around 40% of performers included a female artist or at least one female group member. For metal, all-female performer streams were rare (0.7%), with 7.0% mixed-gender groups.

This suggests the need for not only industry-wide, genre-agnostic follow up studies, but also genre-specific deep-dives that take into account sub-cultural processes, networks and industry structures.

6. PREDICTING ORGANIC CONSUMPTION (RQ2)

To better understand the relationship between programmed and non-programmed 'organic' listening, and the potential influence of recommendations, we then conducted an analysis centering user-level listening. This analysis uses a random US sample, and investigates whether the proportion of female artist streams in recommended playlists predict the proportion of organic streams listened to with various controls.

6.1 Methods

6.1.1 Sample

We limited our sample to US users who had a paid subscription and were between the self-reported ages of 13

and 90. We limited our sample to US users under the assertion that gender preferences in musical taste (whether explicit or implicit) are culturally dependent, and thus a cross-national analysis would present additional complexities beyond the scope of this project. Because of this, we decided to focus on US listeners because it was the largest population of users in our data set, and the market with which our research team was most familiar. One obvious alternative to this choice would be an international stratified sample; we hope future research will consider this approach. Gender was also self reported by users. From this larger population, we randomly sampled 200,000 active users for whom we had organic, editorial, and algorithmic streaming data in a 28-day period ending on September 30th, 2018. We chose a fall month to avoid seasonal and holiday-based differences in listening patterns, which are most pronounced at the end of the calendar year [19]. We allocated 60% of these data for training ($n = 120,000$), 20% for testing ($n = 40,000$), and 20% for validation ($n = 40,000$).

User characteristics, including gender and age, are gathered through the sampled streaming service's on-boarding process, during which new users set up their profile. Within our total sample ($N = 200,000$), 46% of listeners were female and 0.06% identified as non-binary. We also grouped participants into age categories.

For the purpose of this research, a user's *"top genre"* is defined as the highest-ranking genre when dividing their total streams by the number of streams in each genre. In total, there were 30 top genre categories. For 51% of listeners, pop was the most listened-to genre. Rock was the second, with a distant 15.6% of listeners.

6.1.2 Statistical Analysis

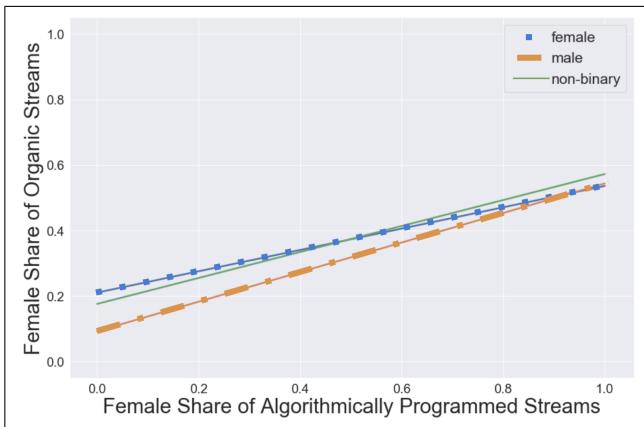
Our outcome variable of interest was the proportion of female artists in tracks streamed organically. In first assessing the data, we modeled the proportion of female artists in organically streamed tracks using ordinary least squares regression. We then introduced controls shown to be important in the larger literature. Finally, we included interaction terms between all main effects features and control features in the OLS regression. The final model equation is:

$$\hat{Y} = \beta_1 X + \beta_2 Z + \beta_3 X \cdot Z + \epsilon \quad (1)$$

In this equation, $\hat{Y}$ is the predicted proportion of female artists streamed organically over a 28-day period, X represents the matrix of the main effects features plus the constant, Z represents the matrix of control variables, and ϵ is the error term.

In the end, we retained five dependent variables and the interactions between them, given that they were theoretically significant, had a reasonable amount of predictive power, and showed no collinearity with other variables. Table 1 summarizes the features selected for our final analysis without their interaction terms.

Thereafter, we applied several basis functions to see whether the model could be improved by including higher order polynomial features. The best fitting basis function was $\phi(X) = (x_1^1, x_1^2, ..., x_1^6, ...x_D^1, x_D^2, ..., x_D^6)$ ($\alpha =$

0.01, R-Squared = .40). However, the small increase in R-squared statistic did not seem to justify increased model complexity and decreased interpretability. Five-fold cross validation was used to ensure the final model was not overfit to the data.


Variable	Description
Outcome Variable	
organic	Share of female artists streamed organically for longer than 30 seconds during a 28-day period
Main Effects Features	
algo	Share of female artists streamed via algorithmically programmed playlists for longer than 30 seconds during a 28-day period
editor	Share of female artists streamed via editor programmed playlists for longer than 30 seconds during a 28-day period
Control Features	
gender	Gender of user. One-hot encoded into female, male, and non-binary
age	Age of user. Self-reported age bucketed and one-hot encoded as categorical variables: 0-17, 18-24, 25-29, 30-34, 35-44, 45-54, and 55+
top genre	User's most listened to genre. One-hot encoded variable categorizes a user's most listened to genre. Such as afropop, atmospheric, blues, brazil, children, christian, classical, comedy, country, edm, hip hop, etc.

Table 1. Feature descriptions for RQ2

6.2 Results

For addressing RQ2, we used a randomly sampled dataset of US users and their streaming behavior. We iteratively built three models [3] to predict the effect of female artist

---

[3] Ideally, we would include all variables and their coefficients for the iterative models, considering space limitations we have limited the description to the final and best fitting model.

Figure 3. Plotting proportion of female artists in algorithmically recommended content on organic streaming of female artists when controlling for user age, gender, and top genre. Line style indicates moderation by listener gender.

share in algorithmic and editor programmed content on organic streaming of female artists. Additionally, we controlled for user age, gender, and top genre, and moderated by user age and gender. This final model's results are discussed below.

6.2.1 User Demographic Differences in Listening

Chi-squared tests revealed that there are no statistically significant differences between male and female users with regard to the share of female artists they stream (Pearson's $\chi^2 = 0.04, p = 0.98$). Additionally, Chi-squared tests revealed that there were no statistically significant differences between users of different age categories with regard to the female artist stream share (Pearson's $\chi^2 = 0.01, p = 1.0$). With this, we conclude that gender and age are independent of female artist stream share.

6.2.2 Linear Regression

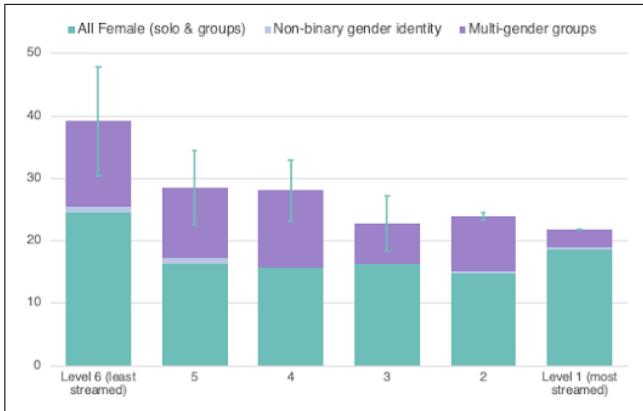
In fitting our model, our null hypotheses were that the (1) there is no effect of programmed female artist share on organic female artist share and (2) effect of programmed female artist share on organic female artist share is not moderated by any of our demographic variables. With regard to listener gender, we found that the estimated effects for men were larger than corresponding effects for women ($\beta_{algoXmale} = .076, p < .001$). That is, compared to the women in our sample, men who streamed more female artists in algorithmically-programmed playlists were also more likely to listen to female artists organically. Figure 3 illustrates the moderated effects of algorithmic female share on organic female share by gender.

There are similar, yet weaker, associations for the interaction between gender and editor programmed content ($\beta_{editorXmale} = 0.014, p < .001$), as well as age and algorithmically programmed content. Notably, we found that the estimated effects for 18-24 year-olds ($\beta_{algoX18-24} = .026, p < .001$) and 25-29 year-olds ($\beta_{algoX25-29} = .047, p < .001$) were larger than corresponding effects for 45-54 ($\beta_{algoX45-54} = -.054, p < .001$) and 55+ year-olds ($\beta_{algoX45-54} = -.060, p < .001$). That is, compared

to the 18-29 year-olds in our sample, those over the age of 45 who streamed more female artists in algorithmically-programmed playlists were less likely to listen to female artists organically. The interaction terms for age and algorithmically programmed content for 30-44 year-olds were not statistically significant.

Further, the strength of the model, as evaluated with the R-squared (r-squared = .374) and Root Mean Square Error (rmse =.152) statistics, was moderate. When evaluating this model's fit using the test set ($n = 40,000$), we found the r-squared statistic of the validation set was .361, meaning the model was not overfit to the training set and was the best performing model we built.

While main effects are often not interpretable in the presence of an interaction term, we can relax this guideline in this model because both features are captured by dichotomous variables where 0 is a meaningful value and within the range of the variable. For example, where a listener self-identifies as a woman, the interaction term is 0. In any cases when the interaction term is equal to 0, we can interpret the main effects. However, additional post-hoc tests were needed to conclude if the difference we have observed is, in fact, statistically significant, and can be inferred at the population level. When we conducted a GLH test of their joint population equality ($F(1, 59) = 1285, p < .001$), we found that we could reject this null hypothesis.

We conclude that we have sufficient evidence that there is a moderate, positive relationship between the proportion of female artists streamed on programmed playlists and the proportion of female artists listened to organically. Additionally, this relationship is moderated by both user gender identity and age in the population.


7. SUPPLY SIDE ANALYSIS (RQ3)

Large-scale analyses may offer insight in the proportion of streams that go to female artists or multi-gender groups being lower than male artists, but do not provide insight whether this reflects the 'supply' of female creators and multi-gender groups.

There is a long tail of less popular artists for whom data is scarce. Self-identification at this scale is not feasible for all artists who are streamed, not in the least for those deceased or without direct service access. This means that, for example, playlists focused on discovery of new artists, or those highlighting historic artists who are less well-known will have less complete, and potentially less accurate, associated metadata. To further investigate the presence, or supply, of female creators at different levels of popularity, we followed up with a manual sample across a wider range of creators.

7.1 Method

For our analyses of creator supply, we randomly sampled artists from six different levels of popularity. This, in an effort to reflect a spectrum of the artist community, from early projects to global superstars. Levels of popularity are defined as such: artists in the first level have 10 times more

Figure 4. Percentage of Female, non-binary and multi-gender group 'supply' from least to most popular artists. Error bars: confidence levels of total (female + non-binary + multi-gender) % due to sample size vs. large (Millions) creator population at lower popularity levels

streams than the ones in the second level, who have 10 times more streams than the next, and so on. These were sampled in Feb 2020, and based on streams within the last 90 days. A professional team of data curators labeled 1330 creators in a similar manner to [22] (who manually sampled 800 chart entries). We here focused on a wider sample beyond charts, as well as including non-binary artists and multi-gender groups. It is noteworthy that information could not be found for at least 300 more creators, even by the expert data curation team.

7.2 Results

Representation of the aggregate of female + non-binary + multi-gender groups appears to differ at different levels of popularity (χ^2 = 12.865, df = 5, p-value = 0.02468). At entry-level, female representation is higher than at the middle levels, where it goes down slightly (see Figure 4). However, there is an uptick of female artists *better* in the superstars category, while less multi-gender groups are present. This suggests success of selected superstars, and influence of popular genres with higher female representation such as pop and R&B.

Even though more data collection would be necessary at lower popularity levels to get to results with higher confidence levels, we do now have a clear indication that both supply and demand matter. This suggests that the research community and services should address representation in streams overall, but that we as a community should especially also pay attention to how certain artists climb -or not- in popularity across platforms, and what factors lead to that climb.

8. DISCUSSION & CONCLUSION

In summary, this study resulted in several key findings. First, we found listeners generally stream fewer female or mixed creator groups than male artists. Second, we found that recommendation-based streaming has a slightly higher proportion of female creators than organic listening, but

this proportion is still relatively low. Third, we found that gender and age of listener are independent of female artist stream share. Fourth, higher proportions of female artists in recommended streaming is predictive of higher proportions of female artists in organic streaming; these effects are moderated by gender and age. Younger age groups exhibited larger effect sizes, which may indicate that younger listeners are more open to taking (new) recommendations, or potentially more influenced by them. An alternative explanation may be that outside factors, such as terrestrial radio exposure, may be more salient for groups with smaller effect sizes. Future research should investigate the role of age, gender, and other identity markers in more depth. Finally, we find that in lower popularity levels, more multi-gender groups and more female creators appear to exist than in the middle - while at the top level (solo) female artists appear more present again. We have also highlighted the influence of hits on high-level stream numbers, as well as genre.

It is noteworthy that while examining gender representation is important, gender labeling in itself can be problematic. Performing labeling without self-identification can cause errors, and demographic data collection in itself presents significant risks. This results in a dilemma between inclusive representation vs. data minimization. In addition, some data ambiguity will always remain. People's expressed gender identities are not necessarily static; artists may come out as non-binary mid-career. Challenges also especially apply for historical as well as international art, and large collectives. Backing bands may or may not be taken into account in credits, orchestras and bands change and add or remove members. Information is scarce for lesser known artists, may be in other languages or terms than data curation or research teams may understand. Thus, striving for comparisons and repeated sampling rather than exact numbers and 'completeness' may be more productive tasks.

In this study, we primarily looked at streaming outcomes in aggregate, rather than who is 'shown' as a recommendation in a specific product context. Results may be skewed by top-level streaming outcomes, and higher popularity genres such as pop which have higher female representation than other genres. Although the results in this study are not causal, they do suggest that further work on the ability of content recommendations to diversify user listening habits are warranted. We primarily discussed descriptive baselines; future studies should explore alternative models and sampling approaches, potentially consider causal inference methods that do not require experimentation, or experimental designs that thoughtfully contend with the ethical concerns of manipulating user experiences on a commercial platform. Future work should also study how gender intersects with genre and subculture, as well as other factors such as race/ethnicity, locale and congruence with existing cultural expectations.

We conclude that there are barriers to entry, and to climbing to the top, but that streaming services may be able to challenge structural inequities by spotlighting underrepresented artists in their recommendations.

ABSTRACT

Data cleansing is a well studied strategy for cleaning erroneous labels in datasets, which has not yet been widely adopted in Music Information Retrieval. Previously proposed data cleansing models do not consider structured (e.g. time varying) labels, such as those common to music data. We propose a novel data cleansing model for time-varying, structured labels which exploits the local structure of the labels, and demonstrate its usefulness for vocal note event annotations in music. We frame the problem as an instance of contrastive learning, where we train a model to predict if an audio-annotation pair is a match or not. We generate training data for this model by automatically deforming known correct annotations to form incorrect annotations. We demonstrate that the accuracy of a transcription model improves greatly when trained using our proposed strategy compared with the accuracy when trained using the original dataset. Additionally we use our model to estimate the annotation error rates in the DALI dataset, and highlight other potential uses for this type of model.

1. INTRODUCTION

Labeled data is necessary for training and evaluating supervised models, but the process of creating labeled data is often error prone. Labels may be created by human experts, by multiple human non-experts (e.g. via crowd sourcing), semi-automatically, or fully automatically. For many problem settings, even in the best case scenario where data is labeled manually by experts, labels will almost inevitably have inconsistencies and errors. The presence of label noise is problematic both for training and for evaluation [1]. During training, it can cause models to converge slower and to require much more data, or overfit the noise thus resulting in poor generalization. During evaluation, it can lead to unreliable metrics with artificially low scores for models with good generalization and artificially high scores for models which overfit noisy data. This issue is particularly timely and relevant for the music informa-

tion retrieval (MIR) community as recent datasets such as LakhMIDI [2], DALI [3] or the Free Music Archive [4] take advantage of large music collections accessible from the Internet but often rely on noisy annotations. Additionally, many common annotation tasks are particularly costly as they have to be aligned in time and require a participant with musical expertise to be done accurately.

Data cleansing is a well studied technique in the machine learning community for mitigating the effects of label noise, with a focus on improving model generalization when training on noisy datasets [1]. A common and effective approach is to build a model to identify and discard data points with incorrect labels. Most methods taking this approach do not assume any structure or correlation between different labels. This is appropriate for many common tasks, such as image recognition. However, in music, labels are often highly structured and time-varying, and the label noise is not random. For example, musical note-annotations, which we focus on in this work, are locally stable in time and follow certain common patterns. Typical noise for note events include incorrect pitch values, shifted start times, and incorrect durations, among others.

Our contributions are as follows. We propose a novel contrastive learning-based [5, 6] data cleansing model which can exploit sequential dependencies between labels to predict incorrectly labeled time-frames trained using likely correct labels pairs as positive examples and and local deformations of correct pairs as negative examples. We focus our experiments on a model for detecting errors in vocal note event annotations, which we believe extends easily to other types of music transcription labels. We then demonstrate the usefulness of this data cleansing approach by training a transcription model on the original and cleaned versions of the DALI [3] dataset. Further, we use the model to estimate the error rates in the DALI dataset, and highlight other potential uses for this type of model, including for reducing manual labeling efforts. Finally, the code used in this work, including the pre-trained error detection model, is made freely available [1] along with the outputs of the model for the DALI dataset [2].

2. BACKGROUND AND RELATED WORK

We first introduce prior work on learning in the presence of label noise, and conclude by summarizing the work rel-

---

[2] https://zenodo.org/record/3576083

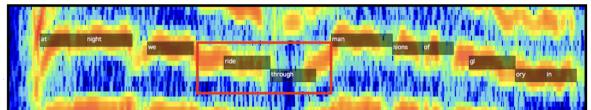
event to our example use case of note event annotations.

2.1 Classification in the presence of label noise

We consider the problem of training a classifier on a dataset where some of the labels are incorrect. One class of solutions attempts to solve the problem by mitigating the effect of label noise, rather than modifying the data used for training. This is commonly done by modifying the loss function to directly model the distribution of label noise, for example, by creating a noise-robust loss with an additional softmax layer to predict correct labels during training [7], or with a generalized cross-entropy that discards predictions that are not confident enough while training, looking at convergence time and test accuracy [8], or by inferring the probability of each class being corrupted into another [9]. However, these approaches are restricted to specific types of loss functions or make restrictive assumptions about the statistical distribution of noise.

Data cleansing [10] and **outlier detection** [11] based approaches aim to identify the correctly labeled data points and train only on them. The vast majority of data cleansing methods are model prediction-based [1]. In their simplest form, model prediction-based methods train a model to remove items from the dataset where the label predicted by the model disagrees with the dataset label. Note that in many cases, the choice of model for data cleansing is often the same as the choice of model used after data cleansing.

These data cleansing approaches have several advantages over learning directly with noisy labels. First, the filtering does not depend on the downstream inference task, thus a cleansing method can be applied to filter data used to train many different models. Second, we can train less complex downstream models, as they do not need to account for label noise. To the best of our knowledge however, prior data cleansing approaches do not exploit the structured nature of labels often seen in MIR tasks.

In addition to developing data cleansing methods, or learning methods that are robust to label noise, there are a variety of less closely related paradigms for dealing with data quality issues. In **semi-supervised learning** reliably labeled data is combined with a large amount of unlabeled data [12]. In **weakly supervised learning** [13–15] low-quality or insufficiently granular labels are used to infer the desired target information. Finally, **active learning** estimates the most valuable unlabeled points for which to solicit additional labels [16, 17].


2.2 Note Event Annotations

Automatic music transcription, one of the core tasks in MIR, involves converting acoustic music signals into some form of music notation [18]. *Musical note events* are a common intermediate representation, where a note event consists of a start time, end time and pitch. They are useful for a number of applications that bridge between the audio and symbolic domain, including symbolic music generation and melodic similarity. Instruments such as the piano produce relatively well-defined note events, where

each key press defines the start of a note. Other instruments, such as the singing voice, produce more abstract note events, where the time boundaries are often related with changes in lyrics or simply as a function of our perception [19], and are therefore harder to annotate correctly.

Datasets providing note event annotations are created in a variety of ways, all of which are error prone. Notes may be manually labeled by music experts, requiring the annotator to specify the start time, end time and pitch of every note event manually, aided by software such as Tony [20]. MIDI files from the Internet can in some cases be aligned automatically as in the LakhMIDI [2] and DALI [3] datasets, with varying degrees of accuracy and completeness. Note data has also been collected automatically using instruments which "record" notes while being played, such as a Disklavier piano in the MAPS [21] and MAESTRO [22] datasets, or a hexaphonic guitar in the GuitarSet dataset [23]. Data collected in this way is typically quite accurate, but may suffer from global alignment issues [22] and can only be achieved for these special types of instruments. Another approach is to play a MIDI keyboard in time with a musical recording, and use the played MIDI events as note annotations [24] but this requires a highly skilled player to create accurate annotations.

Figure 1 shows an example of correct and incorrect note annotations in the DALI dataset. The types of errors produced by the previous methods can vary. A single note can be imprecise in time, resulting in an incorrect start time or duration, or the pitch value can be annotated wrong. Additionally, notes can be annotated where there are no actual notes in the audio, and conversely, notes in the audio can be missed all together. Systematic errors include global shifts and stretches in time and shifts in key/octave. Local errors are difficult to detect, and systematic errors can cause every note event to be wrong in some way. At the individual time-frame level, notes with incorrect start/end times will have errors at the beginning/ending frames, but can still be correct in the central frames.

Figure 1. Example of two incorrect note annotations from the DALI dataset, outlined in red, figure from [25].

3. DATA CLEANSING FOR NOTE EVENTS

Given an input space $\mathcal{X}$ and a label space $\mathcal{Y}$, we propose a model prediction based approach, but rather than training a classifier $h : \mathcal{X} \to \mathcal{Y}$, we directly train a model $g : (\mathcal{X} \times \mathcal{Y}) \to [0, 1]$ which approximates the probability that the label is incorrect. We denote this probability by $g(x, \hat{y})$.

Note that this is mathematically equivalent in the ideal case to the previous model prediction based approaches: Given a perfect estimator h which always predicts a correct label y, $g(x, y) = \mathbb{1}_{h(x) \neq y}$ where $\mathbb{1}$ is the indicator

function. However, for complex classification tasks with high numbers of classes and structured labels, modeling h can be much more complex than modeling g. For instance, consider the complexity of a system for automatic speech recognition, versus the complexity needed to estimate if a predicted word-speech pair is incorrect. Intuitively, you don't need to know the right answer to know if something is right or wrong.

This idea is similar to the "look listen and learn" [26] concept of predicting the "correspondence" between video frames and short audio clips – two types of structured data. It is also similar to CleanNet [27], where a dedicated model predicts if the label of an image is right or wrong by comparing its features with a class embedding vector. However, this approach operates on global, rather than position-dependent labels.

In our approach, we generate training data for g by directly taking pairs (x, y) from the original dataset as positive examples and creating artificial distortions of y to generate negative examples. In this section, we study the use of an estimator $g(x, \hat{y})$ for detecting local errors in noisy note-event annotations. See Figure 2 for an overview of the system.

3.1 Input Representations

As our input representation, instead of using the raw audio signal itself, we compute the Constant-Q Transform (CQT) [28] as a matrix X, where X_{ij} is a time-frequency bin. The time index i corresponds to the time stamp $r_i = \upsilon \cdot i$ where υ is a constant defining the spacing between time stamps, and the frequency index j corresponds to a frequency q_j in Hz. The CQT is a bank of filters transformation centered at geometrically spaced frequencies. We use a frequency bin resolution with 6 octaves, 1 bin per semitone, a sample rate of 22050 Hz and a hop size of 256, resulting in a time resolution of $\upsilon = 11.6$ ms. We compute the CQT from the original mixture and from the isolated vocal version derived from the mixture using a source separation technique [29]. We include the CQT of the isolated vocals to boost the information in the signal related to the singing voice, and couple it with the CQT of the mixture to include information we may have lost in the separation process.

We define the annotated label $\hat{Y}$ as a binary matrix created from the original note-event annotations. For a given track, let K be the set of note annotations, let t_k^0 and t_k^1 be the start and end time of note k in seconds, and f_k be its frequency in Hz. Then $\hat{Y}$ is defined as:

$$\hat{Y}_{ij} = \begin{cases} 1, & \text{if } t_k^0 \leq r_i \leq t_k^1, \, q_{j-1} < f_k \leq q_j, \, k \in K \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

and has the same time and frequency resolution as X.

3.2 Learning Setup

We estimate the label noise at the ***time frame*** level. Let $\ell \in L$ be an index over the set of tracks L, I^ℓ be the index of all time frames for track ℓ, and X^ℓ and $\hat{Y}^\ell$ be its CQT

and label matrices respectively. Let X_i^ℓ and $\hat{Y}_i^\ell$ indicate a time frame of X^ℓ and $\hat{Y}^\ell$ that contains all its frequency bins j, so we index the data points according to their time index only. Finally, let $X_{a:b}^\ell$ and $\hat{Y}_{a:b}^\ell$ denote the sequence of time frames of X and $\hat{Y}$ between time indices a and b.

Our goal is to identify the subset of time frames $i \in I^\ell$ which have errors in their annotation for each track in a dataset by training a binary data cleansing model. Our data cleansing model is a simple estimator that can be seen as a binary supervised classification problem that produces an error detection model. Given a datapoint centered at time index i, g predicts the likelihood that the label $\hat{Y}_i$ is wrong. Critically, we take advantage of the structured labels (i.e. the temporal context); as input to g we use $X_{a:b}$ and $Y_{a:b}$ to predict if the center frame $\hat{Y}_{(a+b)/2}$ of $\hat{Y}_{a:b}$ is incorrect. That is, we aim to learn g such that:

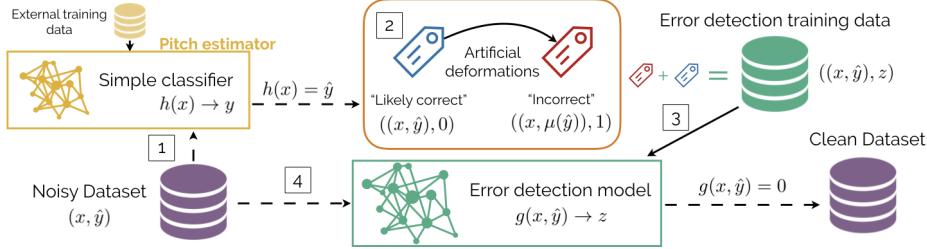
$$g(X_{a:b}, \hat{Y}_{a:b}) = \begin{cases} 0, & \text{if } \hat{Y}_{(a+b)/2} \text{ is correct} \\ 1, & \text{if } \hat{Y}_{(a+b)/2} \text{ is incorrect} \end{cases} \quad (2)$$

Thus, in order to evaluate if a label $\hat{Y}_i$ is correct using n frames of context, we can compute $g(X_{i-n:i+n}, \hat{Y}_{i-n:i+n})$. In the remainder of this work, we will define

$$g_n(X_i, Y_i) := g(X_{i-n:i+n}, \hat{Y}_{i-n:i+n}) \quad (3)$$

as a shorthand. In this work, we use $n = 40$.

Let

$$D = \bigcup_{\ell \in L} I^\ell \quad (4)$$


be the set of all time indices of all tracks in L. Our aim is to use g to create a filtered index F, where:

$$F = \{i \in D : g_n(X_i, \hat{Y}_i) = 0\} \quad (5)$$

3.3 Training data generation

Let z_i be a binary label indicating whether the center frame $\hat{Y}_i$ for an input/output pair $(X_{i-n:i+n}, \hat{Y}_{i-n:i+n})$ is incorrect. To train g, we need to generate examples of correct and incorrect data-label pairs $\left((X_{i-n:i+n}, \hat{Y}_{i-n:i+n}), z_i \right)$. We will again introduce a shorthand $((X_i, Y_i), z_i)$ to refer to data points of the form $\left((X_{i-n:i+n}, \hat{Y}_{i-n:i+n}), z_i \right)$.

Incorrect Data To generate "incorrect" data points (where $z_i = 1$), we can simply randomly distort any of the existing labels in the dataset by applying a modification function $\mu(\hat{Y}_i)$. These modifications $\mu(\hat{Y}_i)$ are not random but rather specific to match the characteristics of typical note-event errors (issues in the positions of the start or end times, incorrect frequencies, or the incorrect absence/presence of a note). These distorted $\hat{Y}_i$ should be contextually realistic, meaning that notes should have a realistic duration and should not overlap with the previous or next note. To do this, we modify the original note events (t_k^0, t_k^1, f_k) described in Section 3.1 by randomly shifting start and end times, frequency values, and by randomly deleting or adding notes. Given these new note events, we generate a new label matrix $\mu(\hat{Y}_i)$ as described in Eqn (1).

Figure 2. Overview of our data cleansing system. The training data for our error detection model g is generated automatically. 1- We predict the f_0 for the whole noisy dataset and compare it with the annotated label. 2- We select as "likely correct" examples those where the prediction is similar to the label, distorting them to generate the incorrect examples. 3- We train our g using this new training set. 4- We filter the noisy dataset obtaining the clean version.

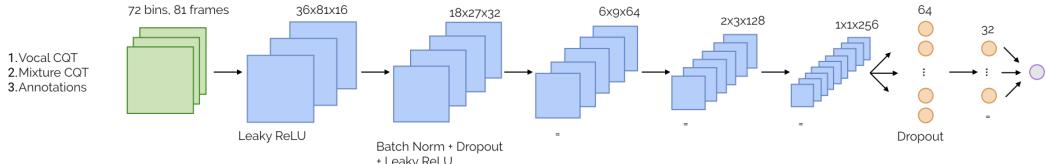
Some note-level modifications may still result in the center frame being "correct" – for example, if a note begins a few frames late, the following frames will still be correct – thus, after modifying creating $\mu(\hat{Y})$, we sample examples from frames where the center frame $\mu(\hat{Y}_i) \neq \hat{Y}_i$.

Likely Correct Data Since we do not have direct access to the true label Y_i (indeed this is what we aim to discover), we first use a "simple classifier" proxy for selecting likely correct data points. There are many possible choices for this proxy – for example, if there is a manually verified subset of a dataset, it can be used directly as the set of likely correct data points – in this work we outline one specific example. We first compute the output of a pretrained f_0 estimation model $s(X_i)$ that given X_i outputs a matrix with the likelihood that each frequency bin contains a note [30]. $s(X_i)$ is trained on a different dataset than we use in the subsequent experiments and has been proven to achieve state-of-the-art results for this task [30]. $s(X_i)$ produces f_0 sequences, rather than note events, which vary much more in time than note events, so we define an agreement function in order to determine when the labels agree. $s(X_i)$ is not a perfect classifier, and while its predictions are not always correct, we have observed that when the agreement is high, $\hat{Y}_i$ is usually correct. However, we cannot use low agreement to find incorrect examples, because there are many cases with low agreement even though $\hat{Y}_i$ is correct. Therefore, we only use κ to select a subset of "likely correct" data points.

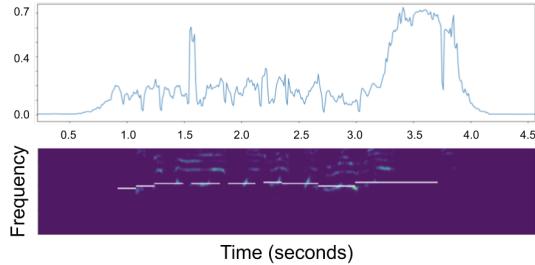
We compute both "local" (single-frame) and "patch-level" (multi-frame) agreement, and use thresholds on both to select time frames which are likely correct. The local agreement, κ_l is computed as:

$$\kappa_l(\hat{Y}_i, s(X_i)) = \max_j \left(\hat{Y}_{ij} \cdot s(X_i)_j \right) \qquad (6)$$

and the patch-level agreement κ_p is a k point moving average over time of κ_l. For the test set of g, we use very strict thresholds and select $(X_i, \hat{Y}_i)$ pair to be a likely correct if $\kappa_l > .999$ and $\kappa_p > .85$. For the training set, we use more relaxed thresholds, and select points with $0.9 < \kappa_l \leq 0.999$ and $0.7 < \kappa_p \leq 0.85$. These values have been found manually and assure the selection of good "likely correct" examples. This procedure gives us a set of positive examples in non-silent regions, but does

not take into account the silent areas. In order to select correctly labeled points from silent regions, we take additional $(X_i, \hat{Y}_i)$ points from regions with low energy in the isolated vocals and no annotations in a window of length v. In this work we use $v = 200 \ (\approx 2, 32$ s$)$.


Finally, the combination of "likely correct" and "incorrect" data results in a dataset of $\{((X_i, \hat{Y}_i), z_i)\}$ with which we can train g.

3.4 Error Detection Model Architecture


We propose a standard convolutional architecture for our error detection model $g_n(X_i, \hat{Y}_i) = z_i$, as shown in Figure 3. The input of the model is a matrix with 72 frequency bins, 81 time frames (0.94 seconds) and three channels: the two CQTs (mixture and vocals) $\{X_{i-n:i+n}\}$ and the label matrix $\{\hat{Y}_{i-n:i+n}\}$. It has five convolutional blocks with 3×3 kernels, 'same' mode convolutions, with leaky ReLU activations for the first block and batch normalization, dropout and leaky ReLU for the rest. The strides are $[(2, 1), (2, 3), (3, 3), (3, 3), (2, 3)]$ and the number of filters $[16, 32, 64, 128, 256]$ generating features maps of dimensions $(36 \times 81 \times 16)$, $(18 \times 27 \times 32)$, $(6 \times 9 \times 64)$, $(2 \times 3 \times 128)$, $(1 \times 1 \times 256)$. Then, we have two fully-connected layers with 64 and 32 neurons, a ReLU activation and dropout and a last fully-connected layer with one neuron and a sigmoid activation. The model is trained using a binary cross entropy loss function.

4. EXPERIMENTS

We test our approach using the DALI dataset, version 2 [25], which contains 7756 user-submitted vocal MIDI annotations from karaoke websites, automatically matched and aligned to polyphonic audio files. The MIDI annotations are crowd sourced and thus have highly varying quality, while the alignment is done automatically and likely to contain mistakes. This dataset is then particularly relevant for this work. The contrastive learning-based error detection model g is trained as described in Section 3.4 using the data generation method described in Section 3.3. The trained model g had a frame-level accuracy of 72.1% on the holdout set, and 76.8% on the training set.

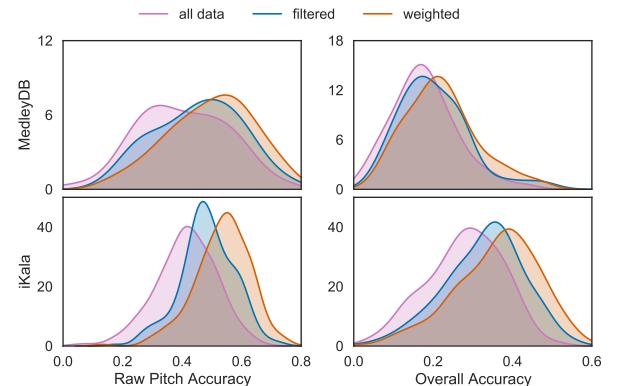
Figure 3. Error detection model architecture.

4.1 Training with Cleaned Data

Figure 4. (Top) The output of the error detection model for a short segment. (Bottom) the corresponding CQT and annotated notes (in white). The error is high at the beginning of the fourth note because it starts late, and at end of the last note because it is too long.

Validating the performance of g is challenging, as we only have likely correct and artificially created wrong examples, but we do not have any "real" ground truth correct and incorrect examples. Thus, we first manually verified the predictions of the error detection model in many random examples (see Figure 4), and found that they appeared to be strongly correlated with errors in y_i. However, a manual perceptual evaluation of the error detection model is both infeasible and defeats the purpose of automating the process of correcting errors. Instead, we validate the usefulness of this approach by applying it to model training. In this section, we address the question: **Is the error detection model useful? How much?**

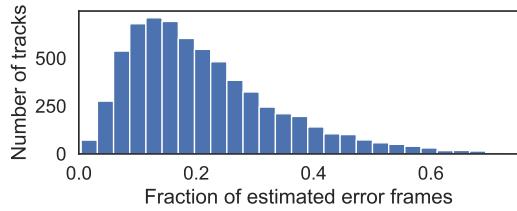
The ultimate goal of a data cleansing technique such as this one is to identify incorrect labels and remove them from the dataset in order to better train a classifier. Thus, one way to demonstrate the effectiveness of the data cleansing method is to see if training a model using the filtered dataset results in better generalization than training on the full dataset.

To validate the usefulness of $g_n(X_i, \hat{Y}_i)$ for improving training, we train the Deep Salience vocal pitch model [30] three times [3] using three different training sets. The training sets are subsets of DALI, and contain the $\hat{Y}_i$ of all the songs that have a Normalized Cross-Correlation $> .9$ [3]. This results in a training set of 1837 songs. The three sets are defined as follows:


1. **All** data. Trained using all time frames, D (Eqn (4)).

2. **Filtered** data. Trained using the filtered, "non-error" time frames, F (Eqn (5)), where the output of g has

been binarized with a threshold of 0.5. With this data we tell the model to skip all the estimated noisy labels.

3. **Weighted** data. Trained using all time frames, D, but during training, the loss for each sample is weighted by $1 - g_n(X_i, \hat{Y}_i)$. This scales the contribution of each data point in the loss function according to how likely it is to be correct.


We test the performance of each model on two polyphonic music datasets that contain vocal fundamental frequency annotations: 61 full tracks with vocal annotations from MedleyDB [31] and 252 30-second excerpts from iKala [32]. We compute the the generalized [4] Overall Accuracy (OA) which measures the percentage of correctly estimated frames, and the Raw Pitch Accuracy (RPA) which measures the percentage of correctly estimated frames where a pitch is present, which are standard metrics for this task [33, 34]. The distribution of scores for each dataset and metric are shown in Figure 5.

Figure 5. Distribution of scores for the three training conditions. Each condition is plotted in a different color. Scores for MedleyDB are shown in row 1 and scores for iKala are in row 2. Raw pitch accuracy is shown in column 1 and overall accuracy is shown in column 2. The y-axis in all plots indicates the number of tracks.

While the scale of the results are below the current state of the art [30] – likely due to the noisiness of the training data! – we see a clear positive impact on performance when data cleansing is applied. The overall trend we see is that training using filtered data outperforms the baseline of training using all the data with statistical significance

---

[3] We train each new model from scratch, not using transfer learning

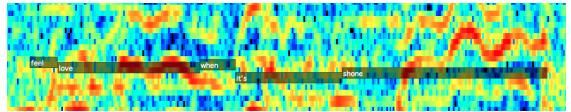
[4] using continuous voicing from the model output and binary voicing from the annotations


Figure 6. Histogram of the estimated error rate per track.

Figure 7. The CQT of an excerpt of the track in DALI with the lowest percentage error ($< 1\%$ error), with it's annotations overlaid. The audio for this excerpt can be found at `https://youtu.be/Wq4tyDRhU_4?t=40`.

($p < 0.001$ in a paired t-test) for all cases, indicating that our error detection model is successfully removing time frames which are detrimental to the model. We also see that, overall, training using all the data but using the error detection model to weigh samples according to their likelihood of being correct is even more beneficial than simply filtering. This suggests that the likelihoods produced by our error detection model are well-correlated with the occurrence of real errors in the data. These trends are more prominent for the iKala dataset than for the MedleyDB dataset – in particular, the difference between training on filtered vs. weighted data is statistically insignificant for MedleyDB while it is statistically significant ($p < 0.001$ in a paired t-test) for the iKala dataset. The iKala dataset has much higher proportion of *voiced* frames (frames with a pitch annotation) than MedleyDB. This suggests that the weighted data is beneficial for improving pitch accuracy, but may not bring any improvement over filtering for detecting whether a frame should have a pitch or not (voicing). Nevertheless, both conditions which used the error detection model to aid the training process see consistently improved results compared with the baseline.

4.2 Estimated Quality of The DALI Dataset

As a final experiment, we ran the error detection model on the full DALI dataset (version 2) in order to estimate the prevalence of errors. We compute the percentage of frames per-track where the likelihood of being an error is ≥ 0.5. A histogram of the results is shown in Figure 6. We estimated that on average, 21.3% of the frames of a track in DALI will have an error in the note annotation, with a standard deviation of 12.7%. 31.1% of tracks in DALI have more than 25% errors, while 18.2% of tracks have less than 10% errors. We also measure the relationship between the percentage of estimated errors per track and the normalized cross correlation from the original DALI dataset [3], and found no clear correlation. This indicates that while the normalized cross correlation is a useful indication of the global alignment, it does not reliably capture the prevalence of local errors.

We manually inspected the tracks with a very high percentage of estimated errors ($> 70\%$) and found that all of them were the result of the annotation file being matched to the incorrect audio file (see [25] for details on the matching process). On the other hand, we found that the tracks with a very low percentage of estimated errors ($< 1\%$) had qualitatively very high quality annotations. For example, Figure 7 shows an excerpt of the track with the lowest error

rate along with a link to listen to the corresponding audio. While this is only qualitative evidence, it is an additional indicator that the scores produced by the error detection model are meaningful. The outputs of our model on DALI are made publicly available.

An error detection model that estimates the quality of a dataset can be used in several ways to improve the quality of a dataset. For one, we can use it to direct manual annotation efforts both to the most problematic tracks in a dataset, but also to specific incorrect instances within a track. Additionally, one of the major challenges regarding automatic annotation is knowing how well the automatic annotation is working. For example, the creation of the DALI dataset used an automatic method for aligning the annotations with the audio, and it was very difficult for the creators to evaluate the quality of the annotations for different variations of the method. This issue can now be overcome by using an error detection model to estimate the overall quality of the annotations for different variations of an automatic annotation method.

5. CONCLUSIONS AND FUTURE WORK

In this paper we presented a novel data cleansing technique which considers the time-varying structure of labels. We showed that it can be successfully applied to a dataset of vocal note event annotations, improving Raw Pitch Accuracy by over 10 percentage points simply by filtering the training dataset using our data cleansing model. Our approach is particularly useful when training on very noisy datasets such as those collected from the Internet and automatically aligned. We also used our proposed error detection model to estimate the error rate in the DALI dataset.

For future work, while our experiments focused on vocal note event annotations, we believe this technique could be directly applied to any kind of note event annotation, as well as extended for other types of time-varying annotations such as chords or beats. We also believe the error detection model could be applied to scenarios other than training. First, a natural use of such a model is to streamline manual annotation efforts by using the model to select time regions that are likely wrong and send them to an expert for correction. Similarly, it could be used as an objective measure to guide the design of automatic annotation methods, which are otherwise forced to rely on manual evaluation. We would also like to explore how this idea can be generalized to other domains beyond music and to test the contribution of different factors including the amount of noise in a dataset and the nature of the noise.

ABSTRACT

The *GrooveToolbox* is a new Python toolbox implementing various algorithms, new and pre-existing, for the analysis and comparison of symbolic drum loops, including rhythm features, similarity metrics and microtiming features. As part of the *GrooveToolbox* we introduce two new metrics of rhythm similarity and four features for describing the significant properties of microtiming deviations in drum loops. Based on a two-part perceptual evaluation, we show these four new microtiming features can each correlate to similarity perception, and be used with rhythm similarity metrics to improve personalized similarity models for drum loops. A new measure of structural rhythmic similarity is also shown to correlate more strongly to similarity perception of drum loops than the more commonly used Hamming distance. These results point to the potential application of the *GrooveToolbox* and its new features in drum loop analysis for intelligent music production tools. The *GrooveToolbox* may be found at: `https://github.com/fredbru/GrooveToolbox`

1. INTRODUCTION

Growing attention has been drawn to the applications of Music Information Retrieval (MIR) within the realm of music creation to improve upon conventional workflows and enhance creativity [13]. Due to their popularity in contemporary music, research into the analysis of drum loops is a field with strong potential to provide genuine value in real-world music production applications.

The problem of similarity modelling is a key element of this research. The ability to compare drum loops according to perceptually relevant qualities is an essential enabling factor in many plausible systems, such as drum loop recommendation systems, automatic drum loop generation systems and interfaces for navigating drum loop libraries.

For the purposes of this paper, one example use case for drum loop similarity modelling is to enable intelligent

drum loop searching tools within *BFD3*, a virtual drum kit plugin [8]. *BFD3* generates realistic drum sounds based on audio renderings of expressive and unquantized symbolic sequences recorded by real drummers on an electronic drum kit. Including third-party expansions, over 7000 of these symbolic loops are available, providing rich potential for intelligent navigation or recommendation tools.

In **Section 2**, we give an overview of work related to intelligent drum production tools (IDPTs) and discuss possible improvements to their methods of drum loop analysis. In **Section 3** we introduce the *GrooveToolbox*, a Python toolbox primarily aimed towards use in drum loop analysis research. It contains implementations of many existing rhythm features and similarity measures for the analysis and comparison of symbolic drum loops with fixed tempo and metre. New algorithms are also provided: models of rhythmic structural similarity, and models of microtiming accounting for timing styles and mixtures of metrical subdivisions. This section gives an overview of the algorithms implemented in the *GrooveToolbox*.

In **Section 4**, we investigate the effectiveness of the algorithms contained within the *GrooveToolbox* via application to modelling similarity for drum loops. We test the effectiveness of our new polyphonic rhythm similarity measures against the commonly used Hamming distance, and test to what extent high-level rhythm feature-based similarity models can be improved with low-level rhythm similarity metrics and microtiming features to build individualized predictive models that could be used in user-aware IDPTs. In **Section 5** we summarize conclusions of this work, and detail further work required on the *GrooveToolbox* itself and in drum loop analysis generally.

2. BACKGROUND

2.1 Intelligent tools for drum loop production

The primary application of the *GrooveToolbox* is towards research into IDPTs. Much of this centres on the symbolic level rather than audio, and it largely centres on two applications: automatic generation of drum loops, and intelligent interfaces for exploring libraries of drum loops.

In general the goals of automatic drum loop generation in a music production context can be both to speed up the production process and help stimulate new ideas in the producer [17]. Much of the work in this area aims to

generate variations on existing patterns to help producers create evolving drum parts. Genetic algorithms have been applied to achieve this, with the target vector derived from similarity metrics like the Hamming distance [21] or a feature set [16]. Also using genetic algorithms, [15] presents a system that interpolates between two existing drum patterns via a feature space. Variational autoencoders have also been used, generating loop variations that adapt to fit structural changes in an existing song [32] or to fit within a musical trio alongside melody and bass instruments [23].

A second area is in intelligent interfaces for exploring drum loop libraries. The design of intelligent user interfaces for improved music collection exploration is a well researched area with many successful applications [18]. Similarly, the mapping of drum loops on a 2D space via a similarity measure or dimensionality reduction of a feature space has potential to enable improved navigation of a large library. In [3], the authors map a large library of drum loops via the Self-Organizing Map, using a modified version of the Hamming distance as the similarity measure. In [11], the authors present a continuous, generative 2D space for drum patterns based on applying Multi-dimensional Scaling (MDS) to a set of rhythm features.

2.2 Improving drum loop analysis

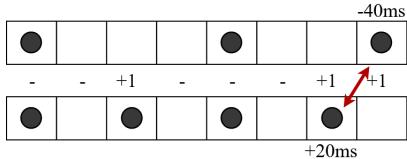
In the IDPTs described above, symbolic drum loops are analyzed using rhythm features, such as density and syncopation, or rhythmic similarity measures such as the Hamming distance [30]. These may not capture all the important characteristics of complex loops. Two possible areas of improvement, informed by recent musicological research, are in the analysis of microtiming and rhythmic structure.

2.2.1 Microtiming

Microtiming can be defined as sub-rhythmic quasi-random or systematic timing deviations from a metrical grid in human performance. Representations of rhythms that are fit to a metrical grid are a requirement for many rhythm similarity measures, such as the Hamming distance, or features relying on metrical profiles like syncopation [20]. However, fitting rhythms to a grid removes microtiming information, which can be musically significant.

The timing 'feel' or 'groove' of a performance may be an important perceptual factor of drum loops; it has been shown that drummers can control the 'pushed' or 'laid-back' feel of their performance [5]. In [25], timing strategies in drumming for 'laid-back', 'ontop' and 'pushed' styles are measured for a group of drummers based on the typical back-beat rhythmic structure. It was found that their strategies can be formalized as specific timing interactions occurring on downbeat metrical positions. These are between the kick or snare and the hi-hat, or the metrical grid (or metronome) when there is no hi-hat present. The reference to hi-hat as well as grid was based on the understanding that when present the hi-hat usually acts as the time-keeper of the pattern. Detecting these timing interactions may be important for analysing groove in human-performed (or human-imitating) drum loops.

Secondly, gridded representations of rhythms do not account for swung rhythms, or loops where multiple subdivisions of a beat occur. Calculating a pattern-based rhythm similarity metric may still be desirable in these cases however. For example, a swung and unswung version of the same rhythm will be somewhat similar. Or, a loop in 4/4 time may have one instance of a triplet rhythm, in a fill for example. By incorporating a measure of deviation outside of a grid, we can manage these cases, whilst keeping the metrical reference required by other rhythm features.

2.2.2 Rhythmic Structure


The Hamming distance for rhythm similarity works by stepping through each metrical position in two rhythms, and counting the distance (difference) as the number of instances where rhythms contain different values (one a rest and the other an onset) in the same positions. Hence, in **Figure 1**, the Hamming distance would be 3. This measure is adapted to variable dynamics by using the difference in intensity or velocity as a weighting factor.

Though possibly the most popular rhythm similarity metric, the Hamming distance's stepwise nature fails to pick up regional rhythmic similarities. Onsets in similar but non-identical positions do not register as similar in the Hamming distance, even though perceptually they may be.

A measure of structural similarity may pick this up but requires the derivation of a structural representation. The recent rhythmic transformation model of [26] provides a means of doing so. In [26], an algorithm is described for characterizing rhythms as combinations of three types of ornamentation: syncopation, pickup (anacrusis) and density. Each of these is classified in terms of its position within a metrical profile and surrounding onsets. Syncopations are onsets placed in weak metrical positions, not followed immediately by an onset in a stronger position. Density ornamentations are placed in weak positions between two events in stronger positions. Pickups are placed in weak positions but followed immediately by an onset on a stronger position. Any rhythm can be defined as an ordered combination of these ornamentations against metrical profile, and any rhythm can be decomposed to a 'metronome' - an onset on each downbeat - in the same manner by reversing (removing) these ornamentations. This decomposition process can be used to simplify rhythms in a musicologically sound manner, where the simplified rhythmic representation is analogous to a structure.

3. GROOVETOOLBOX

GrooveToolbox is a Python toolbox for analysing and comparing rhythmic and microtiming qualities of drum loops in various formats. The toolbox contains functions for a variety of pre-existing features and new ones that account for rhythmic structure and microtiming. They fall within three groups: rhythm features, microtiming features and similarity measures. As the toolbox is designed to work with loops of fixed tempo, it does not contain features for tempo tracking or conventional metre detection. Nor does it provide timbral analysis as it works on a symbolic level.

Figure 1. Measuring similarity of two short rhythms. Hamming distance = 3. With 16th note steps at 120BPM fuzzy Hamming distance = 2.26

Two Python toolboxes in the public domain relate to the *GrooveToolbox*. The *Rhythm Toolbox* [10] presented as part of [9] provides a starting point for drum loop analysis, with functions for two different types of syncopation features plus density features. However the feature set is limited, and it only supports MIDI files. The *Groove-Toolbox* adds many algorithms to this set. It also supports BFD3 [8] format Groove files as an alternative to MIDI, MIREX format [1] and audio files through the integrated *ADTLib* drum transcription library [29].

The *SynPy* toolbox [28] also provides related functionality, consisting of implementations of seven syncopation models. While useful, the toolkit is designed for use on monophonic rhythms, and as such do not immediately apply to drum loops. In the *GrooveToolbox*, we implement one syncopation model [20] also found in *SynPy*, and add another designed specifically for drum patterns [34].

The algorithms implemented in the *GrooveToolbox* are collected from a range of research, with the aim of enabling comprehensive modelling of the perceptual qualities of drum loops. For re-implemented algorithms, we chose those which were experimentally verified as perceptually relevant and ensured they could account for variable onset velocities. The algorithms currently provided in the *GrooveToolbox* are listed in **Table 1**. In this section, we will describe the two new similarity models and four microtiming features. More details may be found at: `https://github.com/fredbru/GrooveToolbox`.

3.1 New Rhythm Similarity Models

3.1.1 Fuzzy Hamming distance

The fuzzy Hamming distance extends the Hamming distance by incorporating one metrical step of displacement along with the microtiming deviations of each onset. Where there is an onset in one rhythm but not the other, the algorithm looks ahead one step to look for a nearby onset. An instance of this is shown in **Figure 1**. If there is a nearby onset, the distance is reduced depending on how close that onset is. The microtiming deviations are also considered when two onsets occur at the same metrical position. In each case the timing difference between the two nearby onsets is incorporated in the similarity calculation. If present, the difference in onset velocity may also be used as a weighting factor as with the Hamming distance.

For the example of **Figure 1**, the value 1 in position 3 is the same as for the Hamming distance. The final two positions add 1 each to the Hamming distance, but the fuzzy Hamming counts the first of these as the timing difference

between the two onsets, divided by the time of two metrical steps. At 120BPM, one 16th note lasts 125ms, so the similarity at this position $= (125 - 20 - 40)/250 = 0.26$.

With this proximity accounted for, the final position is calculated as usual, adding 1 to the distance. The overall distance is therefore 2.26 - close to the Hamming distance (3) but scored as more similar due to the proximity of the last two onsets. In a different case where the microtiming deviations in the two nearby onsets were removed, the fuzzy Hamming distance would be 2.50, higher to reflect the increased distance between the two onsets.

By accounting for possible similarity between nearby onsets, this method reduces the Hamming distance's limitation in detecting regional similarities. It also accounts for rhythms with microtiming deviations, such as swung rhythms, by not discarding them. Accounting for microtiming differences between onsets in the same position may also capture the overall difference in microtiming feel.

3.1.2 Structural Similarity

The structural similarity metric measures the similarity of a structural representation of two loops, derived following [26]'s transformation model (see **Section 2.2.2**). First, we remove any 'ghost notes', below a loudness threshold. Ornamentations are then found and reversed (removed) until any onsets only occur on downbeats. This results in representations of rhythmic structure at the downbeat level upon which the Hamming distance can be calculated.

3.2 Microtiming features

To develop features that describe the perceptual properties of microtiming deviations in drum loops, the first stage is to represent them in a form from which features can be extracted. In the context of drum pattern analysis, a sparse matrix format has been used by [12] to express microtiming. Here a matrix shows the timing deviation from the grid in milliseconds, positive (behind the beat) or negative (in front of the beat), for each onset. **Figure 2** shows this for a simple 2 beat pattern. The features extracted from this representation measure two types of microtiming effect: swing or metrical feel and performance styles.

	1	2	3	4	5	6	7	8
K	5	-	-	-	-	-	-	-
S	-	-	-	-	21	-	-	-
HH	-4	-	-8	-	-10	-	3	-

Figure 2. Matrix representation of timing deviations (ms) from 16th note positions in a 2 beat 120BPM kick, snare and hihat pattern (Laid-back event highlighted).

3.2.1 Swing and metrical feel

Using a sparse matrix representation of microtiming deviations alongside a rhythmic representation, swing can be detected along with the presence of triplets in a quadruple-time pattern. Swung onsets are detected as significantly delayed second eighth-notes, approximating the typically

Type	Feature Name	Description
Syncopation	Monophonic	Comparing onset pattern with hierarchical metrical profile [20]
	Polyphonic	Comparing interaction between instruments with metrical profile [34]
	Weak-Strong Ratio	Number of onsets not occurring on downbeats vs on downbeats [15]
Density	Absolute Density	Total onsets divided by number of possible onsets for any number of parts
	Relative Density	Density of one part divided by total density (cf. hiness feature [9])
	Syncopation Density	Syncopation divided by total number of onsets (cf. hisyness feature [9])
Complexity	Rhythmic Complexity	Quadratic mean of density and syncopation [27]
Periodicity	Autocorrelation Skewness	Skewness of autocorrelation curve [22]
	Autocorrelation Max Amplitude	Maximum amplitude of autocorrelation curve [22]
	Harmonicity	Harmonicity of autocorrelation curve, (primarily pulse clarity) [19]
	Symmetry	Proportion of onsets at the same position in 1st and 2st half of pattern. [22]
Intensity	Average	Mean of all velocity values in pattern [15]
	Standard Deviation	Standard deviation of all velocity values in pattern [15]
Swing and metrical feel	**Swing-ness**	Whether loop is swung, weighted by number of swung notes
	Triplet-ness	Whether loop contains any triplets, weighted by number of triplet notes
Microtiming style	**Laidback-ness**	Microtiming style as number of push/laid-back events
	Timing accuracy	Mean of absolute timing deviation from grid of all onsets
Similarity measures	Hamming distance	Counting number of metrical positions where values (onset/rest)' are different
	Fuzzy Hamming distance	Hamming with 1 step lookahead, distance weighted by microtiming
	Structural similarity	Similarity of patterns simplified using [26]'s transformation algorithm

Table 1. List of features and similarity measures currently implemented in the *GrooveToolbox*. New features are in **bold**.

Figure 3. Matrix representation of timing deviations (ms) for 16th note metrical positions in a 2 beat 120BPM rhythm. Red = swung events, green = triplet events.

understood 2:1 eighth-note swing ratio. Although musically these are considered as eighth notes, they fall into sixteenth note positions when quantized, with significant negative (ahead of the position) deviations. The 'swing-ness' feature first records whether these timing deviations occur or not, returning 0 for no swing or 1 for swing. This is then weighted by the number of swung onsets to model perceptual salience of the swing. The deviation threshold for swing is calculated dependent on the tempo of the rhythm. The 'triplet-ness' feature is calculated in the same way, but also records the second note of a triplet as significantly delayed second eighth note. A triplet note detected from a microtiming matrix is shown in green in **Figure 3**.

3.2.2 Microtiming style

Overall timing accuracy is calculated as the mean of all absolute timing deviations per onset in a loop. For onsets classed as swung or triplets, the deviation is calculated from the 'ideal' triplet or swung note position.

Following the timing interaction classification of [25] as described in **Section 2.2.1** the laidback-ness feature counts the number of laid-back timing events subtracted from pushed events, with a negative score meaning an overall 'pushed' loop and positive a 'laid-back' loop. Thus a pattern's feel is calculated based on the detection of specific timing discrepancies above a perceptual threshold, known to impart a given feel from drumming performance analysis. We modified [25] by also counting for ride cymbal in place of hihat due to their similar musical roles.

Based on analysis of timing accuracy in BFD3's library, we chose a threshold of 12ms as a one that would disregard

performance noise. However, ideally this would be calculated per drummer as in [25]. An example 'laid-back' pattern is shown in **Figure 2**. The highlighted event is 'laid-back', as there is a discrepancy on the downbeat between (in this case) snare and hihat that is above the threshold. For this pattern, the timing accuracy value would be 8.5, and laidback-ness 1.

4. EVALUATION

To evaluate our new algorithms and address open questions in drum loop analysis, a two-part experiment was carried out into modelling similarity for BFD3's drum loops, using perceptual data from humans collected via listening test. Three research questions were addressed:

1. *Should models of similarity for drum loops rely on rhythm similarity metrics, feature sets or both?*
   One approach to modelling drum loop similarity is to adapt rhythm similarity metrics [30] that measure distances between onset patterns, used for example in [3, 21, 31]. An alternative is to model similarity as a combination of higher-level rhythm features [11, 16]. While the two are not usually combined, both may be important as they emphasize different information.

2. *Can the models of microtiming proposed be used in modelling similarity of drum loops?*
   Existing IDPTs, described in **Section 2.1**, tend to assume simpler quantized and unswung rhythms. To apply this work to complex loops that are unquantized or swung, or include multiple subdivisions of the metre, models that can account for microtiming deviations could be important.

3. *How do the new rhythm similarity models compare to the Hamming distance?*
   We investigate alternate ways of measuring rhythmic similarity by testing the two new rhythm similarity measures proposed against the Hamming distance.

4.1 Data collection

The dataset consisted of similarity ratings for 80 pairs of BFD3's drum loops (160 total) as provided by 21 participants in a listening test, first collected in [4]. Loops were generated through the same virtual kit, BFD3's 70s Rock kit, chosen due to its generic timbre. Loops were collated equally from 8 genre groups: Blues/Country, Rock, Metal, Jazz, Funk, Reggae/Latin, Pop and Dance/Hiphop. Tempo, metre and loop length were fixed at 120bpm, 2 bars and 4/4 time. Some were swung, and a small number contained triplet rhythms. The test was distributed online using the Web Audio Evaluation Tool [14], with participants representing a range of musical and technical experience.

The listening test used a pairwise comparison methodology. Participants rated how similar two loops were on a continuous scale with five equally spaced markers (*Completely Different, Different, Slightly Different/Slightly Similar, Similar, Identical*). This was to maximize the number of loops in the study, whilst keeping the test length reasonable (30-40 minutes), ensuring multi-genre validity but giving more fine similarity ratings than in the common triadic comparison test design [2]. 5 training pairs were given at the start of the test, and 10 pairs were repeated at the start and end to test participants' internal consistency. The inter-rater reliability (IRR) calculated for all raters across all comparisons using the intraclass correlation coefficient (ICC) in (2,1) form, was 0.73, a moderate-to-good agreement. This is expected, as it is known that musical similarity perception is very individualized [33], with low IRR a challenge in musical similarity studies [7]. The average internal consistency of all participants, calculated as the median ICC (2,1) between ratings for the 10 repeated pairs, was 0.85, equal to good consistency.

4.2 Evaluation Design

Based on this perceptual data, our evaluation was formed in two parts to address the three research questions. The evaluation was designed with consideration of the individualized nature of similarity perception.

4.2.1 Overall perceptual relevance of new models

First we evaluated the new similarity and microtiming models based on their correlation to listeners' similarity ratings. The extent to which the models relate to perceived similarity was measured as the Pearson correlation between the feature score and median similarity rating of the 21 participants. The spread of ratings per pair was approximately normally distributed (D'Agostino-Pearson test $p > 0.01$) so the median across raters is used. While this indicates if the features proposed relate to overall perceived similarity, limited IRR means that more precise analysis of the performance of these features against an average of ratings may not be valid. The second part of the experiment therefore uses individuals' ratings instead.

4.2.2 Building Individualized Similarity Models

In this part, the third research question is addressed. This experiment will find to what extent rhythm feature-based

models can be adapted for use in complex drum loops when combined with microtiming features, and whether a combination of rhythm similarity metric and feature set can offer a better similarity model than either alone can. The aim here is to build similarity models that are predictive, investigating the utility of the models in practical use-cases that may require precise, fine-grained models. Due to low IRR, this requires we develop models for individuals' ratings separately, echoing the concept of 'user-aware' MIR [24]. The models are tested against individual ratings of 7 participants, chosen as those with highest internal consistency (for repeated pairs median ICC = 0.92), and whose ratings were normally distributed (D'Agostino and Pearson test $p > 0.01$), meaning regression models were applicable. Not all participants' individual ratings fit a normal distribution, and not all had high enough internal consistency for precise prediction, so not all could be used.

For each participant we tested seven feature combinations: rhythm features, microtiming features, the best similarity metric from **Section 4.3.1** and each combination of the three. We used all features in **Table 1**. The density features were calculated across three instrument groups separately: low (kick), mid (snare and toms) and high (cymbals) as in [11]. All other features were calculated with all instruments combined. Fitting a regression model to the 7 participants for 7 conditions, we measured the predictive power of the models as the explained variance (R-squared) for each feature combination and participant.

For the single similarity measure we used linear regression. For the feature sets, Partial Least-Squares (PLS) regression was chosen [35]. This was chosen because the features exhibit a high degree of colinearity, due to the large number of features and the inherent co-dependence of musical qualities. This combined with the high predictor-cases ratio means that linear modelling does not work. PLS regression combines elements from multiple linear and principal component regression, and has been found to work well in multidimensional musical emotion prediction [6]. Its use of principal component analysis to create latent prediction variables alleviates the problems of colinearity and high predictor-cases ratio, but limits interpretability of the significance of specific features. This is partly why we evaluate features differently in **Section 4.3.1**. To choose the best number of principal components for each model consistently, we used the Bayesian Information Criterion (BIC), which accounts for overfitting by penalising model complexity against model performance.

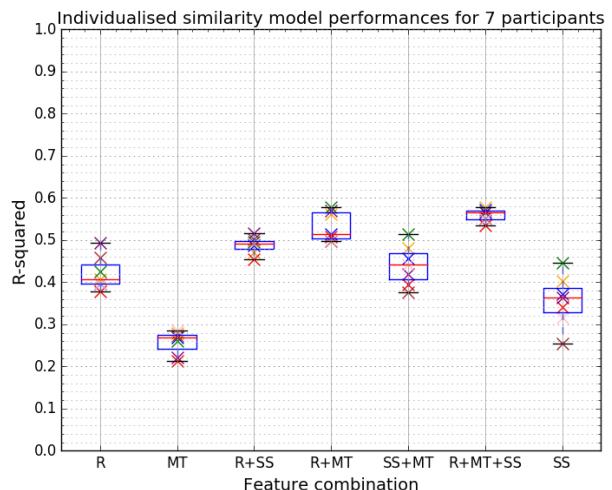
4.3 Results & Discussion

4.3.1 Overall perceptual relevance of new models

The correlation between the features and median similarity ratings is shown in **Table 2**. All models exhibited statistically significant correlation ($p < 0.05$).

The structural similarity measure exhibits higher correlation to the median similarity ratings than the ordinary velocity-weighted Hamming distance (t=1.69, p=0.046). It could therefore be the case for complex drum loops that listeners compare rhythms at a more global structural level

Feature/Model	Correlation r	p
Hamming Distance	0.59	9.7e-9
Structural Similarity	0.65	6.1e-11
Fuzzy Hamming Distance	0.56	6.1e-8
Swing-ness	0.46	1.9e-5
Triplet-ness	0.49	3.4e-6
Timing accuracy	0.33	2.9e-3
Laidback-ness	0.22	0.046

Table 2. Pearson r and *p-value* between median similarity ratings and model difference values.


rather than a precise low level. Alternatively, the structural representation could indicate shared genre between loops by showing the approximate locations of events. Given this seemingly strong performance, using the structural similarity measure over Hamming distance may be advantageous.

For the laidback-ness feature, an issue was that values were typically low, as there is often not a significant difference in microtiming styles between loops. Based on the 12ms deviation threshold, in only 21 of the 80 comparisons was there a difference between timing styles, with the remaining three quarters of the comparisons returning 0. Looking at the correlation between the laidback-ness feature and similarity ratings just for these 21 comparisons where timing style is different, correlation is stronger ($r = 0.47$, $p = 0.0033$). One interpretation is that a feature like this, which models a precise low-level quality, is only relevant for a similarity comparison when there is a significant difference in this quality. While further investigation is required, this may point to the use of adaptive feature weightings for similarity comparisons that select features based on the relevance to a particular comparison.

The other microtiming features exhibited moderate to good correlation, with the swing-ness and triplet-ness features being approximately the same. This may be because loops in our dataset with onsets matching to second triplet positions likely have notes in swung positions too, so there is little practical difference in their values. For a larger dataset this difference may be more significant. The fuzzy Hamming distance did not differ significantly from the regular Hamming distance. The correlations of both the swing and microtiming style features indicate that a better way to incorporate microtiming in similarity models could be as a separate set of features modelling global characteristics of microtiming, rather than being inserted into rhythmic similarity measures. Overall, it appears that these features are able to some extent to capture perceptually salient features of microtiming deviations in drum loops.

4.3.2 Building Individualized Similarity Models

The results of this part are shown in **Figure 4**. Comparing the median r^2 score for the 7 participants, it can be seen that the combination of rhythm and microtiming features with structural similarity measure results in the best predictive model ($r^2 = 0.56$), closely followed by rhythm feature and microtiming model ($r^2 = 0.51$). This confirms that both microtiming and structural similarity models can improve rhythm feature-based similarity models in this case. However, there is still improvement required before they can accurately predict similarity perception.

Figure 4. Model performance as R-squared value for combinations of rhythm **R** and microtiming **MT** feature sets with structural similarity feature **SS** for each participant.

There are a few possible reasons for this. As mentioned in **Section 4.3.1**, the system of deriving a fixed weighting of features in a multidimensional similarity model may not be the best way to model similarity; instead, adaptive weighting schemes may be required that weigh features according to their relevance in a given comparison. While the feature set seems comprehensive, there may be some qualities of drum loops that are not effectively being modelled, in particular features that explicitly detect style or genre. Similarity ratings from more listeners should be collected in the future to construct further personalized models and verify these findings for a wider range of listeners.

5. CONCLUSIONS & FURTHER WORK

We presented a new toolbox for drum loop analysis, with implementations of pre-existing algorithms and new ones for analysing and comparing rhythmic structure and microtiming. These were found to correlate to perceived similarity of drum loops. The rhythmic structural similarity metric was shown to correlate at least as well as the conventional Hamming distance to similarity perception in drum loops. It has been shown that the ideal model of similarity for complex drum loops combines rhythm and microtiming features with a rhythm similarity metric. These results all have implications in future work on IDPTs.

As further work, new algorithms should be developed to improve similarity models in the *GrooveToolbox*, in particular ones that explicitly model stylistic similarity. Here more investigation into rhythmic grouping or structure could be useful. Due to the complex nature of similarity perception it is difficult to infer the practical utility of similarity models from this evaluation. For a more ecologically valid understanding, we will next evaluate them in the context of an IDPT. An approach to combining features that accounts for the possibly attention-based nature of similarity perception could also be a valuable direction. Given the added requirement for personalized models, the next step is to investigate methods such as active learning to learn an adaptive similarity model from a user.

RULE MINING FOR LOCAL BOUNDARY DETECTION IN MELODIES

Peter van Kranenburg

Meertens Instituut, Utrecht University

`peter.van.kranenburg@meertens.knaw.nl`

ABSTRACT

The task of melodic segmentation is a long-standing MIR task that has not yet been solved. In this paper, a rule mining algorithm is employed to find rule sets that classify notes within their local context as phrase boundaries. Both the discovered rule set and a Random Forest Classifier trained on the same data set outperform previous methods on the task of melodic segmentation of melodies from the Essen Folk Song Collection, the Meertens Tune Collections, and the set of Bach Chorales. By inspecting the rules, some important clues are revealed about what constitutes a melodic phrase boundary, notably a prevalence of rhythm features over pitch features.

1. INTRODUCTION

Melody is one of the basic aspects of music. As such, it has been the object of study in numerous research projects in various fields, including music theory, ethnomusicology, music cognition, and music information retrieval. In virtually all those studies, it is generally accepted that a given melody can be analysed in terms of smaller constituents. The availability of a musically sensible segmentation facilitates various music information retrieval tasks [1]. There is, however, no coherent theoretical answer to the questions what exactly are these constituents and how to isolate them from the holistic construct of a melody.

One line of research has been to design computational models to detect segment boundaries at the surface level of the melody. Typically, these models have been tested on a corpus of melodies in which segment boundaries are annotated, mainly the Essen Folk Song Collection [2].

Computational models that have been proposed to partition a melody into a sequence of segments, basically take one of two approaches. In the first approach, which is theory-driven, a set of rules is designed based on theories of human perception and cognition of melodic information, typically drawing on a combination of Gestalt Psychology [3] and Music Theory. These rules are then formalised and quantised in such a way that they can be implemented in software to automatically detect possible segment boundaries in the melodies. The underlying assump-

tion is that these rules reflect the way humans detect patterns in sensory input.

In the other approach, which is data-driven, a model is learnt from data without strong a-priori theoretic assumptions. This approach is based on the idea that a human listener learns to recognise musical events (such as segment boundaries) by exposure.

In this article, we apply a rule mining algorithm that infers from a large corpus of segmented melodies a rule-based model of what is a phrase boundary. The choice for rule mining is motivated by the explainability of the resulting models, which consist of human readable sets of rules. By examining the discovered rules we gain a better understanding of what constitutes a melodic segment boundary, and what features play a role for detecting segment boundaries. We include many features to allow the mining algorithm to choose which features are necessary for the task. We apply the rule-mining algorithm RIPPER [27] as wel as a Random Forest classifier [29] on several subsets of features. By using other data sets next to the Essen Folk Song Collection, we broaden the information on which the models are based, and we are able to compare phrase boundaries across different melodic styles.

2. RELATED WORK

In this section, we review relevant related work. First, we present theory-driven, rule-based approaches (Section 2.1), and then data-driven approaches (Section 2.2).

2.1 Theory-Driven Approaches

The seminal book on *Emotion and Meaning in Music* by Leonard Meyer [4] was one of the first to explicitly relate music expectation to principles of gestalt theory. This publication initiated major lines of research in music cognition and music theory. Tenney and Polansky [5] were among the first to define an implementable, quantitative model for detecting segment boundaries. Their model is based on the principles of proximity (in time) and similarity (in pitch). Several other models are based on gestalt principles as well: the Local Boundary Detection Model (LBDM) by Cambouropoulos [6, 7], the Grouper model by Temperley [8], the preference rules for grouping as defined in A Generative Theory of Tonal Music (GTTM) by Lerdahl and Jackendoff [9], the quantisation of these rules by Frankland and Cohen [10], the Implication-Realization theory by Narmour [11, 12], and the partial quantisation of this theory by Schellenberg [13]. More recently, vari-

ous theory-based approaches have been proposed by Rodríguez López [14]. A rule-based model not explicitly grounded on gestalt principles was proposed by Cenkerová et al. [15].

2.2 Data-Driven Approaches

Explicitly challenging the gestalt principles, Bod [16] introduces Data Oriented Parsing (DOP). A DOP-Markov parser learns probabilities for rewrite rules from a set of examples. One of the applications of this model was the prediction of segment boundaries in the Essen Folk Song Collection. In an error analysis, Bod shows that the DOP-Markov parser is able to learn regularities in phrase-ending patterns that do not adhere to gestalt rules.

Various data-driven approaches are based on information theory. Generally, a phrase boundary is inferred either before an unexpected melodic event or after an event for which the continuation is hard to predict. Methods differ in the way of computing the conditional probability of events given their preceding context. Juhasz [17] takes this approach to segment a collection of Hungarian folk songs. The multiple viewpoint statistical modelling method by Conklin and Witten [18] has been used for many symbolic music processing tasks such as generation, classification, and pattern discovery. The IDyOM model [19] employed the multiple viewpoint method for melodic segmentation. Lattner [20] employs a Restricted Bolzmann Machine to model the probability of a melodic event. This approach outperforms IDyOM, and sets the state-of-the-art for recognising phrase boundaries in the Essen Collection.

Rodríguez López [14] also introduced a data-driven component. A part of his segmentation system needs to be trained on a corpus.

3. DATA

An often used collection of segmented melodies is the Essen Folksong Collection (EFSC). This collection contains thousands of folk song melodies mainly from Germany, but also from other parts of Europe, and a relatively small number of melodies from other continents. In the process of creating this collection, the melodies have been segmented into phrases. Therefore, it offers a large amount of data on melodic segmentation which allows for statistical evaluation. Following earlier work, we use the database Erk, a subset of EFSC consisting of c. 1,700 melodies.

We also employ a recently published corpus from the Meertens Tune Collections (MTC), consisting of collections of thousands of instrumental and vocal songs from Dutch sources [21]. The collection we use in this paper is MTC-FS-INST-2.0, more specifically, those melodies that have lyrics, are dated after 1850, and have a time signature. This results in a selection of c. 7,500 melodies. For reasons that will be explained in section 3.1.2 we apply a further selection: from each tune family, we randomly select one melody. This results in a set of 1,323 melodies.

The third corpus we use is the collection of 371 harmonisations of chorales (CHOR) by Johann Sebastian Bach

Dataset	#songs	#boundary	#noboundary	total
MTC	1,323	7,054	63,856	70,910
ESSEN	1,632	7,703	62,490	70,193
CHOR	370	1,907	15,455	17,362

Table 1. Overview of the datasets indicating the number of songs and the sizes of the classes (number of 5-grams).

(1685–1750). [1] Since our focus is on melodic segmentation, we only use the melodies (i.e., the soprano parts).

An overview of the datasets, the number of songs, and the class sizes is included in Table 1.

3.1 Some Caveats

Employing a collection of folk song melodies has some important consequences that have often not been discussed in previous work. We focus on two problems: tune family relations, and the rest as notational device.

3.1.1 Tune Families

One defining property of folk music is that it has been in oral circulation [22]. In the process of oral transmission, changes are introduced to the melodies and texts. Therefore, in a typical collection of folk songs, several variants of the same melody are included, exhibiting minor to large differences among each other. Such a group of related melodies is often designated as a *tune family* [23]. EFSC and MTC are no exceptions to this. For the collections in MTC, the tune families have largely been identified by collection specialists at the Meertens Institute. The tune family labels are included in the metadata that comes with the collection. For the ESFC this has not been done. From the titles of the songs, which are available in the metadata, it is clear that duplicates and variants of melodies are included, but there is no account of precisely which melodies are related.

The consequence of this for a data mining approach is that the independence of the train and test sets is not guaranteed since members of the same tune family may end up in both the train and test sets. Especially when the differences are small, this is problematic.

To solve this issue, we take advantage of the tune family labels as provided in the metadata of MTC.

3.1.2 Rests

In related work, the presence of a rest appeared to be a strong indicator of a phrase boundary. For example, one of the quantised GTTM preference rules (GPR 2a) states that the boundary strength is proportional to the length of a rest. In LBDM, next to pitch and inter-onset-intervals, rests are explicitly incorporated as one of the three features that contribute to the resulting local boundary strength. Furthermore, the occurrence of a rest is the first of Narmour's six conditions of melodic closure [11, p. 11].

There is, however, a difference between the meaning of a rest in composed music and in folk song transcriptions.

---

[1] This corpus is available as part of the humdrum-data repository: https://github.com/humdrum-tools/humdrum-data

Figure 1. Transcriptions of two variants of the same melody showing different uses of the rest as notational device.

Again, this is related to the process of oral transmission. A composer typically uses common music notation as the primary device to communicate a piece of music to performers. Here, the notation of a rest is *prescriptive*, indicating the performers not to make sound. On the contrary, music notation as found in folk song collections is typically *descriptive*. The melodies have been transcribed from audio recordings, or from aural observation. Here, the rest is an indication of something a performer already has done. The example from the MTC that is shown in Figure 1 illustrates the resulting confusion that can arise if various transcribers contribute independently (or if one transcriber works inconsistently). In the upper transcription, the final note of each phrase is extended to fill the measure, while in the lower transcription, rests are included at the phrase boundaries. Crucially, inspecting the audio recordings that are the sources of these two transcriptions, [2] no noticeable differences are observable between the way the singers separate the phrases.

It appears that the rest as a symbol has a use in folk song transcription to represent a phrase boundary, rather than to indicate absence of sound. As a consequence, using the rest as a feature actually includes the ground truth in the feature set, which obviously results in an optimistic estimation of classification performance. We will therefore report results without using rests, and results including rests – and other ground truth dependent features – separately.

---

[2] These are available at http://www.liederenbank.nl/index.php?lan=en by entering the respective record numbers (73639 and 74427) in the search field.

4. METHOD

The approach in this paper largely is a feature engineering exercise. From previous studies and from general music theoretic considerations, we take inspiration of what features may contribute to the establishment of a phrase boundary. Next, we apply two machine learning algorithms: RIPPER and Random Forest. Thus, we do not take an a-priori theoretical basis, such as the gestalt principles, but we let the learning algorithm explore which features are of value and in what combination.

4.1 Objects and Features

The target of the classification is to find those notes after which a phrase ends. As object of classification we take each note in the melody with its local context of the two preceding and the two following notes, resulting in sequences of five notes, 5-grams. Since the aim is segmentation, the final phrase end, which also ends the melody, is excluded from the data set. Those 5-grams of which the third note is the final note of a phrase get the class label *boundary*, while all other 5-grams get the class label *noboundary*.

For each of the 5-grams we extract a large number of features. Each of those features can be considered a hypothesis of which information contributes to the concept of phrase boundary. We discern various groups of features. For extracting the feature values, the music21 toolkit has been used [24].

Elementary pitch features include for each of the five notes: the scale degree, the absolute pitch value in MIDI-representation, the interval with the previous note in semitones, the pitchcontour (up, down, equal), and the *Harmony* and the *Center of Gravity* as defined in [25].

Elementary rhythm features include the meter 'numerator' and 'denominator', the duration of the beat, the number of beats in the measure, and for each of the five notes: the metric weight, the duration (inter-onset-interval) in units of the beat-length, whether the note starts on or off the beat, and whether the duration increases for each of the first three notes. Furthermore, following the reasoning of Temperley [8, p. 70], we include a boolean feature that is True when the onset time of the fourth note is at the same position in the measure as the onset of the very first note of the melody. This accounts for the preference to start phrases at corresponding positions in the measures. To allow a more fine-grained version of this preference, we also include a boolean feature that is True if the onset time of the fourth note completes the time-span of a beat, starting the first time-span at the onset of the first note (which possibly is not on the beat in case of an anacrusis). The metric weight (beatstrength) and the length of the beat, both included as feature, are computed with the music21 toolkit.

Elementary lyric features (MTC only) include for each of the five notes: whether the lyric syllable is stressed, whether the lyric is a content word, whether the lyric syllable ends a content-word that rhymes with another content-word anywhere in the lyrics, whether the lyric syllable is the final syllable of a word, and whether the note is part

of a melisma. For labeling non-content words, detection of rhyme, and determining the word stress, the methods as described in [26] are used. Furthermore, we measure the distance between the third note of the 5-gram and the most recent rhyming syllable, both as number of notes and as number of beats.

Wherever applicable, we include the first-order contour of these elementary features as separate features, registering whether the value for a note is higher, equal, or lower than the value for the previous note. This provides the rule mining algorithm with relational information for the consecutive notes, which is beneficial because RIPPER is not able to include comparisons between features into the conditions that constitute the rules. Each condition consists of a single feature compared to an absolute value.

Next to these elementary features, we include features that are derived from previous models. For each of the five notes, the following values are included as feature:

- the sum of the values for the quantised GTTM GPRs 2a, 2b, 3a, and 3d, as defined in [10];

- the Local Boundary Strength as computed by the LBDM [7];

- the values for pitch proximity and pitch reversal as defined in [13];

- the prediction of Grouper [8];

- the information content as computed by the IDyOM model according to [19];

- features that are based on the conditions of closure as stated by Narmour [11, p. 11]: the metric weight contour for the third note, whether the third note is longer than the second, whether the interval between the first and second notes is larger than the interval between the second and third notes, and whether the direction of the melodic contour changes between the second and the third note.

Finally, we include several features that are not independent of earlier annotated segment boundaries. In an inspection of classification results, it appeared that often a boundary very close to the beginning of a phrase was predicted. To prevent this, we include the distance between the third note of the 5-gram and the beginning of the phrase, both as number of notes, and as number of beats. Furthermore, we include a boolean feature that is True if the onset of the fourth note is at the same position in the bar as the onset of the first note in the phrase. Lastly, we include for each of the five notes whether a rest follows the note.

In total, we have 162 features (excluding the class label), 31 of which are lyric features.[3] The lyric features are only computed for the MTC dataset, since lyrics are not present in the ESSEN and CHOR collections.

4.2 Learning Algorithms

RIPPER [27] is a rule mining algorithm that infers a set of classification rules from a data set. The basic procedure that is implemented in this algorithm is to split the training data into two folds (1/3 and 2/3), grow a rule on the 2/3 split, prune the rule using the 1/3 split, and remove the objects that are covered by the rule from the training set. This is repeated until no objects remain in the training set. Each iteration results in a rule that is added to the rule set. The algorithm starts finding rules that target the minority class, which is appropriate for the segmentation problem in which phrase boundaries are a minority class. The resulting rules are not independent. To reach a classification, the rules have to be applied in the order as provided by the mining algorithm. The advantage of a rule-set as resulting model is its interpretability. From the rules it is clear how a classification is established.

One important parameter of the RIPPER algorithm is the minimum number of objects per rule. By setting this to a low value, many rules result that might be too specific, while setting this to a high value results in less, and more general rules. We found that in general for our purpose 32 is a sensible value. Smaller values lead to much more rules, without considerably improving classification performance. Furthermore, since songs in general have much less than 32 phrase boundaries, this value forces the algorithm to generalise over songs. We use the implementation that is provided in the Weka workbench [28].

To better show the potential of the feature set, we also use a Random Forest classifier [29]. During training, a large number of decision trees are fitted to random subsets of the data. The classification is a majority vote of these individual trees. The models that result from this approach are not easily interpretable, but they generally reach a higher classification performance compared to a single decision tree or rule set. We experimentally found that the optimal number of trees in the forest is around 40. Larger forests do not considerably add to the classification performance. We use the implementation as provided in the Python module sklearn [30]. For evaluation, we employ a 5-fold cross-validation procedure, both for RIPPER and Random Forest. To further raise the independence between test and train sets in case of the Random Forest, we make the splits between the train and test sets at the level of melody. Thus, the 5-grams from the same melody all are either in the test or in the train set. For MTC, this implies that also tune families are always separated, while for EFSC and CHOR this cannot be guaranteed. The code for this paper is publicly available.[4]

5. RESULTS

Table 2 shows the classification results for the three datasets, the two classifiers, and various feature subsets.

5.1 General Remarks

The separate groups of elementary features (pitch, rhythm, lyrics) only reach moderate performance. Rhythm features consistently score better than pitch features. Lyric features clearly have considerable discriminative power,

NoLyr	**0.85**	**0.77**	**0.81**	**0.95**	**0.86**	**0.90**
All	-	-	-	-	-	-
NoLyr+GT	0.94	0.84	0.89	0.98	0.91	0.94
All+GT	-	-	-	-	-	-

Table 2. Classification results (precision, recall, and F1 for the boundary class) on MTC, EFSC, and CHOR for various feature subsets, both for the rule miner (RIPPER) and for the Random Forest classifier. "El." denotes the elementary features. "NoLyr" denotes all features except for the lyrics features. "Prev." denotes the features from previous models. "GT" denotes the group of features that are not independent of the annotated phrase boundaries.

as is observable in the increase of the recall between the "El. NoLyr" and "El. All" subsets for MTC.

Comparing the performance between using elementary features only and using all features shows some improvement in the later case for MTC and EFSC, but not for CHOR. The "Prev." subset on its own consistently shows a good performance. This implies that the explainable power of the elementary features is comparable to the explainable power of the previous models. A large part of the boundaries remains unexplained with either which method.

Overall, MTC is the hardest to classify. Undoubtedly, this is a consequence of the careful compilation, ensuring only one melody per tune family. Since we have no tune family labels for EFSC and CHOR, the independence of

train and test sets cannot be fully guaranteed. Therefore, the classification results might be too optimistic.

5.2 Rule Sets

The contents of the rules as found by the RIPPER algorithm reveals which features are paramount in detecting phrase boundaries. Although all rule sets give rise to interesting observations, it is not possible to discuss them all within the scope of this article. We show for two cases the first few rules, which typically cover many objects. As these rules are not directly derived from a theory of melodic perception, we are specifically interested to see to what extent the rules confirm existing understanding of melodic closure. Furthermore, these rules have the potential to lead to new hypotheses about what establishes closure in a melody.

First, we focus on the cases in which only elementary features are used. These are the first three discovered rules for MTC using the elementary pitch and rhythm features: [5]

```
Rule 0:
   (IOIbeatfractionthirdfourth = -) and
   (completesmeasuresong = True) and
   (IOIbeatfractionthird >= 1.25) and
   (meternumerator >= 4) and
   (IOIbeatfractionfirst <= 0.666667)
   => class=boundary (739.0/54.0)
Rule 1:
   (IOIbeatfractionthirdfourth = -) and
   (completesmeasuresong = True) and
   (IOIbeatfractionthird >= 1) and
   (IOIbeatfractionsecondthird = +) and
   (beatstrengthfourth >= 1)
   => class=boundary (705.0/88.0)
Rule 2:
   (IOIbeatfractionthirdfourth = -) and
   (completesmeasuresong = True) and
   (IOIbeatfractionthird >= 1.25) and
   (IOIbeatfractionfifth <= 1.5) and
   (VosHarmonyfourth >= 4) and
   (intervalsecond <= 0) and
   (diatonicpitchthird <= 30)
   => class=boundary (272.0/15.0)
```

Rule 0 classifies 739 5-grams from the train set correctly, and additionally covers 54 false positives. `IOIbeatfraction` denotes the duration of the note in units of the beat-length. The first rule mainly states that the fourth note should be shorter than the third, the third note ends at the position in the measure that is parallel to the start of the first note of the melody, the third note is longer than the beat (>=1.25 times), the first note is fairly short, and the `meternumerator` is 4. The last condition excludes all songs in e.g., 6/8 or 3/4 meter. The conditions that have been selected for these rules confirm considerations for several previous models. One of the central properties of a phrase-closing note seems to be its length, which should be longer than the beat. Furthermore, these rules all state that the length of the fourth note should be shorter than the third. This condition is present in 22 of the 30 discovered rules in this set. It contrasts with one of Narmour's conditions of closure [11, p. 11], which states that the closing note is longer than the previous note. Apparently, the data indicates that the relation with the next

---

[5] The full rule set is included in the supplemental material.

Dataset	RIPPER	Random Forest	IDyOM	Grouper	LBDM	Rest	Always
MTC	0.73 0.61 **0.67**	0.80 0.58 **0.68**	0.65 0.51 **0.57**	0.69 0.67 **0.68**	0.60 0.51 **0.55**	0.92 0.26 **0.40**	0.10 1.00 **0.18**
EFSC	0.78 0.63 **0.69**	0.83 0.69 **0.76**	0.71 0.49 **0.58**	0.70 0.61 **0.65**	0.60 0.47 **0.53**	0.96 0.31 **0.47**	0.11 1.00 **0.20**
CHOR	0.84 0.75 **0.79**	0.94 0.85 **0.89**	0.61 0.39 **0.47**	0.64 0.59 **0.62**	0.48 0.42 **0.45**	0.99 0.09 **0.17**	0.11 1.00 **0.20**

Table 3. Classification performance of related models. For each model, precision, recall, and F1 (bold) for the boundary class are reported. Results for RIPPER and Random Forest are for the featureset El. NoLyr.

note is more indicative, instead. One could speculate that the perception of closure at the third note is reinforced in retrospective when noticing that the next note is shorter. The rules that are found for the EFSC bear a similarity to those for MTC. The rules for CHOR differ more. But for all three data sets rhythm features dominate the top rules. This confirms earlier results as reported by Weyde [31]. The pitch features that are included mainly refer to pitch contour and the level of dissonance of the melodic interval (as registered by the features based on [25]).

Next, we consider the top rules that are discovered for MTC with the feature subset of all features ("All"): [6]

```
Rule 0:
  (grouperthird = True) and
  (rhymesthird = True) and
  (lbdmthird >= 0.280929)
  => class=boundary (2413.0/149.0)
Rule 1:
  (grouperthird = True) and
  (wordendthird = True) and
  (informationcontentfourth >= 7.252784) and
  (contourthird = -) and
  (lbdmfifth <= 0.159635)
  => class=boundary (641.0/33.0)
```

It is clear that the combined models of LBDM and Grouper, and the condition of rhyme constitute a very powerful rule that covers 2,413 boundary 5-grams in the training set, and only 149 noboundary 5-grams. In the second rule, also the information content as computed by IDyOM plays a role. But also some elementary features are used.

5.3 Existing Models

Table 3 shows a comparison with the performance of several existing models. The values for the RIPPER and Random Forest classifiers are those for the set of elementary features without the lyrics. This is not the best performing feature subset, but the larger subset would include IDyOM, Grouper and LBDM as features, which would not render a fair comparison. The IDyOM segmentation is computed with the implementation of IDyOM as available on GitHub. [7] Grouper is available as part of the Melisma Music Analyzer. [8] LBDM is implemented according to [7]. The threshold for peak-picking is chosen such that the resulting F1-value is maximised. The Rest model assumes a phrase boundary wherever a rest is notated in the score. This quantifies the effect of including the rest as a feature in a segmentation model that is evaluated on a collection of folk song melodies. As can be seen, the rest model typically results in high-precision, low-recall segmentation.

[8] https://www.link.cs.cmu.edu/music-analysis/

Dataset	MTC	ESFC	CHOR
MTC	0.80 0.58 **0.68**	0.83 0.57 **0.67**	0.85 0.49 **0.62**
ESFC	0.76 0.61 **0.68**	0.83 0.69 **0.76**	0.83 0.68 **0.74**
CHOR	0.77 0.32 **0.45**	0.80 0.37 **0.51**	0.95 0.86 **0.90**

Table 4. Performance of cross-evaluation. The rows show the train sets, the columns the test sets. The values are: precision recall F1 (bold) for the boundary class.

For both MTC and EFSC the occurrence of a rest explains around 30% of the phrase boundaries. This is a considerable effect. Finally, a baseline model is included that classifies each note as a phrase boundary. The Random Forest classifier with the elementary feature set outperforms the other methods for ESFC and CHOR, and performs comparable to Grouper on MTC, although precision and recall are more balanced with Grouper. It also outperforms Lattner's RBM approach on EFSC (0.80 0.55 **0.63**) [20]. Notably the recall is higher. However, the currently presented approach is supervised and uses more features.

5.4 Cross Relations

We now examine the performance of the classifiers on the datasets they are not trained on. We use the Random Forest classifier and the feature subset "El. NoLyr". Most notable in the results as shown in Table 4 is the comparable cross-performance between ESFC and MTC. Apparently, the phrase endings in the Dutch and German folk song styles have comparable properties. The higher self-performance of ESFC might partly be caused by the tune-family problem (Section 3.1.1). The low performances of the classifiers trained on CHOR are mainly caused by low recall. This could indicate that some types of phrase endings that occur in MTC and ESFC are absent in CHOR.

6. CONCLUSION

We presented an approach to melodic segmentation that builds on and integrates elementary melodic features and existing segmentation models in a theory-agnostic way. By deriving a rule-set using a large number of features, we get an indication of which features are crucial for detecting phrase boundaries in melodies. A notable observation is that a phrase boundary is mainly detectable with rhythm features. By employing a Random Forest classification, we get an indication of the discriminative power of the considered feature sets. The resulting classifier outperforms all earlier approaches to the problem of automatic melodic segmentation. By cross-evaluation, we detect a connection between MTC and EFSC.

ABSTRACT

Recent work have addressed the automatic cover detection problem from a metric learning perspective. They employ different input representations, aiming to exploit melodic or harmonic characteristics of songs and yield promising performances. In this work, we propose a comparative study of these different representations and show that systems combining melodic and harmonic features drastically outperform those relying on a single input representation. We illustrate how these features complement each other with both quantitative and qualitative analyses. We finally investigate various fusion schemes and propose methods yielding state-of-the-art performances on two publicly-available large datasets.

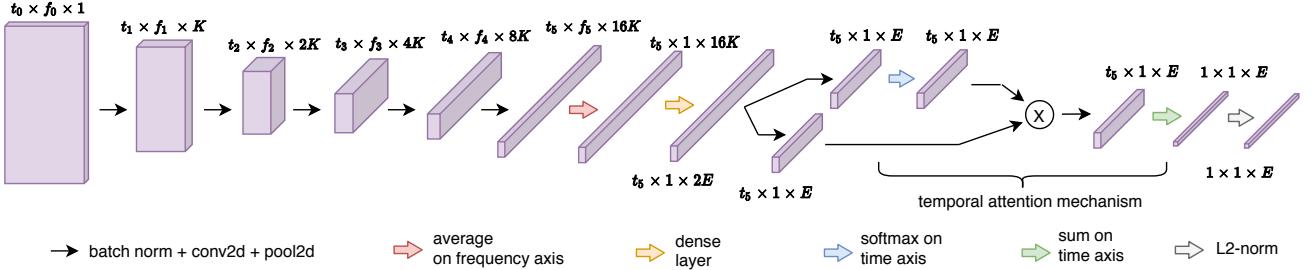
1. INTRODUCTION

Music retrieval has come a long way in the last 25 years. Since the earlier works on symbolic music retrieval [1, 2], applications with increasing complexity have been developed. In the mid-1990's, query-by-humming aimed at retrieving songs based on melodic similarity with a short hummed or whistled audio excerpt [3,4], while fingerprinting in the early 2000's aimed at identifying a song based on one of its excerpts [5]. Music matching at large – the task of retrieving an excerpt based on its musical similarity with another – was developed in the mid-2000's, typically comparing sequences of harmonic features via dynamic programming methods [6–8].

Automatic cover detection – the task of retrieving covers of a given track from an audio corpora – emerged at the same period, and was largely inspired by the previous decade of music retrieval research. Some of the early cover detection systems were relying on dominant melody to assess musical similarity [9, 10], and one of them reached the 3rd place (out of 8 participants) at the first MIREX [1]

---

[1] https://www.music-ir.org/mirex

cover song identification contest in 2006. The same year however, 1st and 2nd ranking algorithms were relying on harmonic features – chroma vectors or estimated chords series [11–13]. These results seem to have fostered the use of harmonic representations – chroma in particular – over melodic ones for cover detection, and all algorithms submitted to the next 2007 MIREX edition were using a tonal representation [14–16]. Enhanced chroma and time series comparison via dynamic programming then became the *de facto* standard method in the field – and remained the state of the art for more than a decade [17, 18].


During the following years, the community focused on improving both accuracy and scalability of existing approaches. As to accuracy, it was proposed to aggregate the results obtained with different methods [19–21] or different input features [22–24]. As to scalability, several strategies were investigated to compress the original representations and to reduce the similarity comparison function to a lightweight distance computation [25–28] or a fast lookup operation in a database index [29, 30].

The advent of efficient machine learning methods in other fields – such as image recognition – encouraged the community to shift from these previous methods based on ad-hoc and handcrafted features toward a new approach based on data-driven feature learning [31–33]. Recently, promising results were obtained using the metric learning paradigm in a cover detection context. The principle is to train a neural network to represent each track as a compact vector – its embedding – so that the distance between embeddings of a cover pair is smaller than that of non-cover pairs. Features used as input data were as varied as the Constant-Q Transform [34], dominant melody or multi-pitch [35, 36] or chord-informed chroma [37].

In this work, we propose a comparative study of these input features and investigate their combinations to improve cover detection performance. In Section 2, we briefly review different works inspiring our approach. In Section 3, we present the features that we consider for this study and their respective performances. In Section 4, we discuss the results obtained using different combinations of these features with a simple averaging fusion scheme, and explain them with a qualitative analysis. We then propose in Section 5 an architecture able to learn to combine various features efficiently. We conclude with future potential improvements.

Figure 1: MICE architecture.

2. RELATED WORK

We present here the main concepts inspiring this work: input features combination and metric learning paradigm.

2.1 Combination of input features

A first attempt to combine information from various input features for cover detection was made by Foucard et al. using a source separation algorithm to obtain three inputs: the mixed original track, the dominant melody – assumed to correspond mainly to the solo singing voice – and the accompaniment [22]. In another study, Salamon et al. argued that, albeit closely related, dominant melody, bass line and harmonic progression embed different and complementary information. To prove this idea, they proposed to compare the systems that use each feature separately and their combinations with different fusion schemes [23]. More recently, Tralie et al. investigated another multi-representation approach, fusing harmonic and timbral features [24]. These studies showed that systems combining several input features outperformed those using each feature individually.

2.2 Classification vs. metric learning paradigm

Different teams recently proposed data-driven feature learning methods to address the cover detection problem. A common approach is to use a Convolutional Neural Network (CNN) to extract a compact representation – an embedding – from a low- or mid-level spectral representation of the audio, for instance Harmonic Pitch Class Profile (HPCP) [38] or Constant-Q Transform (CQT) [34, 39]. These authors considered the problem as a classification task, introducing an additional dense layer as a classifier.

Similarly, Doras et al. used dominant melody or multi-pitch representations [35, 40], while Yesiler et al. used crema-PCP [41], a chord-informed chroma representation [37] to extract the embedding. These input features were obtained with specialized neural networks [36, 41]. These authors also adopted a metric learning approach in which the CNN is trained with a triplet loss to produce embeddings whose pairwise Euclidean distance is lower for covers than for non-covers. Using these melodic or harmonic input features along with the metric learning paradigm yielded promising results and inspired this present work.

3. COMPARING INPUT FEATURES

We compare here performances obtained with a full spectral feature (CQT), two melodic features (dominant melody and multi-pitch) and two harmonic features (chroma and crema-PCP). For brevity, we denote them Cq, Dm, Mp, Ch, and Cp, respectively.

3.1 Input features

We computed Cq and Ch using Librosa v0.7 [42]. We obtained Dm and Mp with the convolutional network we previously described in [36], and we obtained Cp with the model publicly released by [41], as done in [37].

Temporal resolution All features were computed for an audio duration of 180 seconds as in [35], with a frame duration of 93ms (1937 bins). For tracks longer that 180 seconds, the beginning of the 180 seconds is taken at random, while shorter tracks were zero-padded, as in [37].

Frequency resolution All features were computed with a resolution of 1 bin per semi-tone. Cq was computed across 6 octaves. Dm and Mp are originally extracted with a resolution of 5 bins per semi-tone and their resolution is downsampled by a factor 5 via 2D-interpolation, following [35]. For each Dm, only the 3 octaves around its mean pitch are considered, as done in [35]. To account for all possible circular shifts in chroma features, we concatenate on top of the Ch and Cp their 11 lowest frequency bins, following [37, 38]. To summarize: Cq, Dm, Mp, Ch and Cp have 72, 36, 72, 23 and 23 frequency bins, respectively.

Normalization Cq and Ch are log-compressed and trimmed at -80dB. Finally, each feature is globally normalized between 0 and 1.

3.2 Model

Yesiler et al. introduced MOVE, a network containing a convolutional part specially designed to capture Cp patterns and a temporal attention part [37, 43], while Doras et al. used a plain convolutional network to capture Dm and Mp patterns [35, 40]. We introduce here a new model that reuses the plain convolutional part of the latter and the temporal attention mechanism of the earlier. The rationale behind this architecture is twofold: we need a generic model that can be used for all types of input features in order to conduct fair performance comparisons, and we observed in preliminary experiments that the temporal attention mechanism improves the results of the plain CNN. We call this model MICE (Musically Informed Cover Embeddings).

As shown on Figure 1, the first part of the model is the 5-layer CNN of [35]. Each layer block consists of a batch normalization layer, a convolution layer with 3×3 kernels and a mean-pooling layer with 2×2 kernel and 2×2 stride. The number of kernels K of the first layer is doubled at each level. Output is then averaged along the frequency axis, and a dense layer is applied to output a number of channels of $2E$, where E is the final embedding size.

The attention mechanism is then introduced: the tensor is split in 2 on its channels dimension to obtain two tensors of E channels. A softmax function is then applied on the time axis for the first tensor, and the output is multiplied element-wise with the second tensor. The resulting values are then summed along the time axis, which gives a vector of size E. The softmax followed by the multiplication and the sum implements a weighted average along the time axis per channel. The network is thus trained to give preference to the parts along the time dimension that are the most relevant to meet the objective function. The embedding vector is then L2-normalized. We used K=64 and E=512.

3.3 Experiments

In these first experiments, we train a different instantiation of MICE for each type of input feature and evaluate their cover detection performances.

Datasets We used the publicly available training set SHS_{5+} [2], containing Cq, Dm, Mp, Ch and Cp features for ~62k covers of ~7.5k works. It was split into a training/validation set with a ratio of 80/20 with respect to the works, i.e. all covers of a given work belong to one or the other set. We tested our model for each feature with two publicly available test datasets: SHS_{4-} [2], containing ~50k covers of ~20k works, and Da-TACOS [3], containing 13k covers of 1k works and 2k confusing tracks [44].

Loss We used a triplet loss to train this network [45]. Formally, if we let $\{a, p, n\}$ denote a triplet of track embeddings, where a is an anchor, and p or n is one of its covers or non-covers, respectively, the loss to minimize is expressed as $L = \max(0, d_{ap} + \alpha - d_{an})$, where α is a margin and d_{ap} and d_{an} are the distances between anchor a and p or n, respectively. We set $\alpha = 1$.

In practice, we used online semi-hard negative pairs mining [46], where triplets are built within each training batch: instead of using all possible triplets, each track in the batch is successively considered as an anchor, and compared with all its covers in the batch. For each of these positives pairs, if there are negatives such as $d_{an} < d_{ap}$, only the one with the highest d_{an} is kept. If no such negative exists, only the one with the lowest d_{an} is kept. Other negatives are not considered.

Training We train MICE with Adam optimizer [47], with an initial learning rate of $1e^{-4}$, divided by 2 each time the loss on the validation set has not decreased after 5k training steps. Training is stopped after 50k steps, or if the learning rate falls below $1e^{-7}$. The batch size is 64.

---

[2] https://gdoras.github.io/topics/coversdataset
[3] https://github.com/MTG/da-tacos

Testing For each feature, we use the corresponding trained model to compute the embeddings on the two test datasets. For SHS_{4-}, one cover per work is used as a query against the entire test set to compute a 20k×50k distance matrix. For Da-TACOS, each cover is used as a query against the entire dataset to compute a 13k×15k distance matrix. The Mean Average Precision (MAP), the mean number of correct answers in the ten first answers (MT@10) and the mean rank of first correct answer (MR1) are then computed.

3.4 Quantitative analysis

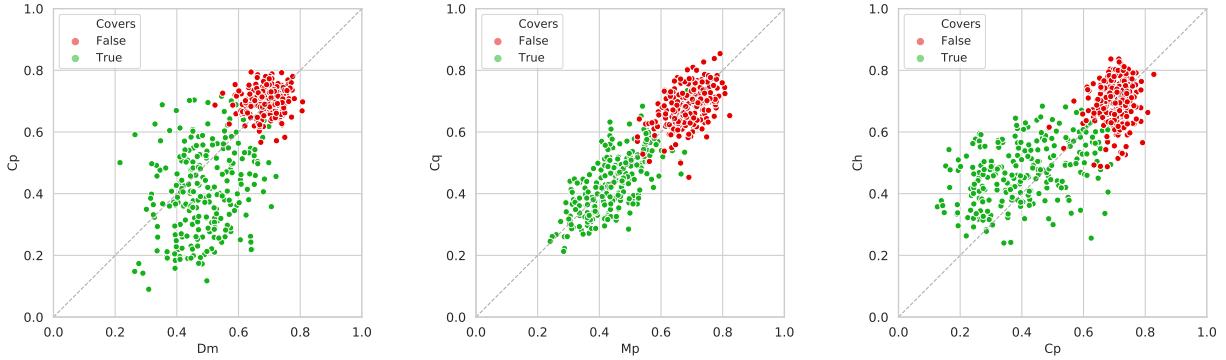
We report in Table 1 the performance scores obtained on Da-TACOS and SHS_{4-} for each type of input feature.

Input	Da-TACOS			SHS_{4-}		
	MAP	MT@10	MR1	MAP	MT@10	MR1
Cq	0.215	2.468	94	0.397	0.718	886
Dm	0.311	3.521	111	0.412	0.722	1431
Mp	0.293	3.290	**71**	0.422	0.760	**862**
Ch	0.121	1.476	117	0.174	0.371	1465
Cp	**0.375**	**4.084**	86	**0.499**	**0.842**	1169

Table 1: Results on SHS_{4-} and Da-TACOS for each feature.

Consistently, the Cp yields by far the best results, followed by the Dm and the Mp. This confirms our initial intuition that both melodic line and harmonic progression are prominent common musical facets between covers. Cq, representing the full spectrum, yields lower performance, which suggests that, albeit also embedded in the spectrum, the melodic and harmonic information is obfuscated, e.g. by percussive sounds information. Finally, the tonal information embedded in the Ch does not seem to be efficiently caught by our model.

From a practical point of view, crema-PCP is probably the best feature among those considered in this work, as it yields the best results with the lowest memory footprint.

4. COMBINING INPUT FEATURES


In this set of experiments, we now investigate if combining different features can improve the performance of each feature considered individually.

4.1 Are features complementary ?

We first compare pairwise embedding distances computed for the same pairs of tracks but obtained with different input features, as shown on Figure 2. The leftmost plot for instance compares the pairwise distances obtained for Dm and Cp. If each track's embeddings extracted from different input features were carrying the same information, the pairwise distance would be the same for a given pair of tracks, independently of the feature used. Figure 2 shows on the contrary that the same pair of tracks can obtain a low distance when using a given input feature, but a notably higher distance when using another one.

Figure 2: Comparison of the normalized distance obtained for the same pairs from SHS_{4-} (cover pairs in green and non-cover pairs in red) with different features: Dm vs. Cp (left), Mp vs. Cq (middle), Cp vs. Ch (right). Other combinations are not shown due to space constraints. For clarity, only 500 pairs randomly picked are drawn (250 covers and 250 non-covers).

All features seem relatively consistent when labeling non-cover pairs (red points exhibit high distances on both axes). Conversely, cover pairs (green points) are more scattered. Dm and Cp in particular seem to give very distinct results, as many pairs are spread far from the diagonal, which means that some cover pairs are more efficiently scored by one or the other feature. Intuitively, it seems logical that Dm and Cp are encoding complementary melodic and harmonic facets. This suggests that combining these features could benefit of this complementarity. We now conduct a quantitative and a qualitative analysis to confirm this intuition and to understand why certain representations yield better results for certain songs and vice-versa.

4.2 Quantitative analysis

We first experiment with a simple fusion scheme, which consists of averaging the pairwise distances obtained for the same pair with different features. We then re-compute the evaluation metrics based on this new averaged distance matrix for each possible feature combination. The rationale behind this approach is that we expect pairs incorrectly clustered with one representation to benefit from the correct clustering obtained with another representation.

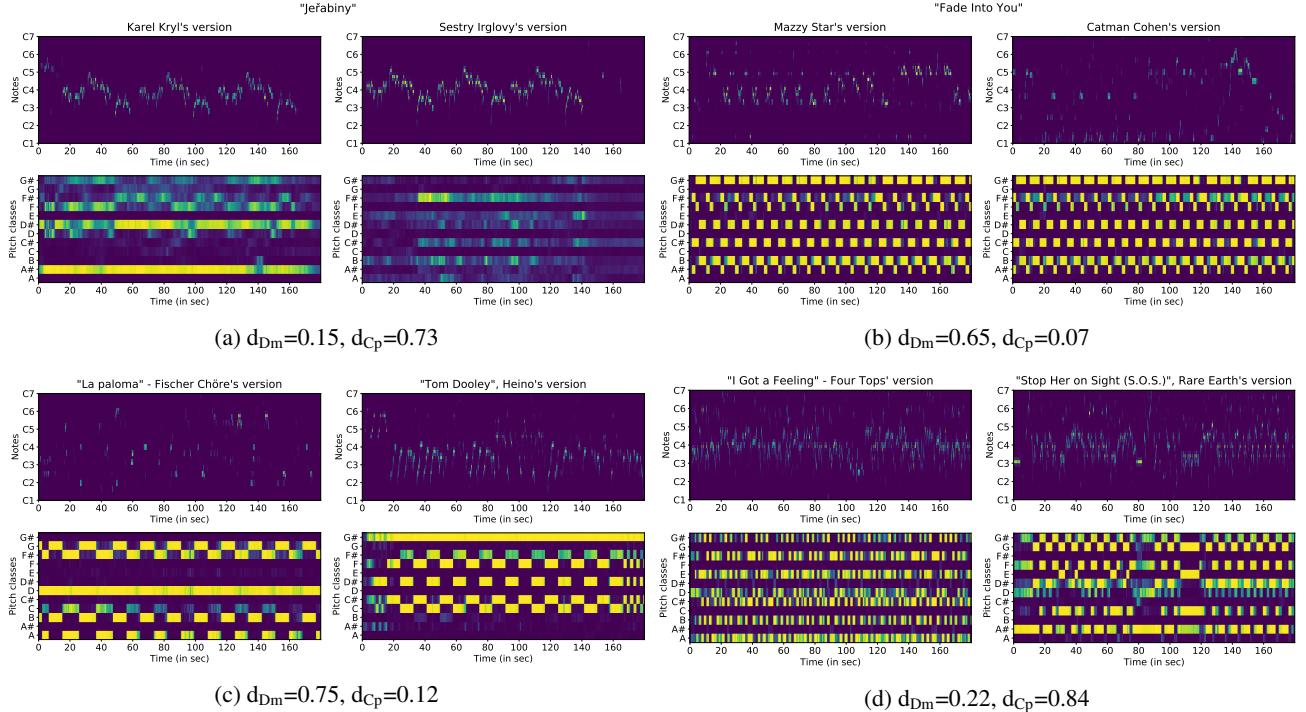
The results are summarized in Table 2 for all combinations of Cq, Dm, Mp and Cp representations (we did not consider Ch here). We also computed the scores obtained by an oracle, which always picks among the distances obtained for each feature the lowest (resp. highest) distance for positive (resp. negative) pairs.

It appears clearly that any combination yields a better performance than any feature isolated (see Table 1). It also appears that the combinations where the Cp is used yield higher scores than the others, which was expected as Cp alone was already obtaining the highest scores. But more interestingly, we observe that the best improvements are obtained when combining melodic and harmonic features, i.e. Dm+Cp or Mp+Cp. The Mp probably embeds some of the information also carried by the Cp, as the improvement is lower when combining Mp+Cp than Dm+Cp.

All in all, the combination Dm+Cp yields the best performances, and an improvement of 15%-20% compared to Dm or Cp alone. Considering a third feature along Dm+Cp

Test set	Da-TACOS			SHS_{4-}		
Input	MAP	MT@10	MR1	MAP	MT@10	MR1
Cq+Dm	0.359	4.002	62	0.590	0.982	567
Cq+Mp	0.324	3.603	62	0.530	0.909	623
Cq+Cp	0.427	4.636	46	0.621	1.024	581
Dm+Mp	0.394	4.347	61	0.571	0.956	614
Dm+Cp	**0.547**	**5.861**	**37**	**0.679**	**1.098**	**529**
Mp+Cp	0.496	5.330	40	0.627	1.034	593
Cq+Dm+Mp	0.403	4.434	51	0.624	1.030	498
Cq+Dm+Cp	0.524	5.640	36	**0.713**	**1.143**	**430**
Cq+Mp+Cp	0.480	5.184	40	0.660	1.078	505
Dm+Mp+Cp	**0.553**	**5.939**	**35**	0.702	1.133	453
Dm+Cp (O)	0.800	8.360	4	0.873	1.344	115
Cq+Dm+Cp (O)	0.881	9.072	1	0.935	1.419	51
Dm+Mp+Cp (O)	0.874	9.022	2	0.924	1.405	63

Table 2: Comparison on Da-TACOS and SHS_{4-} of input feature combinations. Results obtained with the embeddings produced by MICE architecture trained for each feature (O=Oracle).

(Cq or Mp) improves the results slightly further.


We also observe that the oracle scores about 20% above the highest scores obtained with the averaging fusion scheme, which suggests that further improvements are theoretically possible (we also experimented a minimum fusion scheme, which yielded lower performances).

From a practical perspective (e.g. memory footprint), the best trade-off seems to concentrate only on the Dm and the Cp. We will now investigate why the combination of these two features yields a better performance than others.

4.3 Qualitative analysis

To this aim, we selected the tracks where the first feature (e.g. Dm) gives particularly correct results and where the second feature (e.g. Cp) gives particularly incorrect results, or vice-versa. In other terms, we analyzed the pairs of songs for which the two features would give the most contradictory results for positive and negative pairs. The Dm and the Cp obtained for some of these cover and non-cover pairs [4] are shown on Figure 3.

---

[4] The audio of the songs described here can be listened on Youtube with the following IDs: Figure 3(a) clBw3cWgPnE and PNQeBX-tUdgc, Figure 3(b) -uJ61jgFCMM and xXvPFsoNnD4, Figure 3(c) 7nPBAiE76qY and bRrVMte9IQQ, Figure 3(d) pFrTXGEmU2Q and 3IOD9SqSfY4. Last accessed 11/5/2020.

(a) d_{Dm}=0.15, d_{Cp}=0.73

(b) d_{Dm}=0.65, d_{Cp}=0.07

(c) d_{Dm}=0.75, d_{Cp}=0.12

(d) d_{Dm}=0.22, d_{Cp}=0.84

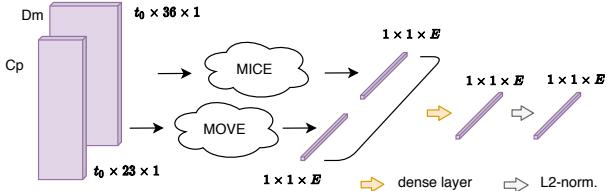
Figure 3: Examples of cover pairs (top, (a) and (b)) and non-covers pairs (below, (c) and (d) where Dm and Cp gives contradictory results due to the melodic or harmonic content of each version. For each pair, Dm is displayed above and Cp below, and the corresponding distances d_{Dm} and d_{Cp} obtained for each feature are indicated.

Cover pairs Figure 3(a) displays two versions of "Jeřabiny", by Czech composer Karel Kryl (left, singing voice and guitar accompaniment) and Sestry Irglovy (right, purely a cappella, and poorly caught by the Cp). The pair is identified as covers thanks to the dominant melody.

Figure 3(b) displays two versions of "Fade Into You", by Mazzy Star (left) and Catman Cohen (right). The accompaniment is similar, but Catman Cohen's voice is very hoarse and rough, thus poorly caught by the dominant melody. The pair is identified as covers thanks to the Cp.

Non-cover pairs Figure 3(c) displays two different tracks: "La paloma" interpreted by a choir (left, mainly choir voices) and "Tom Dooley" by German singer Heino (right, voice and guitar accompaniment). Both songs share the same succession of two chords (but transposed), so the Cp are very similar. The pair is identified as non-covers thanks to the Dm, which are different.

Figure 3(d) displays two different tracks: "I Got a Feeling", by Four Tops (left) and "Stop Her on Sight (S.O.S.)" by Rare Earth (right). Both songs exhibit leading voice, backing voices, piano or strings section, and a brass instruments section. Both Dm appear very confused and look similar. The pair is identified as non-covers thanks to the Cp, which are different.

We could intuitively expect these results: Dm is better suited for songs where a melody is clearly prominent, while Cp is better suited for songs where no clear melody is present or is hidden by a prominent accompaniment. As such, there is no "better" feature: they simply perform differently on different tracks, and their combination performs statistically better on large corpora than separately.


5. LEARNING TO COMBINE FEATURES

Despite its encouraging results, the simple averaging fusion scheme has two flaws. Firstly, it does not guarantee that averaging the distances is the most optimal manner to merge the information contained in different representations. Many tracks might end up scoring around the mean of all distances, which will not help to decide whether they are covers or not. Secondly, it requires to train one model per representation, and consequently to store one embedding per representation, which complicates the operational usage of the system (e.g. indexing various embeddings and combining several search results is sub-optimal). In this section, we study the possibility to train a single model to learn how to fuse several input features efficiently.

We consider here only the combination of Dm and Cp features, as they individually yielded the most promising results with the averaging fusion scheme, while remaining practical from a memory footprint perspective.

5.1 Late fusion scheme

To address these flaws, we propose a two-branch architecture, where each input feature is processed by a dedicated model into an embedding, as previously. These two embeddings are then concatenated and merged into a single one by a final dense layer. We can now use different models for each feature, as we are not comparing their individual performance as previously. In particular, we use MOVE to process the Cp, as it was specially designed for this feature, and keep MICE to process the Dm, as shown on Figure 4.

Figure 4: The late fusion architecture.

Let $\mathbf{e}_{Dm}$ and $\mathbf{e}_{Cp}$ denote the embeddings output by the Dm and Cp branches, $\mathbf{e}$ the final embedding and $\mathbf{W}$ the dense layer parameters. It comes:

$$\mathbf{e} = \mathbf{W}\begin{bmatrix}\mathbf{e}_{Dm}\\\mathbf{e}_{Cp}\end{bmatrix} = \mathbf{W}^{Dm}\mathbf{e}_{Dm} + \mathbf{W}^{Cp}\mathbf{e}_{Cp} \tag{1}$$

where $\mathbf{W}^{Dm}$ and $\mathbf{W}^{Cp}$ are the parameters of $\mathbf{W}$ that are applied to $\mathbf{e}_{Dm}$ and $\mathbf{e}_{Cp}$, respectively. Normalizing $\mathbf{e}$ to unit norm, we can interpret the embedding resulting from this fusion as a weighted mean of the initial embeddings moved to another location on the unit sphere to optimize the loss.

5.2 Experiments

We compare here three training options: **a)** each branch and the last layer are trained simultaneously with random initialization from scratch; **b)** each branch is first pre-trained individually with its corresponding input feature as previously; then their trained weights are reloaded in the late fusion architecture, and are fine tuned while training the last layer; **c)** is the same as **b)**, but the weights of each branch are frozen once reloaded in the fusion model, and only the weights of the final dense layer are learned.

For these three options, we train each architecture on the same proprietary training set that was used in [37]. This set contains 98k tracks and is much larger than the one used in features comparison experiments of Section 4.2. Models trained with this proprietary training set were evaluated with Da-TACOS in order to compare the results with the baseline established in [37]. We also conduct the same experiments for each architecture trained on SHS$_{5+}$ and evaluated with SHS$_{4-}$ as previously, in order to compare the results with the baseline established in [40].

The training procedure for all three options is the same as described in Section 3.3, except that the learning rate is initialized at $5e^{-6}$ for option **b)** and at $1e^{-1}$ for option **c)**.

5.3 Results

The results of the late fusion learning experiments are summarized on Table 3. We indicated the scores obtained for each feature (Dm and Cp) individually, as well as the corresponding distance averaging score for comparison.

For both sets, the two-branch model outperforms the ones where each feature is considered individually, which shows that it jointly learns from both input features. Late fusion with end-to-end training from scratch (option **a)**) scores below the other two options, which suggests that the model learns from each feature but does not make an optimal use of the available information.

Late fusion with fine tuning of the pre-trained branches (option **b)**) yields better results. However, it does not outperform the late fusion where only the dense layer is trained (option **c)**). A possible explanation could be that one feature tends to yield better results than the other (probably the Cp, as seen in Section 3), and allowing the update of branches might confuse the previously acquired knowledge of the weaker one. This assumption should however be investigated further in another work.

Input	Da-TACOS			SHS$_{4-}$		
	MAP	MT@10	MR1	MAP	MT@10	MR1
Dm (MICE)	0.360	4.032	94	0.412	0.722	1431
Cp (MOVE)	0.484	5.214	59	0.533	0.890	1188
Dm+Cp (A)	0.621	6.613	32	**0.697**	**1.120**	517
Dm+Cp (LF-a)	0.570	6.101	**29**	0.617	1.017	686
Dm+Cp (LF-b)	0.592	6.318	32	0.655	1.059	655
Dm+Cp (LF-c)	**0.635**	**6.744**	30	0.660	1.080	657
Doras et al. [40]	n/a	n/a	n/a	0.323	0.615	1476
Yesiler et al. [37]	0.507	-	40	n/a	n/a	n/a

Table 3: Comparison on Da-TACOS (resp. SHS$_{4-}$) of all fusion schemes trained on [37] proprietary training set (resp. SHS$_{5+}$). A=averaging, LF=Late fusion. Note that Cp and Dm+Cp (A) scores are higher here than in Table 2 because Cp is now processed by MOVE.

Training a dense layer on top of two pre-trained frozen branches (option **c)**) thus yields the best scores, similar to the ones obtained by the averaging scheme.

We finally compare these performances to the current state of the art for each set. We observe that all late fusion schemes notably outperform the results obtained in [40] and [37], for the same training and test sets.

6. CONCLUSION

We proposed in this work a comparative study of different input features that have been used in recent works addressing the cover detection problem with a metric learning approach. We observed that the best feature of the one we studied is the crema-PCP, a harmonic feature. We then showed that combining this feature with a dominant melody representation drastically improves the results compared to each feature considered alone. We showed that this can be explained by the fact that using both melodic and harmonic features helps to disambiguate pairs of tracks that don't have a clear melodic or harmonic structure. We finally proposed a late fusion scheme learning to combine input features, which yields to new state-of-the-art performances on two publicly available datasets.

This system could be improved in several ways. As suggested by the oracle results, further strategies could be developed to force the model to focus more adequately on the available features. Also, the need to maintain several dedicated branches in the late fusion scheme could be avoided with a single architecture merging the two branches earlier in the process. But perhaps more importantly, considering the variety of other features commonly shared by covers, such as lyrics, could be a fruitful strategy to build future cover detection systems.

ABSTRACT

Music loops are essential ingredients in electronic music production, and there is a high demand for pre-recorded loops in a variety of styles. Several commercial and community databases have been created to meet this demand, but most are not suitable for research due to their strict licensing. We present the Freesound Loop Dataset (FSLD), a new large-scale dataset of music loops annotated by experts. The loops originate from Freesound, a community database of audio recordings released under Creative Commons licenses, so the audio in our dataset may be redistributed. The annotations include instrument, tempo, meter, key and genre tags. We describe the methodology used to assemble and annotate the data, and report on the distribution of tags in the data and inter-annotator agreement. We also present to the community an online loop annotator tool that we developed. To illustrate the usefulness of FSLD, we present short case studies on using it to estimate tempo and key, generate music tracks, and evaluate a loop separation algorithm. We anticipate that the community will find yet more uses for the data, in applications from automatic loop characterisation to algorithmic composition.

1. INTRODUCTION

Repurposing audio material to create new music—also known as *sampling*—was a foundation of electronic music and is a fundamental component of this practice. Loops are audio excerpts, usually of short duration, that can be played repeatedly in a seamless manner [28]. These loops can serve as the basis for songs, which music makers can combine, cut and rearrange, and have been extensively used in Electronic Dance Music (EDM) tracks [4].

Audio loops have been made available for amateur and professional music makers since the early ages of elec-

tronic music. Currently, large-scale databases of audio offer huge collections of audio material for users to work with. Some databases, like Freesound [1] and Looperman [2], are community-oriented: people upload their sounds so that other users can employ them in their works. More commonly, these collections are commercially oriented: loops are available to paying costumers, either through a subscription service (*e.g.* Sounds.com, [3] Splice [4]) or by allowing customers to buy packs of loops (*e.g.* Loopmasters, [5] and Prime Loops [6]).

Despite the number of loops available on these databases, the technologies used to analyse and navigate these databases still rely on human annotations and human content curation to, for instance, group sounds into packs for specific genres or styles. Loops are being manually annotated with information like instrument, tonality (key), tempo (bpm) and music genre. This is a time-consuming task which is often unfeasible, which results in badly annotated databases and poor user experience when browsing them. In the field of Music Information Retrieval (MIR), a substantial effort has been put into automatically identifying the aforementioned characteristics for musical pieces. However, loops are inherently different from music pieces (*i.e.* with reduced instrumentation and short length). Therefore, existing MIR algorithms need to be tested and (possibly) adapted to work successfully in this scenario. Furthermore, new MIR tasks are emerging with the study of music loops including loop retrieval [12], loop detection [18], loop discovery [19] and extraction [27], loop recommendation [5], exploration of large loop databases [29], and automatic loop generation [26].

In this paper, we present FSLD, an open dataset with 9,455 music loops to support reproducible research in MIR. FSLD contains production-ready loops from Freesound which are distributed under Creative Commons licenses and can, therefore, be freely shared among the research community and industry. Part of the dataset has been manually annotated with information about rhythm, tonality, instrumentation and genre, in a similar way as

[1] `https://freesound.org/`
[2] `https://www.looperman.com/`
[3] `https://sounds.com/`
[4] `https://splice.com/`
[5] `https://www.loopmasters.com/`
[6] `https://primeloops.com/`

commercially available loop collections are annotated. The annotation service is made public[7] so that the community can work on enlarging the annotations of this collection. We expect this dataset to have an impact on the research community as it supports further research into several timely research topics which are also of great interest to the industry.

The rest of the paper is structured as follows. In Sec. 2, we present some of the datasets used in the literature for loop analysis. Sec. 3 details how the proposed dataset was collected and annotated. In Sec. 4, general statistics of the dataset are given. In Sec. 5 and 6, we present some potential applications and provide a benchmark of the dataset using some classic MIR tasks. Finally, in Sec. 7, we conclude and suggest future work directions.

2. RELATED WORK

Early work on the retrieval of loops focused on tempo extraction and transcription from drum loops [11, 15]. Gouyon et al. compared several tempo induction algorithms proposed in the ISMIR 2004 competition [15]. The loop dataset used in this work has been commonly used for evaluating tempo estimation algorithms and is divided into three subsets. One of these comprises two thousand audio loops (with tempo annotations) from Sound Effects Library.[8] These audio loops are not free and a license needs to be obtained to use them for research.

Automatic transcription of drum loops focuses on identifying when the different percussion instruments occur in a loop. Gillet and Richard used a collection of 315 drum loops for evaluating their system and provided "a compressed version of a few drum loops" [11]. The URL to the webpage the authors provide is broken and, presumably, the lower quality versions of the loops do not represent commercial-quality content. The authors also use this dataset for automatically retrieving drum loops from spoken queries [12]. This database was later used by Bello et al. for automatic rhythm modification and analysis of drum loops [1,23].

The work from Gómez-Marín et al. explores rhythmic similarity measures for audio loops [14]. The authors validate the proposed metric using 9 drum break loops from Rhythm Lab.[9] The authors do not specify which are the drum loops used.

Font et al. presented a dataset of audio loops from Freesound [9] in their work on tempo estimation and a confidence measure for audio loops [10]. The authors use two commercial datasets, loops bundled with music production software Apple's Logic Pro[10] and Acoustica's Mixcraft,[11] and two community datasets. The first one is a private collection of loops downloaded from Looperman, which was previously used for research in [24]. Looperman does not allow the re-distribution of loops "as is", and considers as misuse the automatic download of their

loops.[12] A collection of 4000 loops from Freesound, obtained by searching Freesound for sounds with the queries "loop" and "bpm" is also proposed. The sounds' filenames, tags and textual descriptions are parsed to identify tempo annotations provided by the users. However, these annotations are not always accurate, and, to enable further work on audio loops, more information besides the tempo is desired.

In short, existing academic work which employs loops resorts to commercial samples as the source of data and open datasets do not have complete and reliable annotations. This makes it difficult to reproduce existing research. To promote open and accessible research on audio loops, we propose a free and distributable database of loops from Freesound, which provides production-ready sounds with high-quality annotations.

3. DATASET CREATION

In this section the process we have followed to create the dataset is described. We show how we collected the loops to annotate, how they were pre-analysed for a faster annotation procedure and explain what was annotated and how the annotation tool was implemented. Finally, we present how the dataset is distributed and organised.

3.1 Loop Selection

To select an initial pool of candidate loops, we followed the same methodology as in [10]: i.e., we retrieved sounds with both "loop" and "bpm" keywords on Freesound, resulting in 9,490 sounds. Using the Freesound API, it was straightforward to obtain these loops and their metadata— title, tags, textual description, and author's username.

3.2 Loop Annotation

We want the loops in our dataset to be annotated in a way which is similar to commercially available loops. This way, we make sure that the loop characterisation is compatible with industry standards. For this, we decided to annotate the loops' instrumentation, tempo, time signature, key and genre, as described below. The annotation was performed by 8 MIR researchers and students, with knowledge of electronic music production. To make the annotation procedure as efficient as possible, we created a web application for the annotators with several tools at their disposal, which can be seen in Fig. 1. This application was developed using Flask,[13] a web framework for Python.

This interface provides fields for the annotators to fill in the desired information, which will be described in the following sections. The instructions are provided on tooltips for quick access by annotators.

3.2.1 Instrumentation

Instead of annotating instruments in a traditional way, which would not be straightforward in heavily processed

audio or more experimental loops, we chose to annotate general *roles* which can be useful for both music makers and automatic generation of music. We asked annotators to tick all the roles that apply to each loop. Usually, specific instruments could be easily assigned to a specific role. We present the roles along with some examples in Table 1.

Role	Example Instruments
Percussion	Drums, glitches, tuned percussion
Bass	Synth bass, fingered bass
Chords	Piano chords, guitar chords, synth pads
Melody	Instrument playing a melody, arpeggiator
Sound FX	Risers, cinematic sounds, foley, scratching
Vocal	Singing voice, spoken word, vocoder

Table 1. Instrumentation roles and the examples provided for each category.

3.2.2 Rhythmic Characteristics

We asked for annotations on three rhythmic aspects:

Tempo provides an easy measure of rhythmic compatibility and is the most common information provided in commercial loop databases. We ask annotators if the loop has a clear and steady tempo, to identify loops with constant tempo and clear beat (BPM value and steady tempo), with changing tempo (BPM value of the initial tempo

and no steady tempo), and loops with no clear beat but where the tempo can be inferred (BPM value and no steady tempo).

Meter is not a feature we see annotated as often as BPM, which might be due to the common use of 4/4 meter in electronic music. This feature is relevant to annotate, for calculating the number of bars in a loop, from its meter, tempo and duration.

Finally, as sometimes the length of the audio file is not the length of the loop, we also annotate if it is **well-cut**. If there is some silence at the beginning or the end of the file or if there is a "tail" (*e.g.* a decay of a reverb effect) when the audio is exported, it might not loop correctly just by staring the loop again when it finishes playing.

3.2.3 Tonal Characteristics

We annotate if the loop has prominent tonal content and, if so, to indicate a root key and mode that matches the tonal content of the loop (*i.e.*, root note from a chromatic scale and *Major/Minor* mode). We explained "prominent tonal content" as whether it is easy to sing along to the loop or to find a meaningful root note for the loop. For root key annotations, we asked to choose a note from a dropdown with 12 notes, or "Unknown" in case the key could not be found. For annotating mode, the annotators had the choice

of "Major" or "Minor" if the loop sounded good with one of these modes; "None" if the loop could not be clearly assigned to either "Major" or "Minor" (e.g. loop contains a single note); or "Unknown" for other cases.

3.2.4 Genre

We annotate genre in non-exclusive categories, where each is assigned to a loop if it can be used to make music in that genre. To create a taxonomy which would be similar to commercially available ones, we merged the taxonomies of Sounds.com and Splice. These were chosen as they provided several examples for each genre and had similar parent categories. We present the taxonomy in Table 2.

Genre	Examples
Bass Music	Dubstep, Drum and Bass, Jungle
Live Sounds	Rock, Jazz, Disco
Cinematic	Sound FX, Filmscore, Sci-Fi
Global	Reggae, Dancehall, Indian Music
Hip Hop	Trap, Boom Bap, Lofi Hip Hop
Electronic	Ambient, IDM, Chill Out
House / Techno	Deep House, Electro, Tech House
Other Dance Music	EDM, Psy Trance, Hardstyle

Table 2. Taxonomy of genres used for the annotation and examples for each category.

3.2.5 Loop Pre-Analysis and Annotation Tools

We performed a pre-analysis on the loops to obtain tempo, key and genre suggestions. To obtain the tempo information, we followed the same approach of [10], parsing the title, description and the tags of the loop for tempo information provided by users. To propose an initial key and mode to the annotators, we analysed the loops using the algorithm proposed by Faraldo et al. [7], which is implemented in the Essentia audio analysis library [3]. Finally, by taking the genre information from the textual metadata of the loops, we were able to map some of the sounds to the genres to annotate. The checkboxes were selected for the genres which either were mentioned or had a sub-genre mentioned in the textual metadata. Our annotators were familiar with the annotation procedure and took the pre-annotations only as suggestions to speed-up the annotation process.

In the annotation tool, at the top of the display is the loop's metadata: its unique sound id, title, author's username, and the tags and textual description provided by the author (see Fig. 1). The waveform of the loop and a playhead is also shown, which are linked to an audio player. The audio player always restarts the playback of the loop when it finishes, and triggers a metronome with the BPM provided in the BPM annotation field. We provide stop, play and pause controls for the loop and metronome and volume controls for the loop. A button which restarts only the metronome is also present. To ease finding a key and mode which suits the loop, we present a synthesizer which plays the chord present in the tonal annotation section. In case the mode selected is "None" or "Unknown", the synthesizer will just play the root note of the key selected. Using the computer's keyboard, the annotator can cycle

through the options for key and mode, in several octaves. Finally, buttons are provided for submitting the annotation when it is finished, saving the sound for later and discarding the sound in case it is not a loop.

3.3 Dataset Availability

The loops and corresponding annotations (provided in a JSON file) are publicly available on Zenodo. [14] This dataset can be divided into three subsets, defined by their level of annotations. These are:

- Multiple-annotations (MA): the loops annotated by at least two researchers. It contains 1,472 loops.
- Single-annotation (SA): the loops annotated by a single researcher. Currently contains 1,464 loops.
- Automatic-annotations (AA): the loops annotated by the analysis algorithms mentioned in Section 3.2.5. Contains 9,455 loops: the loops in MA and SA and 6,519 more.

In addition to the main dataset, we provide a repository [15] with the code used for the annotation tool interface and server, the pre-analysis that generated the subset of automatic annotations, and the analysis and potential applications presented in Sections 4, 5 and 6.

4. DATASET ANALYSIS

To understand the diversity and reliability of the dataset, we investigate the distribution of annotated characteristics and inter-annotator agreement.

4.1 Annotation Distribution

The human-annotated part of the dataset contains 1,579 sounds which, in total, have been annotated 2,809 times. The distribution of genres, instrumentation, and keys are shown in Tables 3 and 4 and the tempo histogram in Figure 2. It is well-balanced in terms of instrument and genre; reasonably balanced in terms of tempo, although 120 bpm dominates; and highly imbalanced in terms of key, with C Major and Minor dominating.

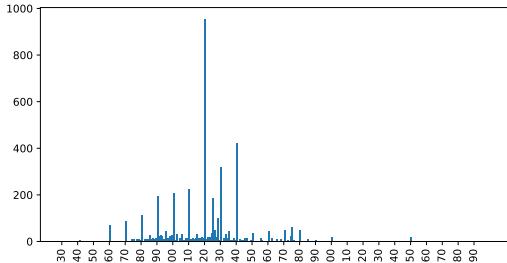
Percussion	54.95%	Bass Music	32.04%
Bass	19.10%	Live Sounds	21.38%
Chords	11.90%	Cinematic	19.95%
Melody	21.31%	Global	14.26%
FX	24.80%	Hip-hop	17.29%
Vocal	2.29%	House/Techno	29.05%
		Other Dance Music	25.63%


Table 3. Distribution of the instrument roles and genre in our dataset.

4.2 Inter-annotator Agreement

To measure the agreement of the annotators in our dataset, we measure the inter-annotator agreement for the MA annotations subset. To do this, we use two metrics: proportion of overall agreement (Agr.) for all the annotations,

---

[14] https://zenodo.org/record/3967852
[15] https://github.com/aframires/
freesound-loop-annotator

Figure 2. Distribution of BPMs in FSLD.

Key	Maj	Min	None	Unknown
C	9.63%	8.38%	3.65%	0.95%
C#	1.38%	2.84%	0.60%	0.43%
D	3.31%	5.37%	1.85%	0.39%
D#	1.29%	2.49%	0.73%	0.21%
E	2.28%	3.65%	1.20%	0.26%
F	4.64%	4.43%	1.16%	0.34%
F#	1.12%	2.49%	1.12%	0.13%
G	2.66%	4.25%	1.93%	0.43%
G#	1.72%	2.58%	0.90%	0.13%
A	3.01%	5.50%	1.68%	0.26%
A#	1.50%	1.89%	0.52%	0.04%
B	0.82%	3.01%	0.64%	0.21%

Table 4. Distribution of the keys in our dataset.

and positive and negative agreement (PA and NA) [8] for binary classification tasks. The proportion of overall agreement reflects the number of cases when both annotators agree on a label, and is calculated by dividing their number by the total number of annotations. This overall metric does not distinguish the agreement in positive and negative cases, so for the binary annotation tasks we also calculated the positive and negative agreement. The formulas for calculating these are given in Eq. 1, where the variables represent the annotations by the annotators (e.g., NP = first annotator answered negative, second positive).

$$PA = \frac{2PP}{2PP + NP + PN} , \qquad (1)$$

$$NA = \frac{2NN}{2NN + NP + PN} , \qquad (2)$$

Table 5 presents the results for this analysis. We can see that overall, the values for the agreement are high. Bass, melody and chords have a lower positive agreement value, despite the high negative agreement. This might indicate that annotators are not able to easily distinguish if an element should fit in one of the 3 roles, but can say when it is not present. The lower value for root key agreement indicates that several keys are used to describe the same sounds. This fits our annotating indications, where we asked annotators to select a key which sounds good with the loop and therefore, personal taste may arise in this choice. Finally, the positive agreement for genres always has values lower than 65%, which might be due to how genre might be perceived subjectively between annotators.

5. BENCHMARKING MIR TASKS

To demonstrate the usefulness of this dataset, we use it in several short case studies. To benchmark tempo, we fol-

Char.	Sub-Char.	Agr.	PA	NA
Inst.	Percussion	85.16%	86.62%	83.35%
	Bass	76.73%	45.83%	85.19%
	Melody	82.33%	60.57%	88.61%
	Chords	87.40%	47.35%	92.84%
	FX	72.04%	43.61%	81.41%
	Vocal	98.66%	71.88%	99.31%
Tempo	BPM	87.84%	NA	NA
	Signature	97.84%	NA	NA
	Well Cut	86.88%	92.73%	32.82%
Key	Root	67.56%	NA	NA
	Mode	69.80%	NA	NA
Genre	Bass Music	69.50%	53.26%	77.37%
	Live Sounds	80.09%	55.28%	87.19%
	Cinematic	81.66%	57.14%	88.33%
	Global	82.33%	51.53%	89.19%
	Hip-Hop	79.05%	31.30%	87.64%
	House/Techno	69.35%	48.56%	78.17%
	Other	73.53%	45.64%	82.50%

Table 5. Inter-annotator agreement for the MA subset.

lowed the evaluation approach of [10] and used the *Accuracy 1* and *Accuracy 2* presented in [16], together with the *Accuracy 1e* proposed in [10]. Due to space constraints, here we only report the mean of the 3 accuracies. Full results can be seen in an accompanying website. [16] The algorithms selected for the tempo benchmarking were the following (details for each algorithm can be found in respective papers):

- **Percival [21]:** We use both the original implementation and the one provided in Essentia.

- **Zapata [31]:** Implementation provided in Essentia.

- **Degara [6]:** We also use Essentia's implementation.

- **Böck [2]:** We use the 3 variants available in the Madmom library [17]: COMB, ACF and DBN.

We validate tempo estimation algorithms on the 3 proposed subsets. Key estimation is only validated on the MA and SA subsets as we do not have original uploader annotations for key. The MA subset, which has at least 2 annotations per loop, was analysed in two ways: BOTH and EITHER. In BOTH, we run the MIR algorithms exclusively on the loops which have the same labels from both annotators. In EITHER, the output of the algorithm was deemed correct if it was at least one of the annotated labels. The results are presented in Table 6

Algorithm	AA	SA	BOTH	EITHER
Percival14	58.09	62.98	65.75	84.13
Percival14e	57.82	64.00	65.49	84.98
Zapata14	51.81	58.79	58.99	77.97
Degara12	52.32	58.77	59.31	79.16
Bock15COMB	44.42	51.17	52.92	71.35
Bock15ACF	48.65	51.96	54.75	74.90
Bock15DBN	45.76	50.60	52.32	70.90

Table 6. Evaluation of tempo estimation algorithms in the proposed subsets.

---

[16] https://aframires.github.io/freesound-loop-annotator/
[17] https://github.com/CPJKU/madmom

We can see that the results are similar to the ones obtained in [10], with Percival14 having better accuracy across all the datasets. We can see that the accuracy increases from AA to SA, and from SA to BOTH. This might be due to the user-annotated loops having incorrect annotations; it may also be that when both annotators agree on a tempo, the tempo is strong and defined. The EITHER evaluation gives the largest accuracies, which may be due to its broader criteria for considering tempos correct.

For benchmarking key estimation algorithms, we used the evaluation metrics from MIREX,[18] which evaluates how *close* the estimated key and the annotated key are to provide an accuracy. The algorithms compared in the evaluation were the following:

- **EDMKey [7]:** We use the implementation in Essentia, with 4 key profiles: Krumhansl [17], Temperley [30], Shaath [25] and the one proposed in [7].
- **EssentiaBasic [3]:** Essentia's implementation of the algorithm presented by Gomez [13].
- **QMUL [20]:** We use the Key Detection implementation available in QM Vamp Plugins.[19]

In Table 7, we present part of the results of the key estimation evaluation. Due to lack of space, only the final MIREX scores for each dataset are presented. The full results can be seen in the accompanying website.[16]

Algorithm	SA	BOTH	EITHER
Edmkey	72.26	88.25	85.63
EdmkeyKrumhansl	66.99	84.85	82.98
EdmkeyTemperley	61.46	71.78	71.77
EdmkeyShaath	72.38	88.25	85.63
EssentiaBasic	71.25	88.80	85.30
QMULKeyDetector	35.09	42.15	46.25

Table 7. Evaluation of key estimation algorithms in the proposed subsets.

We see that EssentiaBasic and EDMkey are the best performing algorithms here. EDMKey has been specially tuned to be used for EDM, which might make it more suitable to the loops we are annotating. We again see that the accuracy increases from SA to BOTH, which might indicate again that when the key is clear and defined, the algorithms are also able to correctly identify it.

6. MUSIC GENERATION AND DECOMPOSITION

Another way the dataset is valuable is for creating synthetic datasets of songs for evaluating loop-extraction algorithms, such as [27]. We created 100 random songs, each using 5 random drum loops and 5 non-drum loops (chosen from a subset of 4/4, 120-bpm, 1-bar, single-instrument loops for which there was no disagreement among the annotators on the instrument role). Each song is a random arrangement of the loops, either in a *sparse* arrangement, in which one drum and one non-drum loop occurs per bar, or a *dense* one, in which 4 loops occur per bar (i.e., 2 drum

and 2 non-drum). For comparison, we also recreated the "composed" and "factorial" layouts from [27]. Examples of each layout are shown on the accompanying website.

We used the public implementation[20] of [27] to extract loops for each song, informed with the true number of loop segments (4 or 10) and the true downbeat boundaries. The metrics SDR, SIR and SAR (the signal to distortion, interference and artefacts ratios [22]) are reported in the left part of Table 8.

These are normally computed by trying all permutations of estimated sources to true sources and using that which maximises the score. This is infeasible for permutations of 10 items, so we first find the permutation that maximises the similarity between the source and true loop spectra.

Layout	SDR	SIR	SAR	F1	Acc.
Sparse	−5.2	−3.9	15.8	0.194	0.691
Dense	−7.9	−7.3	14.4	0.294	0.542
Composed	12.5	18.4	22.6	0.585	0.546
Factorial	19.8	29.2	24.1	0.560	0.551

Table 8. Evaluation of loop source quality (SDR, SIR, SAR) and estimated layouts (F-measure and accuracy) for each song layout.

This permutation is also used to evaluate the quality of the estimated layout. We binarize each row of the estimated layout, using the row's mean as threshold. We then compute the raw accuracy (as in [27]), but here we propose also using the F-measure, so as not to weight true negatives unduly. The results are in the right columns of Table 8.

SDR, SIR and SAR are all lower for the random 10-part songs than for the 4-part songs, showing that we have created a more challenging testing ground for loop extraction systems. For the layout evaluation, our evaluation makes clear that the raw accuracy gives undue weight to true negatives: the highest accuracy was obtained for the sparse layouts, despite having the lowest F-measure. This short evaluation is a proof of concept; with more space, we could study the impact of the instrumentation, number of loops, loop duration, and other factors on the separation quality. We can also generate layouts with loops of many durations and evaluate hierarchical loop extraction systems.

7. CONCLUSION

In this paper, we presented our work on addressing the lack of standard loop datasets to carry MIR tasks. We presented FSLD, a dataset of audio loops annotated at a level similar to commercial loop collections. These loops are licensed for redistribution and can be used and redistributed for research purposes. We provide a detailed analysis of the dataset and its annotations and provided several use cases for tempo and key benchmarking, music generation and loop separation. Furthermore, we present the online annotation tool used to build the dataset, and we make it available online so other researchers and the general public can contribute and extend the dataset.

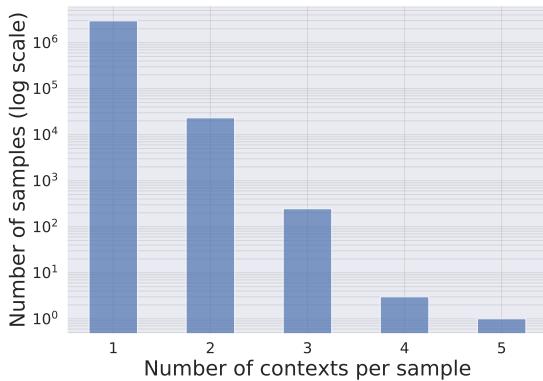
ABSTRACT

Music tags are commonly used to describe and categorize music. Various auto-tagging models and datasets have been proposed for the automatic music annotation with tags. However, the past approaches often neglect the fact that many of these tags largely depend on the user, especially the tags related to the context of music listening. In this paper, we address this problem by proposing a user-aware music auto-tagging system and evaluation protocol. Specifically, we use both the audio content and user information extracted from the user listening history to predict contextual tags for a given user/track pair. We propose a new dataset of music tracks annotated with contextual tags per user. We compare our model to the traditional audio-based model and study the influence of user embeddings on the classification quality. Our work shows that explicitly modeling the user listening history into the automatic tagging process could lead to more accurate estimation of contextual tags.

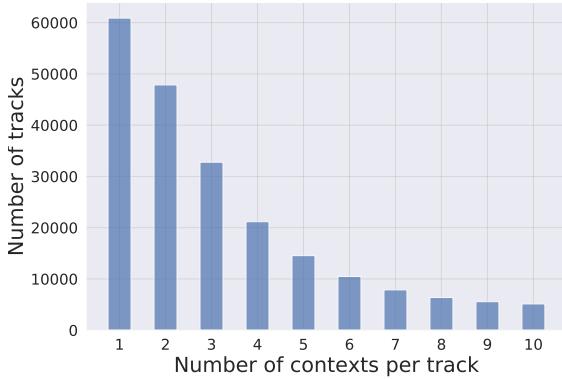
1. INTRODUCTION

Tags are a popular way to categorise music in large catalogues in order to facilitate their exploration and music retrieval on demand [17]. Music tags include different categories such as emotions (sad, happy), genres (rock, jazz), instrumentation-related (guitar, vocals), or listening activities (dance, relax, workout). Traditionally, tags were assigned to music items by humans, either through editors or through crowdsourcing. However, with the expanding availability of online music, there have been also increasing efforts towards developing music auto-tagging models, i.e. systems that do not require to manually annotate the tracks [1]. Music auto-taggers are models trained to automatically predict the correct tags for a given music track from the track content. Several models have been proposed that use the audio content, either as raw signal [15, 20, 26] or pre-processed spectrograms [4, 5, 25, 26], to predict the appropriate tags. However, certain tags largely depend on

users and their listening preferences, in particular, the tags referring to the context of music listening such as 'running' or 'relaxing' [21]. Thus, traditional auto-tagging models that rely only on the audio content without considering the case where tags depend on users, are not ideal for describing music with user-dependent tags like contexts. Additionally, their evaluation protocol should be also adapted to account for different users.

Previous studies showed that user context has a clear influence on the user's music selection [10, 18]. Hence, context is progressively becoming the focus of music streaming services for reaching a personalized user experience [14]. The user context, e.g. activity or location, can change frequently while listening to music, which leads to changes in user preferences. Consequently, users often need different recommendations. Automatically inferring the user context is often not feasible due to privacy issues. Hence, giving users the option to select a specific context and propose him/her related personalized tracks is a potential alternative [7]. Another use case is automatic continuation or generation of context-specific playlists for each user which are made available to them to select based on their current context [2]. Thus, describing tracks with contextual tags provides a means to improve music exploration and playlist generation in a dynamic way, suitable for the frequent changes in the user context. However, previous work [13] showed that using only the audio might not be sufficient to predict the right contextual tag of a track without putting the user in the loop. Here, we investigate the impact of including user information in context auto-taggers.


In this paper, we propose the following contributions: 1) a dataset of ∼182K user/track pairs labelled with 10 of the most common context tags based on the users' contextual preferences presented in Section 2, which we make available for future research; 2) a new evaluation procedure for music tagging which takes into account that tags are subjective, i.e. user-specific in Section 3; 3) an auto-tagging model using both audio content and user information to predict contextual tags in Section 4. Our experiments in Section 5 clearly show the advantage of including the user information in predicting contextual tags compared to traditional audio-only-based auto-tagging models presented.

2. DATASET


To properly study the influence of including user information in context auto-tagging models, we need a dataset of

Figure 1. Distribution of the number of contextual tags per sample (user/track pair) in the initial dataset.

Figure 2. Distribution of the number of contextual tags per track in the initial dataset.

tracks labelled with their contextual tags according to different users. For this purpose, we rely on the user-created context-related playlists. Users often create playlists for specific contexts and the titles of these playlists may convey these contexts. Thus, similar to [13, 19], we exploit the playlist titles to label tracks with their contextual use. Additionally, we put the users in the loop as playlist creators by explicitly including them in the dataset.

2.1 Dataset Collection

To retrieve contextual playlists, we used a set of contextual keywords collected from the literature [9, 18, 24, 27]. Then, we added keywords that were semantically similar. Ninety six keywords were categorized in one of four categories: location, activity, time, and mood. This is similar to the categorization proposed in [14]. To construct our dataset, we selected, out of all collected context-related keywords, 10 which were the most frequent keywords found in the playlist titles in the Deezer catalogue [1]. We selected the keywords that shared a similar number of playlists to avoid any bias due to the popularity of some contexts. The contextual tags we finally selected are: *car*, *gym*, *happy*, *night*,

	#Samples	#Track	#Users
Train	102K	15K	40K
Validation	30K	4.4K	21K
Test	50K	7.5K	16K

Table 1. Number of samples (track/user pairs), unique tracks and users in the train, validation and test datasets.

relax, *running*, *sad*, *summer*, *work*, *workout*.

We collected all the public user playlists that included any of these 10 keywords in the stemmed title and applied a series of filtering steps to consolidate the dataset, similar to our previous work in [13]. We removed all playlists that contained more than 100 tracks, to ensure that the playlists reflected a careful selection of context-related tracks, and not randomly added. We also removed all playlists where a single artist or album made up more than 25% of all tracks in the playlist, to ensure that the playlist was not intended for a specific artist, similar to [13]. Finally, to properly study the effect of the user on the contextual use of a track, we only kept the tracks that were selected by at least 5 different users in at least 3 different contexts. Hence, our dataset reflects how user preferences change the contextual use of tracks. Finally, we tagged each sample, the track/user pair, with the contextual tag found in the corresponding playlist title.

2.2 Dataset Analysis

In Figure 1, by observing the distribution of contextual tags per track/user pairs in the dataset, we noticed that most of the pairs were assigned to a unique contextual tag. Let us remind that the log scale is used and a sample represents a user/track pair labelled with the contextual tags. It appears that the majority of users tend to associate a track with a single context. Out of ∼3 millions samples, ∼2.9 millions are labelled with a single context. Nonetheless, ascertaining if this observation is generally valid requires further empirical investigation. For this study though, we limited our final dataset to track/user pairs with single context tags, i.e. we excluded users that assigned the same track to multiple contexts.

Observing the distribution of contextual tags per tracks in Figure 2, we find that tracks often have multiple contexts associated with them. This shows that the suitability of a track for a specific context varies from user to user. However, as previously outlined, given the user, the track is most frequently associated with the same unique context.

The final dataset for this study contains ∼182K samples of user/tracks pairs made of ∼28K unique tracks and ∼75K unique users. We collected the dataset such that each context is equally represented, ensuring a ratio of ∼ $\frac{1}{10}$ of all user/track pairs. We split our dataset in an iterative way to keep the balance between classes across subsets, while preventing any overlap between the users and minimising the overlap between tracks in these subsets [22]. The distribution of our final split dataset is shown in Table 2.2. The dataset is publicly available to the research community [2]

3. PROPOSED EVALUATION PROTOCOL

Previous studies on music auto-tagging [4, 20] performed the evaluation in a multi-label classification setup, therefore focusing on assessing the correctness of the tags associated with each track. This is suitable for datasets and tags that are only music-dependent. However, in the case of tags that are also user-dependent, the previous evaluation procedures are limiting.

3.1 User Satisfaction-focused Evaluation

The purpose of our study is to measure the influence of leveraging the user information on the quality of the prediction of contextual tags. Consequently, we are interested in measuring the potential satisfaction of each user when predicting contexts, instead of relying on a general evaluation approach that could be biased by highly active users or by the popularity of certain tags. Hence, we propose to compute the model performance by considering each user independently. To assess the satisfaction of each user, the evaluation metrics are computed by considering only the contextual tags specific to a user. Then, to assess the overall user satisfaction, we average the per-user results yielded by each model.

Formally, let $\mathbb{U}$ denote a finite set of users in the test set, $G_u = \{0,1\}^{n_u \times m_u}$ denote the groundtruth matrix for user u, n_u is the number of tracks associated with the user u, and m_u is the number of contextual tags employed by the user. Similarly, $P_u = \{0,1\}^{n_u \times m_u}$ denotes the matrix outputted by the model for all active tracks and contextual tags for the given user u. First, we compute each user-aware metric, hereby denoted by S, for a given user u as:

$$S_u = f(G_u, P_u) \qquad (1)$$

where f is the evaluation function. In our evaluation, we use standard classification metrics such as the area under the receiver operating characteristic curve (AUC), recall, precision, and f1-score [12]. While the protocol is defined for the general case of multi-label setting, in our current work, given the dataset, it is applied to the case of single-label. Then, we compute the final metrics, by averaging over all users in the test set:

$$S_{\mathbb{U}} = \frac{1}{N} \sum_{u \in \mathbb{U}} S_u, \text{ where } N = |\mathbb{U}|. \qquad (2)$$

3.2 Multi-label Classification Evaluation

In this work, we develop a system that takes both the audio and the user information as input. As seen in Section 2.2, for a given track and user, there is a single groundtruth context to be predicted. The problem is said to be single-label. However, if we want to compare this system with a system that only takes audio as input, we need to consider during training various possible groundtruth contextual tags for a track, each from a different user. Then, the problem becomes multi-label. The comparison of the two systems is therefore not straightforward. Indeed, for the user-agnostic case, we can train a multi-label system, i.e. a system with

a set of sigmoid output activations optimized with a sum of binary cross entropy, and estimate it either as single-label by taking the output with the largest likelihood, or as multi-label by selecting all outputs with a likelihood above a fixed threshold. For these reasons, in the current evaluation, we consider the following scenarios:

1. Multi-output / multi-groundtruth (MO-MG): This is the classical multi-label evaluation where the model outputs several predictions and each track is associated with several groundtruths. This evaluation is however independent of the user.

2. Multi-output / single-groundtruth (MO-SG): In this scenario, a model trained as multi-label (such as a user-agnostic model) is still allowed to output several predictions. However, since the groundtruth is associated with a given user, there is a single groundtruth. The obtained results are then over-optimistic because the model has several chances to obtain the correct groundtruth.

3. Single-output / single-groundtruth (SO-SG): this is the case that is directly comparable to our single-output user-aware auto-tagging model. As opposed to the MO-SG scenario, models trained as multi-label are now forced to output a single prediction, the most likely contextual tag. This prevents them from being over-optimistic as they only have one chance to obtain the correct groundtruth, as does the single-label model too.

4. PROPOSED MODEL FOR CONTEXTUAL TAG ESTIMATION

We propose to build a user-aware auto-tagging system. Given that contextual tags are interpreted differently by different users, we hypothesize that considering the user information in training a personalized user-aware contextual auto-tagging model may help. For this, we propose to add to the system, along with the audio input, a user input. We study the effectiveness of representing the user via 'user embeddings', obtained from user listening history.

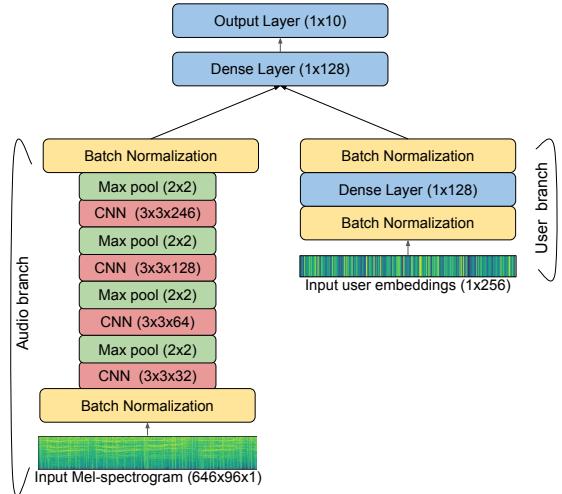
4.1 Traditional Audio-based Auto-tagger

In this paper, we chose the prevalent audio-based auto-tagging model proposed by Choi et al [4]. The model is a multi-layer convolutional neural network. The input to the network is the pre-processed Mel-Spectrogram of the music track. This multi-label classification model predicts, for a given track, the set of all possible tags.

We trained the network with the Mel-spectrogram as an input of size 646 frames x 96 mel bands, which corresponds to the snippet from 30 to 60 seconds for each track. The output is the predictions for the 10 contextual tags. The input Mel-Spectrograms is passed to a batch normalization layer then to 4 pairs of convolutional and max pooling layers. The convolutional layers have a fixed filter size of (3x3) and (32, 64, 128, 256) filters respectively, each followed by a ReLu activation function. The max pooling

filters have a size (2x2) each. The flattened output of the last CNN layer is passed to a fully connected layer with 256 hidden units with ReLU activation function. We apply a dropout with 0.3 ratio for regularization. Finally, we pass the output to the final layer of 10 output units each with a Sigmoid activation function. The loss function is the sum of the binary cross entropy optimized with Adadelta and a learning rate initialized to 0.1 with an exponential decay every 1000 iterations. We applied early stopping after 10 epochs in case of no improvement on the validation set, and kept the model with the best validation loss.

4.2 Proposed Audio+User-based Auto-tagger

The Audio+User model that we propose is an extension of the Audio-based auto-tagger described above. Our model has two branches, one for the audio input and one for the user embeddings input. The audio branch is identical to the one described above, i.e. 4 pairs of convolutional and max pooling layers with ReLu activation. The input to the user branch is the user embedding of size 256. We apply batch normalization to it followed by a fully connected layer with 128 units and Relu activation. We concatenate the output of the audio branch and the user branch after applying batch normalization to each. We pass the concatenated output to a fully connected layer with 256 hidden units with ReLu activation function and apply a dropout with 0.3 ratio for regularization. The final layer is made of 10 output units with a Softmax activation function. We train the model with minimizing the categorical cross entropy using the same configuration as in the previous model, described in Section 4.1. We present the flowchart of the complete model in Figure 3


4.3 User Embeddings

The user embeddings are computed by applying implicit alternating least squares matrix factorization (ALS) [11, 16] on the users/tracks interactions matrix. The matrix represents the user listening count of the tracks available, with an exponential decay applied based on the lapse since the last listening, i.e. the more recent and frequent a track is listened to, the higher the interaction value. The user embedding is represented as a 256-dimensions vector.

However, the user listening histories are proprietary and represent sensitive data. Additionally, the detailed derivation of the embeddings is an internal procedure at Deezer for the recommendation algorithm. Hence, in order to allow the reproducibility of the current work, we directly release the pre-computed embeddings for the anonymized users present in our dataset.

5. RESULTS

We evaluate the two models according to the evaluation protocol proposed in Section 3. First, we evaluate the audio based model with the 3 scenarios: MO-MG, MO-SG, SO-SG. Then, we evaluate the User+Audio model in the SO-SG scenario. Last, we perform the user satisfaction-based evaluation on both models for the SO-SG scenario. In all evaluation protocols, the metrics were macro-averaged.

Figure 3. Architecture of the Audio+User-based model.

	AUC	Recall	Precision	f1-score
car	0.56	0.96	0.47	0.63
gym	0.71	0.87	0.58	0.7
happy	0.58	0.87	0.37	0.52
night	0.59	0.97	0.48	0.64
relax	0.77	0.8	0.61	0.69

average	0.65	0.89	0.52	0.65

Table 2. Results of the audio-based model (multi-label outputs) on the user-agnostic dataset (multiple groundtruth), MO-MG scenario.

5.1 Audio-based Multi-output Multi-groundtruth (MO-MG Scenario)

Table 5.1 shows the results of the audio-based multi-label classification model on our collected dataset without considering the user. The results are consistent with previous studies on context auto-tagging [13]. They show that certain contexts are easier to predict using only the audio input. These are general contexts with similar music style preferences by different users, e.g. 'gym' and 'relax'. By contrast, other contexts are harder to predict from audio only as users listen to more personalized music, e.g. 'work' and 'car'. In consequence, we hypothesis that the variance of the AUC scores across contexts is related to the context dependency on users. Precisely, some contexts could depend more on users than others, making the latter harder to classify without considering the user information.

5.2 Audio-based Multi-output Single-groundtruth (MO-SG Scenario)

Table 5.2 shows the results of the same audio-based multi-label classification model which we now evaluate considering the user. The same audio track will now be presented

	AUC	Recall	Precision	f1-score
car	0.54	0.87	0.09	0.17
gym	0.66	0.6	0.18	0.27
happy	0.57	0.67	0.08	0.14
night	0.57	0.6	0.11	0.19
relax	0.74	0.53	0.25	0.34
running	0.6	0.57	0.15	0.23
sad	0.75	0.52	0.21	0.3
summer	0.58	0.78	0.17	0.29
work	0.52	0.55	0.09	0.15
workout	0.71	0.41	0.17	0.24
average	0.62	0.61	0.15	0.23

Table 3. Results of the audio-based model (multi-label outputs) on the user-based dataset (single ground-truth), MO-SG scenario

	AUC	Recall	Precision	f1-score
car	0.54	0	0.03	0.001
gym	0.66	0.44	0.17	0.24
happy	0.57	0	0	0
night	0.57	0.004	0.14	0.007
relax	0.74	0.6	0.23	0.33
running	0.6	0.05	0.15	0.07
sad	0.75	0.003	0.16	0.006
summer	0.58	0.36	0.18	0.25
work	0.52	0	0.2	0
workout	0.71	0.13	0.18	0.15
average	0.62	0.16	0.14	0.11

Table 4. Results of the audio-based model (forced to single-label output) on the user-based dataset (single ground-truth), SO-SG scenario

several times to the system, i.e. for each user who has annotated this track. While the groundtruth is now single-label and will change for each user, the system will output the same estimated tags independently of the user, i.e. the system does not consider the user as input. We observe a sharp decrease in the precision of the model due to false positive predictions for each user. Indeed, since the output of the system is multi-label, it will output several labels for each track, many of them will not correspond to the current user. The high recall of the model shows that it often predicts the right contextual use for many users. However, it also predicts wrong contexts for many other users. That is due to the limitation of the model which predicts all suitable contexts for all users.

5.3 Audio-based Single-output Single-groundtruth (SO-SG Scenario)

Table 5.3 shows the results of the same audio-based multi-label classification model when restricted to a single prediction per track. While this is not the real-world case of using the audio-based model, it allows a direct comparison to the single-label User+Audio based model. In this case, we see a sharp drop in the recall due to the limitation of a single prediction per track.

	AUC	Recall	Precision	f1-score
car	0.61	0.12	0.13	0.13
gym	0.71	0.16	0.24	0.19
happy	0.64	0.22	0.12	0.16
night	0.61	0.03	0.14	0.05
relax	0.76	0.41	0.29	0.34
running	0.69	0.26	0.22	0.24
sad	0.83	0.5	0.33	0.4
summer	0.65	0.2	0.3	0.24
work	0.58	0.03	0.12	0.04
workout	0.75	0.37	0.2	0.26
average	0.68	0.23	0.21	0.2

Table 5. Results of the audio+user model (single-label output) on the user-based dataset (single ground-truth), SO-SG scenario.

	Accuracy	Recall	Precision	f1-score
Audio	0.21	0.204	0.243	0.216
Audio+User	0.254	0.246	0.295	0.26

Table 6. Comparison of user-based evaluation for the two models

5.4 Audio+User Single-output Single-groundtruth (SO-SG Scenario)

Table 5.4 shows the results for the proposed Audio+User model. Comparing these results with the ones presented in Table 5.3, we observe that the model is performing better than the audio-based model for almost all metrics and labels. The f1-score almost doubles when adding the user information. Additionally, for certain labels as *car, happy, running, sad, summer, work*, the influence of adding the user information is obvious compared to all cases of audio-based evaluation when comparing the AUC values. This is consistent with our hypothesis that for certain labels the influence of user preferences is much stronger than for other labels.

5.5 User Satisfaction-focused Scenario

Finally, we assess the user satisfaction by evaluating the performance of the two models on each user independently. We replace the AUC metric with accuracy because AUC is not defined in the case of certain users where a specific label is positive for all samples. Table 5.5 shows the average performance of each model when computed per user. In this case, we observe how the Audio+User model satisfies the users more on average in terms of all evaluation metrics. By investigating the recall and precision, we noticed that our model results in a larger number of true positives, i.e. predicting the correct context for each user, and a lower number of false positives, i.e. less predictions of the wrong contextual tags for each user. The audio-based model is prone to a higher false positives due to predicting the most probable context for a given track regardless of the user. To sum up, including the user information in the model has successfully proven to improve the estimation of the right contextual usages of tracks.

6. CONCLUSION AND FUTURE WORK

Predicting the contextual use of music tracks is a challenging problem with multiple factors affecting the user preferences. Through our study, we showed that including the user information, represented as user embeddings based on the listening history, improves the model's capability of predicting the suitable context for a given user and track. This is an important result towards building context-aware recommendation systems that are user-personalized, without requiring the exploitation of extensive user private data such as location tracking [3]. However, there is still large room for improvement to successfully build such systems.

Our current model relies on using the audio content, which is suitable for the cold-start problem of recommending new tracks [6, 23]. However, constructing representative user embeddings requires active users in order to properly infer the listening preferences. Future work could investigate the impact of using different types of user information, such as demographics [8], which could be suitable for the user cold-start or less active users too.

Additionally, we focused on the case of a single contextual tag for each user and track pair. In practice, a user could listen to the same track in multiple contexts, i.e. tag prediction would be modelled a multi-label classification problem at the user level. Future studies could further investigate this more complex case of adding the user information in the multi-label settings.

Finally, while we have proven the advantage of our system on a subset of contexts. Extending the study to a larger number of possible contexts still needs to be addressed. In reality, users listen to music in more diverse contexts, adding levels of complexity to the addressed problem.

ABSTRACT

This paper addresses the extraction of multiple F0 values from polyphonic and *a cappella* vocal performances using convolutional neural networks (CNNs). We address the major challenges of ensemble singing, i.e., all melodic sources are vocals and singers sing in harmony. We build upon an existing architecture to produce a pitch salience function of the input signal, where the harmonic constant-Q transform (HCQT) and its associated phase differentials are used as an input representation. The pitch salience function is subsequently thresholded to obtain a multiple F0 estimation output. For training, we build a dataset that comprises several multi-track datasets of vocal quartets with F0 annotations. This work proposes and evaluates a set of CNNs for this task in diverse scenarios and data configurations, including recordings with additional reverb. Our models outperform a state-of-the-art method intended for the same music genre when evaluated with an increased F0 resolution, as well as a general-purpose method for multi-F0 estimation. We conclude with a discussion on future research directions.

1. INTRODUCTION

Ensemble singing is a well-established practice across cultures, found in a great diversity of forms, languages, and levels. However, all variants share the social aspect of collective singing, either as a form of entertainment or expressing emotions. In *The Science of the Singing Voice* [1], Sundberg claims that choral singing is one of the most widespread types of singing. In Western classical music, a *choir* is usually a group of singers divided into four sections: soprano, alto, tenor, bass (SATB); however, there exist many other forms of polyphonic singing, involving a diverse number of singers, parts, and vocal ranges. One example of such variants is a vocal quartet, where four singers—commonly with distinct vocal ranges—sing in

Figure 1. Overview of the proposed method. **(a)** Input features. **(b)** Convolutional architecture diagram. **(c)** Output salience map. **(d)** Peak picking and thresholding step to obtain F0 values from the salience activation in (c). **(e)** Multiple F0 representation, output of the framework.

harmony. Vocal quartets usually follow the SATB configuration; therefore, they are different from a *standard* choir in that there is only one singer per section.

Ensemble singing has not been widely studied in the field of Music Information Retrieval (MIR) in the recent years. We find a few early works focused on the acoustic properties of choral singing [2–4], and also a few more recent studies about some expressive characteristics of polyphonic vocal music, such as singer interaction and intonation [5–10], analysis of unison singing [11, 12], or choir source separation [13]. Most of these studies rely on individual recordings of each voice in the ensemble, which enable the automatic extraction of fundamental frequency (F0) contours from each isolated voice. The general applicability of these approaches is limited by the fact that vocal groups are rarely recorded with individual microphones. Another common strategy is using the polyphonic audio recordings along with their associated synchronized scores. However, the process of synchronizing a choral audio recording to a score is not straightforward, and therefore results are not always entirely trustworthy. Manual an-

notation is also one solution to obtain reliable F0 contours, but the process is highly time-consuming and expensive.

An alternate approach is to analyze a mixed, polyphonic recording to produce multiple F0 estimations simultaneously. This process enables the use of polyphonic singing recordings in the wild, and eliminates the need for separate audio recordings for each singer. However, multi-F0 estimation in polyphonic vocal music has been less often studied, likely due to the complexity and variety of sounds that a singer can produce, the timbre similarity between singers' voices, as well as the scarcity of annotated data of this kind [14].

In this paper, we focus on multiple F0 estimation for vocal ensemble audio mixtures. We build upon previous work on using neural networks to obtain an intermediate salience representation suitable for several tasks, including multi-F0 estimation [15]. In particular, we experiment with a set of convolutional neural networks (CNN), and combine magnitude and phase information, which is commonly neglected in the literature. We experiment with different fusion strategies and analyze the generalization capabilities of deep learning models in the presence of unison and reverbs. Figure 1 shows a diagram of the proposed method.

Following research reproducibility principles, data generation scripts and models are accessible [1] .

2. RELATED WORK

Multiple F0 estimation (also referred to as multi-F0 estimation, or multi-pitch estimation) is a sub-task of automatic music transcription (ATM) that consists of detecting multiple concurrent F0 values in an audio signal that contains several melodic lines at the same time [14, 16, 17]. Benetos et al. [17] summarize the main challenges of ATM as follows: polyphonic mixtures having multiple simultaneous sources with different pitches, loudness, and timbre properties; sources with overlapping harmonics; and the lack of polyphonic music datasets with reliable ground truth annotations, among others. They organize ATM approaches into four categories: frame-level (or multi-F0 estimation), note-level (or note-tracking), stream-level (or multi-F0 streaming), and notation-level. Our work focuses on the first category.

While monophonic F0 estimation is a well-researched topic, with state-of-the-art systems with excellent performances [18–21], multiple F0 estimation is still challenging. Research on this topic is commonly divided into several groups according to the nature of the employed methods. For instance, in [17] they report four categories: traditional signal processing methods, probabilistic methods, non-negative matrix factorization (NMF) methods, and neural networks.

Klapuri [22] proposed a signal processing based method for multi-F0 estimation in polyphonic music. He calculates the salience of F0 candidates by summing the amplitudes of its harmonic partials, and then uses an iterative method

where at every step an F0 is estimated and cancelled from the mixture before moving to the next iteration to estimate the next F0. The same author presented in [23] a similar method that incorporates information about human perception by means of an auditory model before the iterative process.

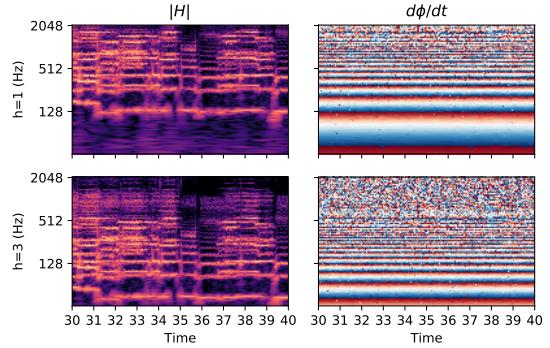
The system presented by Duan et al. [24] uses maximum-likelihood approach with the power spectrum as input. Spectral peaks are detected and two separate regions are defined accordingly: the peak region and the non-peak region, using a tolerance of half semitone from the detected peaks. In the maximum-likelihood process, both sets are treated independently, and the process of detecting F0 consists of optimizing a joint function that maximizes the probability of having harmonics that explain the observed peaks and minimizing the probability of having harmonics in the non-peak region. The F0 estimates are post-processed using neighbouring frames' estimates to produce more stable F0 contours.

A recent example of a multiple F0 estimation framework that employs neural networks is the system by Bittner et al. [15], DeepSalience (DS): a CNN trained to produce a multi-purpose pitch salience representation of the input signal. It is designed for multi-instrument pop/rock polyphonic music, and it provides an intermediate representation for MIR tasks such as melody extraction and multi-F0 estimation, outperforming state-of-the-art approaches in both cases. Following the premise that a pitch salience function is a suitable representation to extract F0 values, also exploited in [22, 23, 25, 26], this work keeps up with the advancements of deep neural networks to build data-driven salience functions. They use the harmonic constant-Q transform (HCQT) as input feature, which is a 3-dimensional array indexed by harmonic index h, frequency f, and time t: $\mathcal{H}[h, f, t]$. It comprises a set of constant-Q transforms (CQT) stacked together, each of them with its minimum frequency scaled by the harmonic index: $h \cdot f_{min}$.

While the above methods are well-suited for multiple F0 estimation in multi-instrumental music, *a cappella* polyphonic vocal music has several particularities that justify the need for dedicated techniques. One of the most significant challenges of analyzing vocal ensembles is due to harmonies occurring between distinct, overlapping vocal ranges. The timbre similarity, strong harmonic relationships, and overlapping frequency ranges hinder the extraction of concurrent F0 values in such music signals.

McLeod et al. [27] present a system for automatic transcription of polyphonic vocal music, which includes an initial step of estimating multiple F0s, and a second step of voice assignment, where each detected F0 is assigned to one of the SATB voices. They combine an acoustic model based on the factorization of an input log-frequency spectrogram for the multi-F0 estimation with a music language model based on hidden Markov models (HMM) for the voice assignment step. An earlier version of this method was presented in [14]; however, in the latter work the authors include a model integration step where the output of

Dataset	# of songs	Duration (hh:mm:ss)
Choral Singing Dataset [8]	3 songs	00:07:14
Dagstuhl ChoirSet [29]	2 songs	00:55:30
ESMUC Choir Dataset	3 songs	00:21:08
Barbershop Quartets [2]	22 songs	00:42:10
Bach Chorales [3]	26 songs	00:58:20

Table 1: Overview of the datasets used in this paper. The reported durations refer to the original mixtures before re-mixing stems and data augmentation. Dagstuhl ChoirSet and ESMUC Choir Dataset contain several takes per song.


the music language model is further used in the acoustic model to improve the estimation of F0s. Their results show that integrating both parts of the system improves the performance of the voice assignment, and also of the multi-F0 estimation, since it eliminates many false positives.

Su et al. [28] also address some of the aforementioned issues by proposing an unsupervised method for multi-F0 estimation of choir and symphonic music. Their approach uses time-frequency reassignment techniques such as the synchrosqueezing transform (SST), which aims to better discriminate closely-located spectral components, such as unisons. They use an improved technique called ConceFT, which is based on the idea of multi-taper SST, but was proved to estimate instantaneous frequencies in noisy signals more precisely. These methods measure pitch salience and enhance the stability and localization of the F0 features needed for multi-F0 estimation.

3. DATASET

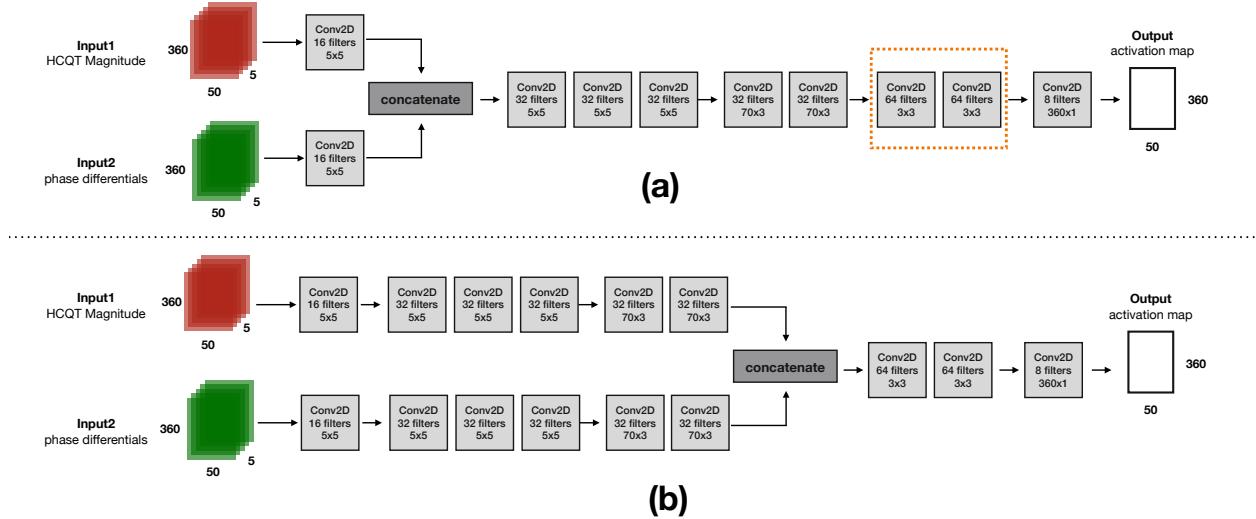
The lack of an appropriate and large enough annotated dataset has been a bottleneck in the use of machine learning techniques for multiple F0 estimation in ensemble singing. We address this difficulty by constructing a dataset that comprises several multi-track datasets of polyphonic singing with F0 annotations. We created a dataset by aggregating several existing multi-track polyphonic singing datasets. Table 1 shows an overview of the characteristics of each dataset individually. In this section, we describe them in more detail, as well as explain the process of data augmentation.

We use five datasets of similar characteristics. First, the Choral Singing Dataset (CSD) [8], a publicly available multi-track dataset of Western choral music. It comprises recordings of three SATB songs performed by a choir of 16 singers, four per section (4S4A4T4B), and it contains separate audio stems for each singer. Besides, it includes F0 annotations for each singer, which are automatically extracted and manually corrected. Similarly, the ESMUC Choir Dataset (ECS) is a proprietary dataset that comprises three songs performed by a choir of 13 singers (5S3A3T2B); it also includes audio stems for each

Figure 2. Input features examples for 10-seconds excerpt of a file from the training set. HCQT magnitude is depicted in the left column, and HCQT phase differentials in the right column, for $h = 1$ (top) and $h = 3$ (bottom).

singer and F0 annotations. The third dataset with comparable characteristics is the Dagstuhl ChoirSet (DCS) [29]: it consists of recordings of two songs performed by a choir of 13 singers (2S2A4T5B), and two different SATB quartets. This dataset also provides the audio stems and automatically extracted F0 annotations. Finally, we also add two commercial datasets: the Bach Chorales (BC) [3] and the Barbershop quartets (BSQ) [2]. They contain 26 and 22 songs, respectively, performed by vocal quartets—SATB in the first case, and tenor, lead, baritone, bass in the second case—as well as automatically extracted F0 annotations.

We exploit the multi-track nature of all datasets to create artificial mixtures of stems. We use PySox [30] to create all the possible combinations of singers, with the constraint of having one singer per part (SATB). In parallel, we also generate the multi-F0 annotations by combining the individual F0 contours of each singer in the mixture.

Besides creating the audio mixtures from individual recordings, we include two additional steps to improve generalization. First, we augment our dataset by means of pitch-shifting individual voices and re-mixing them. Particularly, we use pitch-shifting at a semitone scale: -2 to $+2$ semitones from the original signal. Second, our dataset contains two versions of each audio clip: the original one (obtained by mixing together individual stems), and the same song with reverb. We use the *Great Hall* impulse response (IR) from the Room Impulse Response Dataset in Isophonics [31], and convolve it with the audio mixtures of our dataset. For both tasks, we use MUDA, a software framework for musical data augmentation [32].


The dataset consists of 22910 audio files of diverse durations, from 10 seconds to 3 minutes. We split it into training (75%, 17184 files), validation (10%, 2291 files), and test (15%, 3435 files) subsets.

4. PROPOSED METHOD

In this section, we describe the input features, the target representations, the convolutional architectures we design, and the experiments we conduct.

Figure 3. Proposed convolutional architectures. **(a)** Early/Shallow and Early/Deep: the two layers inside the orange dotted rectangle are only part of Early/Deep. **(b)** Late/Deep: the concatenation of both inputs' contribution happens later in the network. In all networks, each layer is preceded by a batch-normalization step and the output of each layer is passed through a rectified linear unit activation function, except for the last layer, which uses a sigmoid.

4.1 Input features

Our networks have two separate inputs: the HCQT magnitude and the HCQT phase differentials. The HCQT is a 3-dimensional array $\mathcal{H}[h, t, f]$, indexed by harmonic (h), frequency (f), and time (t). It measures the hth harmonic of frequency f at time t, where $h = 1$ is the fundamental. This representation is based on computing a standard constant-Q transform (CQT) for each harmonic where the minimum frequency (f_{min}) is scaled by the harmonic number, $h \cdot f_{min}$. Detailed descriptions of the HCQT are presented in [15, 33]. For the HCQT calculation we use 60 bins per octave, 20 cents per bin, 6 octaves, and a minimum frequency of 32.7 Hz, which corresponds to a C1. We use five harmonics, so that $h \in \{1, 2, 3, 4, 5\}$ to compute the frequencies of the partials. Phase information is often discarded from neural network inputs, which commonly use magnitude representations such as the magnitude of the short-time Fourier transform (STFT). However, we also use the associated phase differentials. From signal processing theory we know that the phase differential of a signal contributes to a more precise calculation of the instantaneous frequency (ω_{ins}) [34]:

$$\omega_{ins} = \frac{\delta\varphi(t)}{\delta t} \rightarrow f_{ins} = \frac{1}{2\pi}\frac{\delta\varphi(t)}{\delta t} \tag{1}$$

where $\varphi(t)$ is the phase spectrum of the audio signal.

All audio files are resampled to a sampling rate of 22050 Hz, and we use a hop size of 256 samples. An example of the two input features examples is displayed in Figure 2.

4.2 Output representation

The output targets we use to train our networks are time-frequency representations with the same dimensions (2-D) as one of the input channels, i.e., $\mathcal{H}[1]$. We use the

ground truth F0 annotations (see Section 3) and assign each F0 value to the nearest time-frequency bin in the 2-D representation—which has the same time and frequency resolutions as the input—with a magnitude of 1. Non-active bins are set to 0, and we apply Gaussian blur with standard deviation 1 in the frequency direction to account for possible imprecisions in the predictions. We follow the same procedure as in DeepSalience and set the energy decay from 1 to 0 to cover half a semitone in frequency.

4.3 Models

Figure 3 depicts three convolutional architectures we propose: Early/Shallow, Early/Deep, and Late/Deep.

4.3.1 Early/Shallow and Early/Deep models

These models, inspired by DeepSalience, are illustrated in Figure 3a. They both consist of a fully convolutional architecture with two separate inputs: one for the HCQT magnitude and a second one for the HCQT phase differentials. Each of these inputs is first sent to a convolutional layer with 16 (5×5) filters. Then, the outputs of these two layers are concatenated. (5×5) filters cover approximately 1 semitone in frequency and 50 ms in time. After the concatenation, data passes through a set of convolutional layers including two layers with 32 (70×3) filters, which cover 14 semitones in frequency and are suitable for capturing harmonic relations within an octave. In the Early/Deep model we add two 64 (3×3) layers before the last layer with 8 filters that cover all frequency bins.

4.3.2 Late/Deep model

Late/Deep diagram is displayed in Figure 3b, and it follows a similar structure to Early/Shallow and Early/Deep. However, in this case both inputs are handled separately

until the layer with (70×3) filters; then, we concatenate both data streams and add the same layers: two layers with 64 filters (3×3), and the last layer with 8 filters that cover the whole frequency dimension, i.e., 360 bins.

In all models, batch normalization is applied at the input of every layer, and the outputs are passed through rectified linear units (ReLU), except for the output layer, which uses logistic activation (sigmoid) to map the output of each bin to the range [0, 1]. Using sigmoid at the output enables the interpretation of the activation map as a probability function, where the value between 0 and 1 represents the probability that a specific bin belongs to the set of F0s present in the input signal. All models in the experiments described next are trained to minimize binary cross-entropy between the target, $y[t, f]$, and the prediction, $\hat{y}[t, f]$, both of them values in the range [0, 1]:

$$L(y, \hat{y}) = -y \log(\hat{y}) - (1 - y) \log(1 - \hat{y}) \qquad (2)$$

We use the Adam optimizer [35] with a learning rate of 0.001, and train for 100 epochs with a batch size of 16 patches of shape $(360, 50)$. We perform early stopping when the validation error does not decrease for 25 epochs.

4.4 Experimental setup

4.4.1 Evaluation metrics

We evaluate the models using the frame-wise metrics Precision, Recall, F-Score (or F-measure) as they are defined in the MIREX multiple-F0 estimation task [36] using the `mir_eval` library [37].

4.4.2 Experiment 1: fusion strategy

In the first experiment we use the whole dataset split into train-validation-test subsets (see Section 3), to measure the general performance of the three models. With this experiment we study the influence of magnitude and phase information fusion at an early stage of the network, i.e., Early/Shallow-Deep, or later, i.e., Late/Deep. For each model, we use the validation set to optimize the threshold we apply to the peaks extracted from the output salience representation. The optimal threshold is the one that maximizes the average accuracy across the validation set in each case. In addition, we train the Late/Deep model without the phase information, i.e., we remove the branch of the network dedicated to the phase. We intend to verify the hypothesis that including the phase as input to the network leads to more precise results.

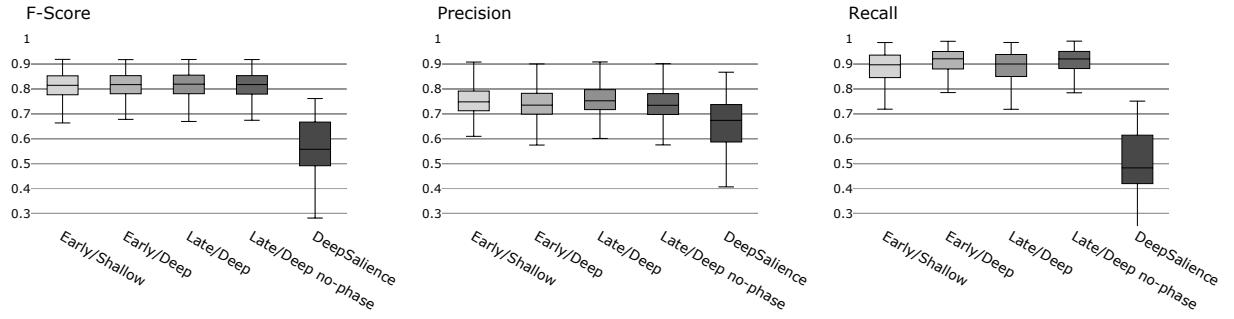
4.4.3 Experiment 2: comparative analysis

In this experiment we evaluate the performance of our best-performing model from Experiment 1 on the BSQ [2]. This is one of the datasets used in [27, 38], allowing for a direct comparison between their method—also designed for ensemble singing—and the model we propose. These data are part of our original training dataset, but in this experiment we train the model excluding all the BSQ audio files, and then use them for exclusively for evaluation.

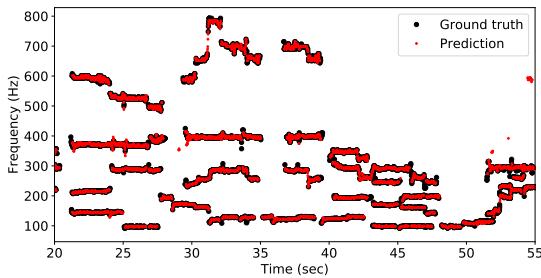
4.4.4 Experiment 3: generalization

In this last experiment, we aim to explore the effect of unison and reverb. Since vocal ensembles are commonly captured using a room microphone, such recordings usually contain reverb or similar effects, caused by the room acoustics. We train our best-performing model excluding all audio files with reverb from the dataset, and then evaluate it with conventional choir recordings from the dataset presented in [28], which is not part of our working dataset. In addition, we evaluate this model on a subset of reverb files from the original test set and compare the performance of this model to the model trained in Experiment 1.

5. RESULTS

5.1 Experiment 1: fusion strategy


Results for Experiment 1 are depicted in Figure 4. While the three models have similar results, Late/Deep is slightly better in terms of F-Score, suggesting that the late fusion of magnitude and phase information is more robust than the early fusion. Figure 5 shows an excerpt of the multiple F0 output (red) together with their associated ground truth reference (black). We compare these results to DeepSalience using a detection threshold of 0.2 (optimized beforehand on the evaluation material), which has a lower performance, which we attribute to distribution shift from its training set. Additionally, we observe how the Late/Deep without phase information has a similar F-Score but lower precision, showing that including phase differentials as input is helpful for obtaining more accurate results. Since Late/Deep is the model with the best performance, we use it in the subsequent experiments.

5.2 Experiment 2: comparative analysis


Experiment 2 results are summarized in Table 2 in terms of F-Score, and Precision and Recall (when available). We evaluate the predictions from our model on the BSQ dataset, and compare the results to the ones reported with MSINGERS [14], and VOCAL4-VA, the fully-integrated model from [27]. We use two different pitch tolerances: one semitone (100 cents) and 20 cents. While one semitone resolution is enough for transcription purposes, for analysis such as the ones described in Section 1, i.e., intonation and singer interaction, more pitch resolution is required. We observe that our model outperforms both baseline methods with two different pitch tolerances. In the 20 cents evaluation, the baseline models experience a performance drop (-17% and -26%), whereas the decrease in our model is much smaller, around -2% in the F-Score. This difference presumably resides in the fact that our model uses phase information to refine F0 estimates, therefore extracting a more precise value.

5.3 Experiment 3: generalization

Results from this experiment show that our model outperforms the method in [28] on their choir dataset: when we

Figure 4. Evaluation results on the non-pitch-shifted audio files of the test set. We compare our three models to Deep-Salience as a baseline, as well as to the Late/Deep network trained without the phase differentials (Late/Deep no-phase). Note that outliers are excluded from the plots for an easier visualization.

Figure 5. Example output from Experiment 1, Late/Deep model. Predictions (red) are plotted over the ground truth reference (black).

Method	100 cents			20 cents		
	F	P	R	F	P	R
MSINGERS [14]	0.708 (0.06)	0.685 (0.06)	0.736 (0.07)	0.537 (0.07)	0.620 (0.07)	0.477 (0.08)
VOCAL4-VA [27]	0.757 (0.06)	-	-	0.490	-	-
Late/Deep	**0.846** (0.03)	0.812 (0.03)	0.884 (0.04)	**0.831** (0.03)	0.797 (0.03)	0.868 (0.04)

Table 2: Multi-F0 estimation results (F-Score (F), precision (P), and recall (R)) on the Barbershop quartets, for different pitch tolerances. Values in parentheses refer to the standard deviation. Best scores are highlighted in bold.

calculate the average F-Score across the whole dataset, using the threshold optimized on the validation set, we obtain 0.704, while their best-performing method reaches an average F-Score of 0.653. Note that this dataset contains short excerpts of commercial choir recordings, with several singers per section and a large reverb effect, which differs from our training material. Therefore, these results suggest that our model is robust to recordings in such context. However, a larger experiment with similar data would be necessary, since this dataset is very small. The second part of this experiment is the evaluation of a subset of ten reverb files from the test set. In terms of F-Score, and as expected, the model that includes reverb files in the training set (Experiment 1) improves by slightly more than 10% on

average with respect to the model that excludes these files (Experiment 3). Therefore, we conclude that the presence of both reverb and dry signals in the training set is beneficial for the performance of a wider range of recording conditions such as reverb.

6. CONCLUSIONS

In this paper, we proposed a set of novel convolutional architectures for multiple F0 estimation in *a cappella* ensemble singing, combining magnitude and phase information. For training, we created an annotated dataset of polyphonic singing voice by aggregating several existing datasets, and augmented it by means of pitch-shifting and reverberation.

We conducted several experiments to evaluate different aspects of the detection process. We evaluated the overall performance of three models as compared to a deep learning based multi-purpose multiple F0 estimation system, and found that our models outperform the baseline when applied on ensemble singing. We also verified that using phase information at the input, together with the magnitude, improves the precision of the F0 estimates. We compared our best-performing model to one existing approach for multiple F0 estimation in vocal ensembles, and demonstrated that it outperforms it with two different F0 resolutions (100 and 20 cents). In addition, we compared our model to an approach specifically designed for choir and symphonic music and found that our model is robust in conditions of unison and high reverb. However, further experiments with a larger amount of data are required to verify these findings.

Although our results are a strong contribution to addressing the limitations of deep learning architectures for vocal music, there are some further steps that would potentially improve the performance of our models. Informal experiments showed that post-processing the output F0 contours increases their time continuity; therefore, the overall quality of the output improves. Further steps also include not only estimating the F0 values frame-wise, but also assigning each of them to a singer, which is a challenging task if the number of singers is not known a priori.

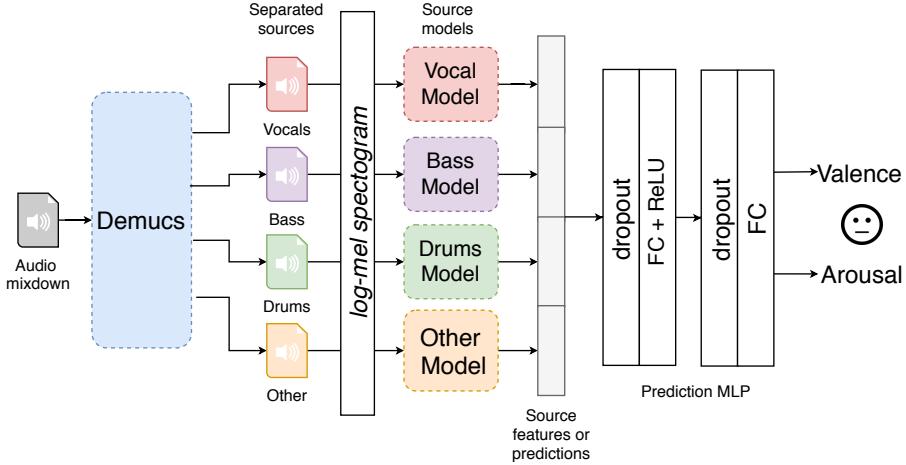
ABSTRACT

Despite the manifold developments in music emotion recognition and related areas, estimating the emotional impact of music still poses many challenges. These are often associated to the complexity of the acoustic codes to emotion and the lack of large amounts of data with robust golden standards. In this paper, we propose a new computational model (EmoMucs) that considers the role of different musical voices in the prediction of the emotions induced by music. We combine source separation algorithms for breaking up music signals into independent song elements (vocals, bass, drums, other) and end-to-end state-of-the-art machine learning techniques for feature extraction and emotion modelling (valence and arousal regression). Through a series of computational experiments on a benchmark dataset using source-specialised models trained independently and different fusion strategies, we demonstrate that EmoMucs outperforms state-of-the-art approaches with the advantage of providing insights into the relative contribution of different musical elements to the emotions perceived by listeners.

1. INTRODUCTION

The ability of music to express and induce emotions [15,21] and act as a powerful tool for mood regulation [28] are well-known and demonstrable. Indeed, research shows that music listening is a commonly used, efficacious, and adaptable device to achieve regulatory goals [31], including coping with negative experiences by alleviating negative moods and feelings [17].

Crucial to this process is selecting the music that can facilitate the listener to achieve a determined mood regulation target, which often is not an easy task. In order to support listeners in this process, emotion-aware music recommendation systems became popular as they offer the possibility to explore large music libraries using affective cues. Indeed, recommending music based on the emotion of the listener at home [10] or background music personalised for the ones present in a restaurant would provide a more personal and enjoyable user experience [14].

At the core of these systems is music emotion recognition (MER), an active field of research in music information retrieval (MIR) for the past twenty years. The automatic prediction of emotions from music is a challenging task due to the subjectivity of the annotations and the lack of considerable data for effectively training supervised models. Song et al. [29] also argued that MER methods tend to perform well for genres such as classical music and film soundtracks, but not yet for popular music [25]. In addition, it is difficult to interpret emotional predictions in terms of musical content, especially for models based on deep neural networks. Although a few approaches exist for interpretable MER [5], the recognition accuracy of these methods is compromised, with the resulting performance loss often referred to as "cost of explainability".


As different voices within a composition can have a distinct emotional impact [13], our work leverages state-of-the-art deep learning methods for music source separation (MSS) to reduce the complexity of MER when limited training data is available. The proposed architecture (EmoMucs) is based on combining source separation methods with a parallel block of source-specialised models trained independently, subsequently aggregated with a fusion strategy. To benchmark our idea, we evaluated EmoMucs on the popular music with emotional annotations (PMEmo) dataset [38], and compared its performance with two reference deep learning models for MER. Experimental results demonstrate that our method achieves better performance for valence recognition, and comparable ones for arousal, while providing increased interpretability.

The main technical contributions are manifold: (i) we provide an in-depth evaluation of two reference models for MER, (ii) we propose a computational model that achieves an improved performance on the current baselines, under similar experimental conditions, and finally (iii) we show that our model provides no cost of interpretability.

The rest of the paper is structured as follows: Section 2 gives a primer on MER and an overview of related work on content-based methods, whilst Section 3 outlines the base-

Figure 1. An overall architecture illustrating our proposed model, EmoMucs.

line architectures and our novel EmoMucs model. Section 4 details the experimental evaluation carried out, including our results on interpretability. Finally, Section 5 draws conclusions and gives direction for future work.

2. BACKGROUND AND RELATED WORK

2.1 A primer on music emotion recognition

Prior to introducing content-based methods for MER, we provide the reader with the fundamentals concepts of the task and refer to [3, 16, 34, 35] for a detailed overview.

Induced vs perceived emotions. Perceived emotions refers to the recognition of emotional meaning in music [29]. Induced (or felt) emotions refer to the feelings experienced by the listener whilst listening to music.

Annotation system. The conceptualisation of emotion with its respective emotion taxonomy remains a longstanding issue in MER [29]. There exist numerous emotion models, from miscellaneous [19] to domain specific [36], categorical [11] and dimensional [24], with the latter two being the prevailing ones. Whilst the categorical model focuses on all the emotions evolving from universal innate emotions like happiness, sadness, fear and anger [11], the dimensional model typically comprises an affective two-dimensional *valence-arousal* space. Valence represents a pleasure-displeasure continuum, whilst arousal outlines the activation-deactivation continuum [24].

Time scale of predictions. Predictions can either be static or dynamic. In the former case, the representative emotion of a song is given by one valence and arousal value [16]. Emotion annotations can also be obtained over time (e.g. second-by-second valence-arousal labels), thus resulting in dynamic predictions [27].

Audio features. Musical compositions consist of a rich array of features such as harmony, tempo, loudness and timbre and these all have an effect on emotion. Previous work in MIR has fuelled around developing informative acoustic features [16]. However, as illustrated in other works [18, 22, 26] and to the best of our knowledge, there exists no dominant single feature for MER.

2.2 Methods for content-based MER

The field of MIR has followed a similar path to other machine learning ones. Prior to the deep learning era, most methods relied on manual audio feature extraction. Huq et al. [12] give an overview on how musical features were traditionally extracted and fed into different architectures such as support vector machines, k-nearest neighbours, random forests, deep belief networks and other regression models. These methods were tested for MER on Russell's well-established arousal and valence emotion model [24].

These were succeeded with deep learning methods. Such techniques, like binarised and bi-directional long short-term memory recurrent neural networks (LSTM-RNN) and deep belief networks, have also been successfully employed for valence and arousal prediction [33]. Other methods again used LSTM-RNNs for dynamic arousal and valence regression, on the acoustic and psychoacoustic features obtained from songs [6]. Most of these works stemmed from entries in the MediaEval emotion challenge [2]. Multimodality has also been an interest for this research community, where [9] looked into MER based on both the audio signal and the lyrics of a musical track. Again, deep learning methods such as LSTM-RNNs are at the core of the architectures proposed.

An important factor in machine learning has been to build interpretable models, to make them applicable to a wider array of applications. To the best of our knowledge, only a few works have attempted to build an interpretable model for MER. In [37], different model classes were built over the extracted and selected features. These vital features were filtered and wrapped, followed by shrinkage methods. In [5], a deep network based on two-dimensional convolutions is trained to jointly predict "*mid-level perceptual features*", related to emotional qualities of music [1], with emotion classes in a categorical annotation space.

Our work focuses on the prediction of induced emotions at a global time scale (static predictions). This is done in a continuous annotation space, as adopting a categorical one would not exhibit the same richness in induced human emotion [35]. The idea of using MSS methods for MER was first investigated in [32]. Our work differs in

the following: (i) we focus on valence-arousal MER and address the former as a regression task; (ii) our methods rely on state-of-the-art deep learning methods with no need of traditional methods for audio feature extraction; (iii) we investigate different fusion strategies and training approaches, and (iv) we provide an insightful analysis for the interpretability of our models.

3. METHODOLOGY

Our approach is based on the observation that different musical sources in a composition can evoke distinct emotional responses from the listeners [13]. Given a music piece, they can contribute differently to the overall induced emotion. For instance, the bass and the vocal lines of a track can be more informative to predict valence, whereas drums might have more impact on arousal. Nevertheless, our aim here is not to provide a general explanation of the emotional influence of musical parts, as this is often an individualistic property belonging to each track.

Instead, we propose a computational model for MER based on a decomposition of the original audio signal to the possible sources (e.g. vocals, drums, bass) that can be detected from it. By doing so, it will be easier for the model to process the audio stream whilst searching for emotion-related patterns in every single source. The aggregation of the resulting source-specific models within a single architecture would also account for the possible inter-source relationships. This approach can thus be considered as a way to provide prior knowledge to a model in order to reduce the complexity of the learning task when limited data is available – a recurring issue in MER.

Considering the technical challenges in MER, the design of a computational model based on music source separation has the potential to (i) improve the performance of the current solutions with the same amount of training data; (ii) provide a modular architecture which can be further adapted and fine-tuned with respect to each source-specific module, and (iii) quantify the contribution of each source to the final prediction for improved interpretability.

Our model, EmoMucs, achieves this through a multiplexed framework for emotion recognition. The architecture of our model is illustrated in Figure 1, with its building blocks explained in the following subsections.

3.1 Music source separation module

In the final step of music production, the tracks corresponding to each individual instrument [1] are mixed together in a single audio file known as mix-down. Music source separation (MSS) aims at reconstructing the individual sources from a mix-down. A reference categorisation of these sources is the *SiSec Mus* evaluation campaign [30], which is based on the following classes: (i) *vocals*, (ii) *drums*, (iii) *bass* and (iv) *other*. Given a mixdown, the goal of a MSS model is to generate a waveform for each of the four original sources.

Most of the approaches for MSS operate on the spectrograms generated by the short-time Fourier transform

_____

[1] We use *voice*, *instrument* and *source* interchangeably.

(STFT). They are trained to produce a mask on the magnitude spectrums for each frame and source [8]. The output audio is then obtained through an inverse STFT on the masked spectrograms, reusing the input mixture phase. However, a technical limitation of these approaches is the information loss resulting from the mix of sources, which cannot be easily recovered through masking.

For this reason we use *Demucs* [8], a recent deep learning model for MSS directly operating on the raw input waveform. Instead of relying on a masking approach, Demucs is inspired by models for music generation in the waveform domain. It implements a U-net architecture with a convolutional encoder-decoder, and a bidirectional LSTM between them to increase the number of channels exponentially with depth [7].

Given an audio track, our system starts by feeding it to Demucs. This results into four different source tracks – one for each SiSec Mus class. To ensure comparability of our architecture with the baseline methods for MER, we compute the log-mel spectogram of each source track.

3.2 Source models and fusion strategies

As illustrated in Figure 1, the log-mel spectrogram of each source track is then passed to the specific model associated to that source (e.g. the vocal's spectrogram is fed to the vocal model). By disentanglement, each sub-model processes a single voice independently, and learns the corresponding source-specific musical features for emotion recognition. This approach thus provides a high degree of flexibility, as it makes it possible to design the architecture of each sub-model specifically for the corresponding source. Nonetheless, to guarantee a fair comparison of our architecture with the current methods for MER, we use one of our baselines as the architecture for all source models.

The baseline models are based on two common deep learning architectures for MER, illustrated in Figure 2. The first is a one-dimensional convolutional neural network (C1D) that was proposed in [9] as an audio model for multimodal MER. The architecture consists of two one-dimensional convolutional layers followed by max-pooling and batch normalisation. Its resulting feature maps are then passed to two fully-connected layers with dropout masks to improve generalisation. The second baseline comprises a VGG-style network, demonstrated to be effective in several MIR tasks [4]. This musically-engineered model, C2D, consists of 5 two-dimensional convolutional blocks, each separated by max pooling and dropout layers. The two-dimensional pooling operators progressively decrease the size of each feature map, while keeping the same number of kernels (32) after each block. After the convolutional blocks, two-dimensional average pooling is applied to ensure that the resulting feature map is of size 32×1. Following dropout, a single fully-connected layer is then employed to predict arousal and valence.

The architecture of our source models can be either C1D or C2D, resulting in two different implementations of EmoMucs – *EmoMucs-C1D* and *EmoMucs-C2D*. To yield a final prediction of valence (V) and arousal (A), the features from the source models are concatenated and passed

Figure 2. The baseline models our system C1D and C2D. These are the building blocks for the source models.

to two fully-connected layers with dropout. Assuming C1D is chosen as the architecture for our source models, there are three possible ways to access the features of a source model. This gives three fusion strategies: *early* (E), *mid* (M) and *late* (L), depicted in Figure 2. The first strategy considers the features obtained after the convolutional layers; *mid* fusion concatenates the features learned after the first fully-connected layers; and the *late* strategy considers the output of each source model, which correspond to the VA predictions. From the definition of C2D, the *mid*-level fusion strategy is not possible with this architecture.

3.3 Our training approach

Considering the different role of each source model, there are three main strategies for training EmoMucs: *full*, *freeze* and *fine-tune*. The first approach consists in training the whole network from scratch and propagating the gradient back to the source models from the last fully-connected layer of EmoMucs. In contrast, the last two strategies are based on pre-training each source model separately as a first step. The full network is then trained until the concatenation level, for the *freeze* mode, or until the first convolutional layer of each source model, for the *fine-tune* mode. This last choice can be considered as a sort of fine-tuning strategy and should be implemented with small learning rates to avoid the source models to catastrophically forget what they have already learned independently.

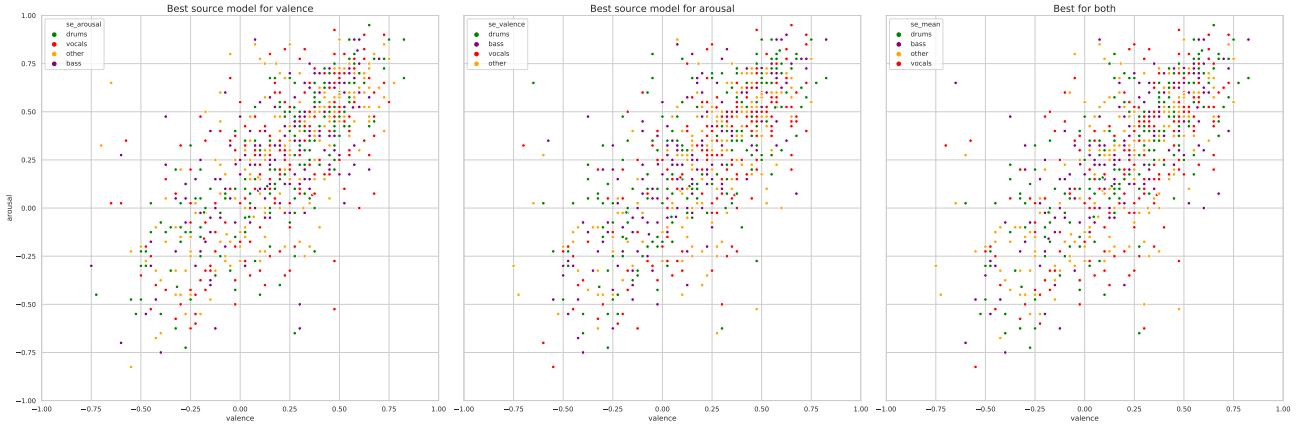
4. EXPERIMENTS

Our method is validated using the baseline models C1D and C2D trained on the mix-downs as reference models. These are denoted as C1D-M and C2D-M respectively. The performance of the baselines is then compared with each source model trained independently. In particular, we compare CXD-M with CXD-{V | B | D | O}, where V, B, D, O denote the *vocals*, *bass*, *drum*, and *other* sources respectively, and X is a placeholder for 1, 2. This allows to verify how informative each source model is, and whether one of them outperforms the correspondent mix-down baseline.

Secondly, we experiment with the different fusion and training strategies of EmoMucs using all the source models. Similarly to the previous case, the performances of EmoMucs with either C1D or C2D architectures for its source models (denoted as EmoMucs-C1D and EmoMucs-C2D) are compared to C1D-M and C2D-M.

We evaluate the accuracy of the valence-arousal predictions with the root-mean-squared error (RMSE) and the R^2 score. The latter is the coefficient of determination, with the best score being 1 when the variability of the target data is fully captured by the regressor. Conversely, a score equal to 0 corresponds to a model always predicting the expected value of the target. To avoid biasing our evaluations on a single test set, each run employs nested cross-validation with 5 splits for the outer and inner folds.

4.1 Dataset

As mentioned in [25, 29], the current methods for MER perform well for genres such as classical music and film soundtracks, but their performances are still poor for popular music. For this reason, we chose the *popular music with emotional annotations* (PMEmo) dataset [38] for our experiments. This collection contains valence-arousal induced emotions for 794 songs, annotated by 457 subjects, and also provides: song metadata, music chorus clips in MP3 format and pre-computed audio features.


For our experiments, we consider the static valence-arousal annotations. As our model needs raw-audio data to feed Demucs and generate the separated sources from a given mix-down, we use 20-second randomly selected clips from each chorus. For 59 tracks with duration shorter than 20 seconds, we apply zero padding at the end of the clip to ensure fixed-size input. On average, the padding operation is used to compensate for 4.35 seconds. The arousal and valence annotations are scaled to the $[-1, 1]$ interval for improving the stability of the model. We choose not to augment the dataset as such strategy can potentially affect the emotional impact of music on listeners.

4.2 Implementation details

We use Librosa 0.7.2 [20] for computing the log-mel spectograms from the tracks, with a fast Fourier transform (FFT) window size of 512, 256 samples between successive frames and 96 Mel bands. Our models are implemented in PyTorch [23], and the source code to replicate these experiments is available at `github.com/jonnybluesman/emomucs`.

4.3 Experimental results

The results of our experiments are reported in Tables 1 and 2. From Table 1, we notice that the C2D architecture is

Figure 3. Target valence-arousal annotations of PMEmo in the $[-1, 1]$ interval, using colours to distinguish the C2D-based source model that better predicted each single annotation w.r.t. valence and arousal RMSE, together with their mean.

more accurate than C1D in all scenarios. In addition, the former baseline is also a more parsimonious model, due to the less number of parameters. All the baselines trained on the mix-down are considerably better than the source models considered independently. For both the architectures, we find that the drums model is the best between the source models at predicting valence, whereas the bass model is the worst for arousal. The performance disagreement for the source models using different architectures (e.g. C1D-V and C2D-V) suggests that the convolutional architecture plays a crucial role for the type of musical features that can be learned.

Baseline	# params	Input	RMSE		R2

		D	.2587	.2855	.3613	.4024
		O	.2633	.2748	.3381	.4462

Table 1. Evaluation of the baseline models trained on the mix-down (C1D-M, C2D-M) together with the corresponding source models. V, B, D, O denote *vocals*, *bass*, *drums* and *other* and they refer to the source models. Bold text highlights the best results for each baseline model. For both cases, the mix-down model achieves the best results.

As can be seen from Table 2, combining all source models in a single network has a crucial impact on the performance of the model. We conjecture that this is achieved by the architecture of EmoMucs, which makes it possible to account for all the possible inter-source relationships. In particular, EmoMucs-C1D with mid-level feature fusion and *freeze* mode training achieves a R^2 score of 0.4332 for valence, which is a considerable increase compared to 0.3489 for C1D. This is also reflected with a decrease of

the RMSE for valence, accounting for 0.2428 instead of 0.26. Considering that the valence-arousal annotations are scaled to the $[-1, 1]$ interval, we divide these values by 2 for a more intuitive interpretation of the error. Hence, 0.2428 and 0.26 can be considered as errors of 12.14% and 13% in the annotation interval. Analogously, EmoMucs C2D with late fusion and *freeze* mode training achieves valence $R^2 = 0.4814$ and RMSE = 0.2320 (11.6%), instead of $R^2 = 0.4143$ and RMSE = 0.2466 (12.33%) for the C2D baseline. On the other hand, the arousal predictions of EmoMucs are comparable to those of the baselines.

4.4 Interpretability

As the architecture of EmoMucs is based on a concatenation of features learned by each source model at a specific layer, it is possible to trace the contribution of each voice as well as those emerging from their interrelated connections. This form of interpretability is architecturally supported by our deep neural network, and it comes at no performance loss. This contrasts the work of Chowdhury et al. [5], who measured the "cost of explainibility" of their model by trading accuracy for interpretability.

A simple way to interpret EmoMucs is to isolate the performance of each model independently, as done in Table 1. It is also compelling to analyse the regression accuracy for each track in the dataset and visualise them together with the target annotations in the valence-arousal space. In Figure 3, this is done separately for valence and arousal by associating each target data point with a colour related to its best source model (the one with lowest valence and arousal RMSE for that target). If source models specialise in certain regions of the annotation space, e.g. drums and high arousal, we would expect them to form clusters in the annotation space. However, this hypothesis is rejected as Figure 3 does not suggest any clear specialisation of the source models in the annotation space. This supports our previous observation that each track has intrinsic features related to its emotional impact. For instance, two distinct tracks with very similar annotations can have a considerably different emotional influence from their sources.

Figure 4 reports the performance (R^2 score for valence

Figure 4. EmoMucs-C2D trained with different combinations of source models.

and arousal) of EmoMucs-C2D using late fusion and *freeze* training mode for different combinations of source models. The best performance is achieved when using all sources (V-B-D-O). The contribution of source models varies with their combination. When using two sources, the combination of the *bass* and the *other* models gives better performance in the valence space, but for the arousal space an improved result is achieved when combining *vocals* with *other*. When three sources are considered, the combination of *drums*, *bass* and *other* achieves the best R^2 for valence, whereas, for arousal, excluding *bass* gives comparable results to EmoMucs-C2D with all the sources.

5. CONCLUSIONS

The task of computational music emotion recognition (MER) is particularly challenging due to several factors such as subjectivity within annotations, scarcity of labelled data for training supervised models, and inadequate data augmentation strategies. There is common belief that the current models perform well for classical music and film soundtracks, but their performances are still poor for popular music. To the best of our knowledge, improving the interpretability of MER models jeopardises their performance, thus introducing a "cost of explainability".

In this paper we introduced EmoMucs, a deep learning architecture for MER based on music source separation. First, our method separates the audio signal into different sources associated to vocals, drums, bass and other voices of the mix-downs. Different sub-models are then used to process each source independently, with their features being aggregated according to a fusion strategy.

We evaluated EmoMucs on the popular music with emotional annotations (PMEmo) dataset, and compared its performance with two common deep learning models for

MER trained on the mix-downs. Our results demonstrate that EmoMucs outperforms the baseline models for valence, and achieves comparable performance for arousal, while providing increased interpretability.

Our work achieves the following: (i) improved performance of the current solutions with the same amount of training data; (ii) a modular architecture which can be further adapted and fine-tuned with respect to each source-specific module, and (iii) a quantified contribution of each source to the final prediction for more interpretability.

The implementation of EmoMucs considered in our experiment is designed to prioritise the comparability of our approach to other baselines. In our future endeavours, we plan on optimising the architecture and hyper-parameters of each source model in order to specialise their design to the corresponding sources. Additionally, a study based on the analysis of the activations of the fusion layer would provide more detailed insights regarding the contribution of each source-model, thereby increasing the interpretability of our method and its potential applications.

ABSTRACT

This paper develops the hypothesis that symbolic drum patterns can be represented in a reduced form as a simple oscillation between two states, a Low state (commonly associated with kick drum events) and a High state (often associated with either snare drum or high hat). Both an onset time and an accent time is associated to each state. The systematic inference of the reduced form is formalized. This enables the specification of a rhythmic structural similarity measure on drum patterns, where reduced patterns are compared through alignment. The two-state representation allows a low computational cost alignment, once the complex topological formalization is fully taken into account. A comparison with the Hamming distance, as well as similarity ratings collected from listeners on a drum loop dataset, indicates that the bistate reduction enables to convey subtle aspects that goes beyond surface-level comparison of rhythmic textures.

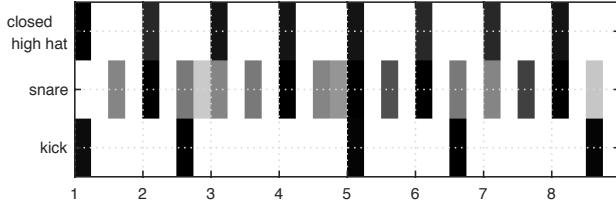
1. INTRODUCTION

One of the most fundamental areas of both Music Information Retrieval (MIR) and music cognition research concerns the modelling of musical similarity, due to the essential importance of similarity in music perception and the practical utility of similarity models in music retrieval applications such as recommendation systems. Modelling similarity for drum patterns is a particular challenging variant of this research, though one with potential application in a wide range of intelligent music production tools such as drum pattern recommendation systems or automatic drum pattern generation systems.

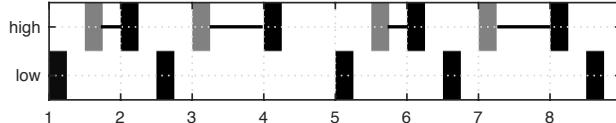
The challenges of drum pattern similarity modelling lies in the complex nature of polyphonic rhythm perception. The integration of coincident rhythms into a resultant 'multirhythm' has been argued to be an essential feature of polyphonic rhythm perception, especially in the context of drumming music [1]. Rhythmic interactions may also be a significant aspect of polyphonic rhythm perception, with complex rhythmic structures said to emerge from the interaction between rhythmic levels [2]. In the context of drum

patterns specifically, rhythmic interaction and instrumental configuration has been shown to have a significant affect on the perception of syncopation, a fundamental rhythmic property [3]. However, in much existing work on drum pattern similarity modelling, similarity is modelled as a linear combination of monophonic rhythm similarity models calculated on each instrument part, without consideration to rhythmic interactions or integration.

Our aim is to design new models of similarity for drum patterns that take into account both rhythmic interaction and rhythmic integration. The bistate reduction algorithm proposed in this paper attempts to extract the core structure of drum pattern as an interaction between two states, 'Low' and 'High', and to use this reduced representation to compare drum patterns through alignment.

The drum patterns used in this paper are part of a varied set of 160 stylistically accurate symbolic patterns recorded by human drummers on an electronic drum kit, taken from the Groove library of BFD3 [4], a commercially available virtual drum kit plugin. Originally collected by [5], the pattern dataset is drawn from a wide range of genres and subgenres, with 8 genre groups used: Hiphop/Dance, Funk, Blues/Country, Pop, Reggae/Latin, Rock, Metal and Jazz. In addition to multiple genres, they are of varied complexity and function, with some containing fills.


In Section 2, we discuss in greater detail approaches to modelling monophonic rhythm similarity and assess the state-of-the-art in drum pattern similarity modelling and its limitations. In Section 3 and Section 4, we begin discussion of the bistate reduction algorithm and bistate sequence alignment technique respectively as a novel means of representing complex drum patterns and estimating the perceived similarity between them. In Section 5, the sequence alignment algorithm is evaluated in its ability to predict human similarity ratings for pairs on drum patterns in our dataset.

2. RELATED WORK


Models of rhythmic similarity are significant in both music perception and music informatics research due to rhythm's fundamental importance in music. For drum patterns in particular, models of rhythmic similarity have various practical applications such as automatic generation of variations on drum patterns [6,7], or in visually mapping drum patterns by similarity to facilitate exploration of drum pattern libraries [8,9].

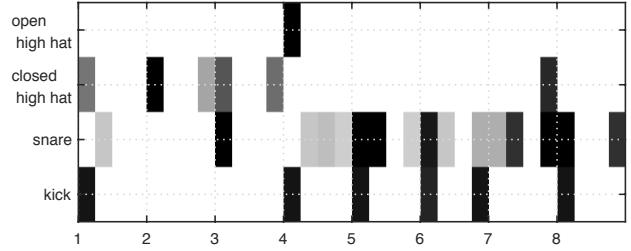
Figure 1. Drum pattern *Early RnB 33*. Velocity is represented in grey level, from 0 in white to maximum value in black.


Figure 2. Reduction of *Early RnB 33*. State accents are shown in black and state onsets (if different from accents) in grey. 'Low' corresponds to ↓ and 'high' to ↑.

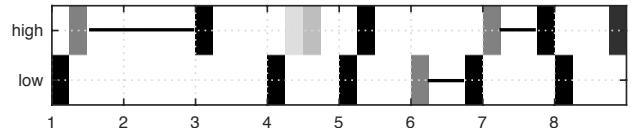
Figure 3. Drum pattern *Reggae Grooves Fill 3*.

Figure 4. Reduction of *Reggae Grooves Fill 3*.


Many models of rhythmic similarity for drum patterns are based on monophonic rhythm similarity models. These methods are based on multiple possible representations of rhythms. The most common method is as a vector consisting of either an onset or silence at each metrical position of the rhythm. The Hamming distance, a simple and popular model, works by counting the number of metrical positions in two rhythm vectors that differ in value (one onset, the other rest) [10]. The swap or directed-swap distance can also be calculated between rhythm vectors by counting the number of swap operations (exchanges between adjacent metrical positions) that need to be performed to turn one rhythm into the other [11]. Other possible rhythm similarity measures use inter-onset intervals (IOIs), vectors of the distance between each successive onset as a multiple of the smallest possible metrical position. An example of this is the chronotonic distance [10]. A thorough overview of numerous approaches to rhythm similarity modelling can be found in [10].

Typically, drum pattern similarity is modelled by stacking these monophonic rhythm similarity models calculated on each part separately. This has been found to be successful in a few cases; [7] found that the Hamming distance and directed-swap distance correlated strongly with human ratings of similarity for drum patterns, with the Hamming distance outperforming the directed-swap. In [8], the authors found a 2D projection of the Hamming distance could partially cluster drum patterns in a way that matched their genre tags for a small dataset of patterns. In a pilot study, a model similar to the Hamming distance was also found to correlate to listeners' similarity ratings for drum patterns [12]. This model counts whether the number of metrical positions where rhythms differ, but adds a weighting metric based on metrical awareness.

The limitation of these models is that by stacking monophonic rhythm similarity measures calculated on each part separately, they fail to account for effects of rhythmic interaction between instrument parts, or the perception of re-

sultant 'multirhythms' due to the perceptual integration of simultaneous rhythmic streams. Additionally, while fixed weighting schemes have been used to weight more perceptually important kit instruments [6], these may not be flexible enough to account for the possibly changing contextual importance of different instruments in a drum pattern.

3. BISTATE REDUCTION

Basic drum patterns are usually defined by the alternation of, typically, bass (or "kick") drum and snare drum strokes, with a further subdivision on the ride cymbal or hi-hat [1]. The ordering in this definition implicitly indicates that the bass and snare drums alternation is of higher level of salience, while the cymbal or hi-hat subdivision is of lesser importance.

3.1 Dominant Drum Selection

The first hypothesis guiding the approach presented in this paper is that drum patterns can be reduced by only focusing on these two most dominant classes of drum strokes. In the definition of basic drum patterns above, the two dominant drums are said to be bass and snare drums. But sometimes the snare drums can be replaced by, for instance, closed hi-hat.

For a given drum pattern, we propose a simple method for selecting the two dominant drums. It consists in ordering the drums in a decreasing hierarchical order, and selecting the two first drums, in this ordered list, that are active in the given drum pattern. The first selected drum will be called the *Low* drum, as it often relates to the bass drum and to the use of lower frequencies, while the second selected drum will be called the *High* drum.

For the drum patterns discussed throughout the paper, the reduction was performed by using the following hierarchical ordering: 1. kick drum, 2. snare drum, 3. closed hi-hat. It was not necessary to consider other drums, since at least two of these three drums were active in each drum

---

[1] Cf. for instance `https://en.wikipedia.org/wiki/Drum_beat`

pattern. In other words, a drum pattern featuring kick drum and closed hi-hat, but no snare drum, will use kick drum as Low and closed hi-hat as High. A drum pattern featuring snare drum and closed hi-hat but no kick drum will use snare drum as Low and closed hi-hat as High.

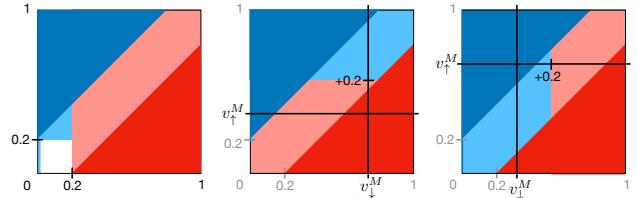
For the example shown in Figures 1 and 3, the closed hi-hat sequence is considered as of less importance and therefore ignored.

3.2 Two-State Alternation

The second hypothesis developed in the proposed approach is that drum patterns can be reduced as an *alternation* between the Low and High drums. This can be formalised as an alternation between two states, respectively designated ↓ and ↑. Figures 2 and 4 shows the reduction corresponding to the sequences in Figures 1 and 3.

3.2.1 Handling of Simultaneous Strokes

At first sight, to detect the ↓ and ↑ *states*, we would simply need to look for the location of alternation between the Low and High drums. The difficulty comes from the fact that the two drums are often played together. In such occasions, inference of ↓ or ↑ state relies on the context defined by the recent past.

For instance in Figure 3, kick and snare drums are played together at the beginning of beats 5, 6 and 8. Because the kick drum plays a clear ↓ at the beginning of beat 4 (i.e., 4.1), which continues with snare drum playing gently (from 4.2 to 4.4). We haven't heard any clear ↑ state. Therefore, when snare drum and kick drums are superposed on the next beat (5.1), this is perceived as a ↑. But because the snare drum is played loudly on the next tick (5.2), the next beat (6.1) is rather perceived as a ↓. Same for 8.1.


We propose to explain this phenomenon by hypothesising that the categorisation ↓ vs. ↑ is based on comparing each new drum stroke (or superposed strokes) to mental models of ↓ and ↑ states. And in our modelling, this can be simplified by comparing to only the mental model related to one of the states ↓ and ↑, namely the state considered as currently active.

More precisely, the mental model is represented by a state $s \in \{\downarrow, \uparrow, 0\}$ (where state 0 is used solely when starting the analysis, before the first actual state ↓ or ↑ has been detected) altogether with a series of two velocities $(v_\downarrow^M, v_\uparrow^M) \in [0,1]^2$, called *profile* of the mental model, and first initiated to $(0, 0)$. The profile is updated with the current configuration

$$(v_\downarrow^M, v_\uparrow^M) = (v_\downarrow, v_\uparrow) \qquad (1)$$

every time there is a state transition.

At any given successive point in the drum pattern, featuring at that instant a Low drum stroke of velocity $v_\downarrow \in [0,1]$ (with 0 indicating no stroke) and a High drum stroke of velocity $v_\uparrow \in [0,1]$, we consider the following alternatives, which are tested in the indicated order until a suitable condition is found:

Figure 5. State transition diagrams, where the current state is respectively 0 (left diagram), ↓ (middle) and ↑ (right). For given values for $v_\downarrow$ (X axis) and $v_\uparrow$ (Y axis) is indicated the next state: ↓ (red) ↑ (blue), 0 (white). See the text for more explanation.

1. If $v_\downarrow > v_\uparrow + .2$, the next state is ↓. This corresponds to the region in dark red in each diagram in Figure 5. The profile is updated. In other words, when the Low stroke is significantly stronger than the High stroke, the new state is clearly ↓.

2. Similarly, if $v_\uparrow > v_\downarrow + .2$, the next state is ↑ (dark blue region in Figure 5) and its profile updated.

3. If the current state is 0 (i.e, undefined), the next state is ↓ if $v_\downarrow > .2$ (light red region in the left diagram of Figure 5). In other words, at the very beginning of a drum pattern, an ambiguous mixture of Low and High drums is associated with ↓, because it is considered as the default state (while ↑ is a departure from the default state). If on the contrary $v_\downarrow \leq .2$ the next state is ↑ if $v_\uparrow > .2$ or if $v_\downarrow = 0$ (light blue region).

4. If $v_\downarrow = 0$ and if the current state is ↓, the next state is ↑ if $v_\uparrow > \frac{v_\uparrow^M}{2}$. If on the contrary the current state is already ↑, the profile is updated only if $v_\uparrow > v_\uparrow^M$.

5. If the current state is ↓ and $v_\uparrow > v_\uparrow^M + .2$, the next state is ↑ (light blue region in the middle diagram of Figure 5). In other words, a significant increase in velocity of the High strike (even if the velocity remains lower than the Low strike's one) triggers a transition to the ↑ state.

6. Similarly, if the current state is ↑ and $v_\downarrow > v_\downarrow^M + .2$, the next state is ↓ (light red region in the right diagram of Figure 5).

3.2.2 State Onset and Accent Times

The approach presented in the previous section leads to the generation of a sequence of states ↑ and ↓. Successive repetitions of a same state are reduced into one single state. This practically means in particular that successive repetitions of a given drum (while the other drum remains silent) are collapsed into one single state.

However, if the most accented stroke is not the first one, this needs to be specifically indicated in the pattern description, as it plays an important role in the pattern characteristics. For that reason, with each state (excepted the initial 0 state) are associated three attributes:

	↓!	(↓)	↑!	(↑)
↓!	$S\downarrow$	$S\downarrow$	O	$A\downarrow$
(↓)	$S\downarrow$		$B\uparrow$	
↑!	O	$A\uparrow$	$S\uparrow$	$S\uparrow$
(↑)	$B\downarrow$		$S\uparrow$	

Table 1. Alignment configurations, triggered by state transitions, in the first sequence (left column) or/and in the second sequence (top row). In the absence of transition in any of the two sequences, no alignment configuration needs to be defined.

- whether it is $\downarrow$ or $\uparrow$

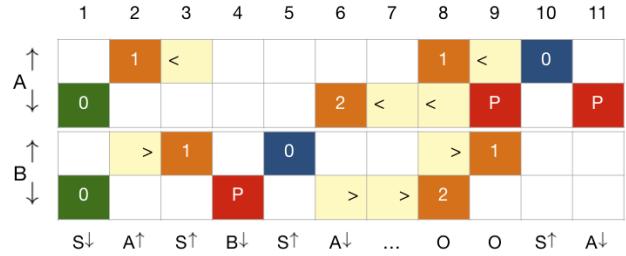
- the *onset time*, i.e., the temporal position of the first stroke in that successive repetition of strokes

- the *accent time*, i.e., the temporal position of the most accented stroke.

4. BISTATE SEQUENCE ALIGNMENT

The third hypothesis developed in this paper is that the perceived distance between two drum patterns can be approximated by aligning the two corresponding bistate sequences and estimating the alignment mismatches.

4.1 Alignment principle

To allow the formalisation of this alignment, the set of two states $\{\downarrow, \uparrow\}$ is further decomposed into four states $\{\downarrow!, \uparrow!, (\downarrow), (\uparrow)\}$ in order to take into account all the temporal relationships:


- $\downarrow!$ and $\uparrow!$ corresponds to a new transition to, respectively, $\downarrow$ and $\uparrow$.

- $(\downarrow)$ and $(\uparrow)$ indicates a continuation of the corresponding states $\downarrow$ and $\uparrow$.

This leads to a 4×4 matrix of possible alignment configurations, shown in Table 1. We can distinguish three types of alignment configurations:

- The two sequences are in same state ("S"), both low ("$S\downarrow$") or both high ("$S\uparrow$").

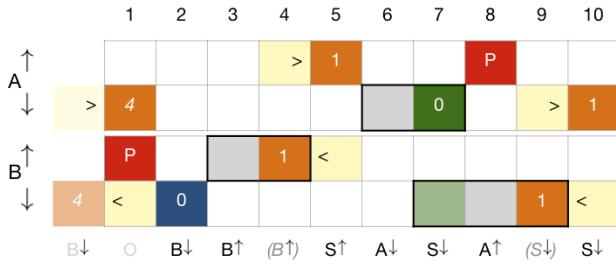
- One sequence introduces the opposite state ahead of the other sequence: "A" if it the first sequence ahead, "B" if the second sequence.

- The two sequences are in opposite states ("O").

The possible transitions between configurations are the following, as described in Table 1:

- Starting from the same state (for instance $S\downarrow$), then both sequences transition at the same time (for instance $S\uparrow$).

- Starting from the same state (for instance $S\downarrow$), then one sequence transitions first (for instance $A\uparrow$).

Figure 6. Alignment between two reduced drum patterns A and B. Penalties are given for each individual state, indicated with a number or 'P'. See the text for more explanation.


- From configuration A or B, if only one sequence transitions, this leads to S, while if both sequences transition at the same time, this leads to opposite states O.

- From O, another double-transition leads to another O, while a single transition leads to either A or B.

4.2 Numerical distance estimation

The proposed distance model is based on an evaluation of how well each of the two drum patterns aligns with the other. For each successive state of each drum pattern, a penalty is given if that state is not found in the other sequence around the same temporal position. Offset in the temporal positions of the state on the two sequences also contributes to the penalty.

The basic mechanisms are illustrated below using the toy example shown in Figure 6. In this first example, we assume that both sequences start at the same state ($\downarrow$).

- The first state starts at the same time ($t = 1$) on both sequences, leading to a $S\downarrow$ configuration with 0 penalty (shown in green in the Figure).

- The next event appears first in sequence A ($A\uparrow$ at $t = 2$). The same transition appears next in sequence B ($S\uparrow$ at $t = 3$). It is thus a quasi-synchronised transition, with 1 tick delay between the two sequences. A penalty of 1 is therefore given to the new state in each sequence. (The onset of each state is shown in orange while the position of the opposite state is shown in yellow.)

- A transition $B\downarrow$ at $t = 4$ is followed by another transition back to $S\uparrow$. This state $\downarrow$ is deleted by giving the maximum penalty P (in red) and the new state $\uparrow$ at $t = 5$ (in blue) is ignored.

- A transition $A\downarrow$ at $t = 6$ is followed by a double transition O at $t = 8$, which is considered as both a 2-tick-delayed transition of B to state $\downarrow$ and as the start of a new transition $A\uparrow$. Same for the subsequent double transition O at $t = 9$. The new transition $A\downarrow$ being followed by a transition $S\uparrow$, that state $\downarrow$ is removed.

321

Figure 7. Alignment between two reduced drum patterns A and B. Boxed series of cells show states containing repeated strokes, where the accent is the rightmost cell.

- Sequence A continuing after the end of sequence B, any transition to the opposite state $A \downarrow$ (here only at $t = 11$) is deleted.

In Figure 7, the sequences starting in opposite states, an additional $\downarrow$ state is added before the start of sequence B, to which is given a penalty of 4. In this example, since the next event is a $\downarrow$ in sequence B, the previous $\uparrow$ is removed.

The rest of Figure 7 illustrates the handling of states containing repeated strokes with the accentuated stroke appearing after the initial onset. Concerning the transition to $\uparrow$ first by B at $t = 3$ and then by A at $t = 5$, the penalty is only 1 because it is computed between the accent in sequence B (at $t = 4$) and the onset of sequence A. For the same reason, the next transition to $\downarrow$ at $t = 7$ is considered without penalty. While B remains in $\downarrow$, with its attack at $t = 9$, A transitions to $\uparrow$ with an attack at $t = 8$, which is therefore deleted.

Each penalty is weighted with respect to the corresponding accent velocity. For instance in the case of a drum stroke of very low intensity (such as a ghost note), the contribution of this penalty to the overall distance will be low. Finally the distance between the two sequences is defined as the maximum between the two weighted sums.

5. EVALUATION

To investigate the potential use of the bistate sequence alignment algorithm for drum pattern similarity modelling, we examined its calculated distances between 80 pairs of drum patterns in our dataset in relation to human-provided perceptual similarity ratings.

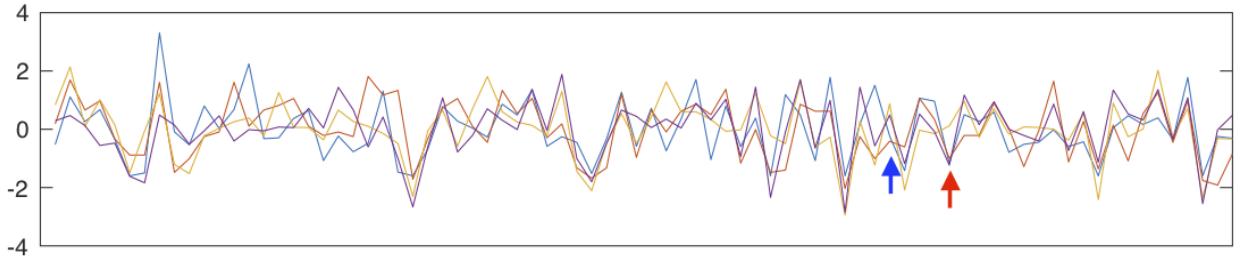
5.1 Methodology

We collected similarity ratings for the drum patterns via an online listening test. The symbolic patterns were first synthesized into audio via a generic sampled drum kit. 21 listeners rated similarity for the 80 pairs of patterns using a continuous scale. Median internal consistency for all participants calculated using the ICC (2,1) for the repeated pairs was 0.85, equaling good agreement. The inter-rater agreement for the 21 listeners calculated using the same ICC (2,1) was 0.73, equally moderate-to-good agreement. The spreads of ratings for each comparison were normally

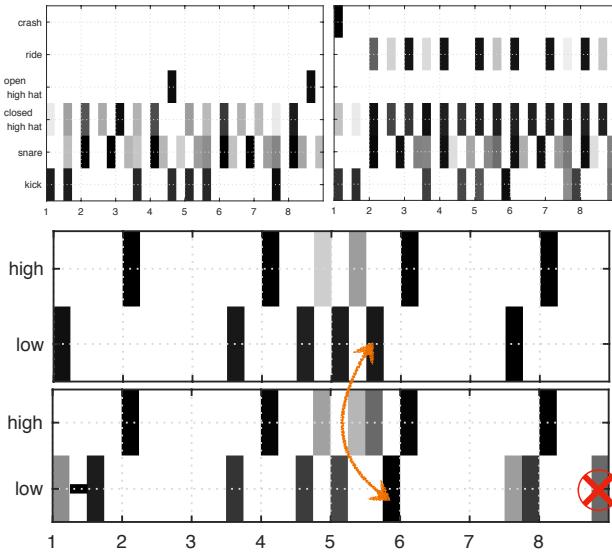
Similarity Model	r	p
Hamming Distance	0.604	2.97e-9
Hamming Distance (2 channels)	0.539	2.58e-7
Bistate Sequence Alignment	0.556	8.49e-8
min(Hamming (2 chan), Alignment)	0.606	2.65e-9
min(Hamming, Alignment)	0.692	1.21e-12

Table 2. Pearson correlation coefficient r and *p-value* between mean similarity ratings and distance models.

distributed. More information on the collection of this dataset may be found in [5].

To test the overall extent to which the bistate sequence alignment algorithm corresponds to perceived similarity, we calculated the Pearson correlation between the distance calculated by the bistate sequence alignment algorithm and the mean of human-supplied similarity ratings. We used the established Hamming distance as a reference for evaluation, since, as indicated in Section 2, it gave the best results in previous works. The first step of our approach, presented in section 3.1, can be studied separately by also computing the Hamming distance on the two main channels of the drum patterns.


5.2 Results and Discussion

The results can be seen in Table 2. Various values for the parameter P were tried and the best results were obtained with $P = 8$. The Hamming distance's correlation on the complete drum patterns is slightly stronger than the bistate sequence alignment, which is itself very slightly better than the Hamming distance computed on the two main drum channels.


When combining the Hamming distance (computed on the whole drum loops) with the alignment by taking the minimum of them both, the correlation is better than the Hamming distance alone, with a correlation of 0.692 vs 0.604. This increase in correlation was found to be statistically significant (t=1.748, p=0.04). This could indicate that both these two algorithms capture fundamentally different aspects of similarity, with the Hamming distance capturing low-level similarities between rhythms, and the bistate sequence alignment capturing qualities relating to rhythmic interaction and structure.

The difference between the distances can be seen in Figure 8 where the similarity ratings of all 80 pairs are plotted alongside distances calculated by both the Hamming distance and the bistate sequence alignment algorithm.

The differences between the bistate sequence alignment algorithm and Hamming distance can be further demonstrated through viewing of some particular examples. Figure 9 shows a pair of *Soul Grooves* patterns that share very similar kick and snare drum patterns while differing on other drum tracks. Since the similarity was judged by the listeners as high, this demonstrates the interest, in particular cases such as this one, in focusing the comparison of drum patterns on the main kick and snare drums. And indeed, computing the Hamming distance on those two main channels leads to a similarly low distance value (cf. red arrow in Figure 8).

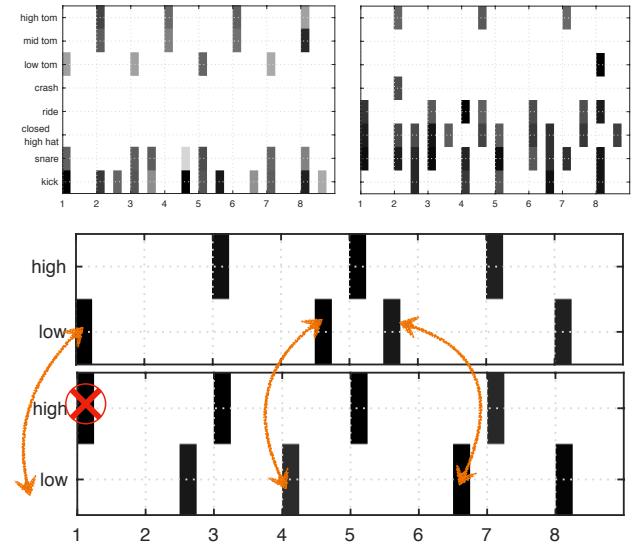
Figure 8. Comparison of the Z-score of the new proposed distance (in blue), the Hamming distance (in yellow), the Hamming distance on the two main channels (in purple) and the listeners' ratings (in red), for each of the 80 pairs of drum patterns. The red and blue arrows indicate the examples shown in, respectively, Figures 9 and 10.


Figure 9. Alignment between drum patterns *Soul Grooves 2* (top left and center) and *Soul Grooves 31* (top right and bottom). The only penalties contributing to the distance is a 1-tick offset (in orange) and a deleted state (in red).

Figure 10. Alignment between drum patterns *Batucara 3* and *Cascara 5* using the same conventions as in Figure 9.

Figure 10 illustrates the interest of the method beyond the simple selection of two main channels. In this example, the two sequences differ significantly at the surface level, even if we restrict the scope on the kick and snare drums. On the other hand, the corresponding reduced bistate sequences are similar and show a clear alignment, leading to a relatively low distance on par with the listeners' jugement.

6. CONCLUSIONS

This article proposed an attempt to reduce drum patterns into an underlying core structure with the aim to compare drum patterns by aligning their reduced representation one with each other. Clearly the problem of rhythmic reduction is of high complexity, and is addressed here solely as an intermediary step for the establishment of a distance measure between drum patterns. These mechanisms of selection of dominant drums and of inference of Low and High states could be studied further in order to provide more advanced description of drum patterns.

As it could have been expected, the comparison between the proposed distance and a simple surface-level Hamming distance concerning their abilities to mimic listeners similarity judgments shows that for the most part, listeners rely on surface characteristics of the overall rhythmic texture to compare drum patterns. However, in particular cases the underlying core structure can be of importance as well, and this is where the proposed distance can be of interest. Combining surface-level and deeper-level representations seems to improve the overall similarity modelling. We may hypothesise that further progress in this endeavour could be made possible through the integration of more refined cognitive models.

ABSTRACT

This paper describes a clustering-based music transcription method that estimates the piano rolls of arbitrary musical instrument parts from multi-instrument polyphonic music signals. If target musical pieces are always played by particular kinds of musical instruments, a way to obtain piano rolls is to compute the pitchgram (pitch saliency spectrogram) of each musical instrument by using a deep neural network (DNN). However, this approach has a critical limitation that it has no way to deal with musical pieces including undefined musical instruments. To overcome this limitation, we estimate a condensed pitchgram with an existing instrument-independent neural multi-pitch estimator and then separate the pitchgram into a specified number of musical instrument parts with a deep spherical clustering technique. To improve the performance of transcription, we propose a joint spectrogram and pitchgram clustering method based on the timbral and pitch characteristics of musical instruments. The experimental results show that the proposed method can transcribe musical pieces including unknown musical instruments as well as those containing only predefined instruments, at the state-of-the-art transcription accuracy.

1. INTRODUCTION

The problem of estimating the fundamental frequencies of multiple periodic signals, which is called multi-pitch estimation (MPE) [1], is an important task of music information retrieval (MIR) since it plays a basic role in automatic music transcription (AMT), which is a task of converting music signals into a symbolic form of music notation [2]. The conventional approaches to MPE primarily focused on transcribing single-instrument music signals. The accuracy of this single-instrument MPE (SI-MPE) has been greatly improved by deep learning. Recently, some studies have extended SI-MPE and have tackled the problem

Figure 1. Each bin of a condensed pitchgram is embedded on a spherical latent space taking into account the timbral characteristics. Piano rolls of each instrument part is obtained by deep spherical clustering on the space.

of multi-instrument MPE (MI-MPE) for further generalization. An MI-MPE is a task which estimates the pitchgrams (pitch saliency spectrograms) of every musical instrument from a music signal consisting of multiple instruments. The difficulty of MI-MPE in addition to SI-MPE is the necessity of estimating the corresponding instrument part which the pitchgram belongs to. To alleviate this difficulty, previous studies [3, 4] for MI-MPE limited their target musical instruments to a small number of predefined instruments. One of the solutions to this problem is applying a classification technique to MI-MPE and separate the music signal into each pitchgram.

These classification-based methods have been successful [3, 4] in the framework of supervised learning, especially for classical music where the constituent instruments are mostly fixed. However, in modern music (*e.g.*Pops and EDMs) where a larger number of instruments often appear, it would be ideal to have no limit on target instruments in order to achieve better AMT.

In the field of speech separation, several studies [5–7] have attempted a similar task of separating arbitrary speakers. When handling arbitrariness of the target sources in DNNs, technical problems related to permutations arise. Specifically, DNNs deterministically map inputs to a defined set of sources in each dimension, and thus does not allow permutation between different targets. To solve this permutation problem, a method called deep clustering

has been proposed that treats speech separation for arbitrary speakers as a clustering problem, rather than a classification problem [5]. This approach avoids the above-mentioned problem and achieves optimal clustering at the same time by constructing an affinity matrix.

In this paper, we propose a new method to estimate the piano rolls of arbitrary musical instrument parts from multi-instrument polyphonic music signals based on deep clustering (Figure 1). We estimate a condensed pitchgram which shows all played pitches, with an existing instrument-independent neural multi-pitch estimator, and then separate the pitchgram into a specified number of musical instrument parts with a deep spherical clustering technique. Also, by considering the spectrogram in addition to the pitchgram in clustering phase, the optimal part estimation can be performed based on both the timbral and pitch characteristics of the instruments contained in the music signal. Furthermore, since there is a complementary relationship between MPE and sound source separation [8–10], we propose a joint spectrogram and pitchgram clustering method which can improve the transcription accuracy.

To verify that our method can transcribe arbitrary musical instruments, we conducted experiments of MI-MPE for various musical instruments. Experimental results show that the method can successfully handle a wide variety of instruments including those unseen during training. Although our method does not set any limitation on applicable instruments, the results suggest that it performs comparably to the state-of-the-art classification method [3].

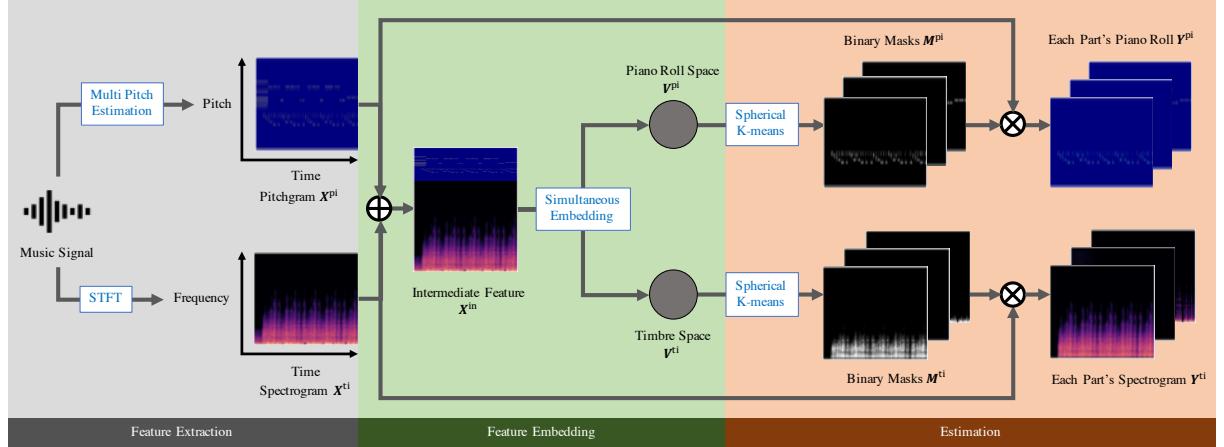
Our main contribution of this study is the proposal of a new clustering-based method to transcribe arbitrary musical instrument parts from a music signal. To our knowledge, this is the first attempt of MI-MPE at frame-level without any restriction on used instruments. Furthermore, we show that the deep clustering method can be applied to tasks other than speech separation, and describe its potential in several sound related tasks.

2. RELATED WORK

In this section, we limit our scope to studies related to MI-MPE and methods dealing with arbitrariness of DNNs. Brief explanations of each study will be provided in the following subsections.

2.1 Multi-instrument Multi-pitch Estimation

Although AMT has been well studied, it still remains a challenging task [11]. Among the various tasks associated to AMT, MI-MPE is particularly difficult because it requires to simultaneously perform SI-MPE and instrument part estimation for each estimated note [2].

MI-MPE has commonly been tackled as a problem of stream-level transcription: grouping estimated notes and making continuous pitch contours for each part. Duan *et al.* [12] proposed a constrained clustering approach against the result of MPE. The clustering is performed under the constraint of consistency in each part of uniform


discrete cepstrum. Their method can be used in complement with various MPE algorithms [13–15], and does not require any source model trained with isolated recordings of the underlying instruments. Following this study, Arora *et al.* [16] took a similar approach. They used probabilistic latent component analysis for MPE and source-specific feature extraction, and hidden Markov random fields for clustering into each instrument part. These two methods can deal with a variety of instruments, but due to their algorithms, each instrument must be a monophonic instrument which plays only one note at a time. Unlike these methods, Benetos *et al.* [17] focused on the differences in the sounds played by each instrument. They used spectral templates that correspond to sound states, supported by the shift-invariant probabilistic latent component analysis method. To conduct MPE for each instrument, they controlled the order of these templates by using hidden Markov model-based temporal constraints.

In recent years, some studies have tackled MI-MPE as a frame-level simultaneous MPE and musical instrument recognition problem. Wu *et al.* [3] proposed a DNN model based on the DeepLabV3+ [18] and U-Net structure [19]. They considered MI-MPE as a semantic segmentation problem on the time-frequency bins generated from music signals, where each object class represents a certain musical instrument. Most recently, Cerberus Network was proposed by Manilow *et al.* [4]. This model was built upon the preceding Chimera Network [20] which was developed for speech separation, adding a module that produces separated piano rolls for each instrument. The drawback of these methods is that only musical instruments included in the predefined set can be transcribed. In order to apply classification-based methods to source separation, output classes and object instances must be represented explicitly. Therefore, it is difficult to use these methods in the general case.

2.2 Arbitrariness with DNNs

In order to allow extraction of a piano roll of arbitrary instruments from an audio signal, the prediction itself must take place in a process where the instruments are unidentified, *i.e.*, individual piano rolls are referred to as instrument one, two, three instead of their specific identity such as piano, guitar, violin, etc. However, when doing so by using a DNN based approach, a problem of permutation arises as previously mentioned. Specifically, when the piano rolls of individual instruments are extracted but the instrument type is unknown, the loss between predicted piano roll and ground truth cannot be calculated straightforwardly since the correspondence of instrument type between these two remains unknown.

A similar problem has been addressed in the studies for speaker-independent speech separation [5–7], whose goal is to separate a piece of audio consisting of multiple people speaking simultaneously into individual speakers audio. Unless given an image or video of the target speaker, correspondence between separated audio and ground truth audio cannot be established, and hence the task poses the

Figure 2. Overview of the proposed method. We extract two audio features $\boldsymbol{X}^{\mathrm{pi}}$ and $\boldsymbol{X}^{\mathrm{ti}}$ from an input music signal and concatenate them as an intermediate feature $\boldsymbol{X}^{\mathrm{in}}$. The feature $\boldsymbol{X}^{\mathrm{in}}$ is mapped into two latent space, piano roll space $\boldsymbol{V}^{\mathrm{pi}}$ and timbre space $\boldsymbol{V}^{\mathrm{ti}}$. We generate binary masks $\boldsymbol{M}^{\mathrm{pi}}$ and $\boldsymbol{M}^{\mathrm{ti}}$ from each space by clustering. These masks are applied to corresponding features, and we obtain piano rolls for each musical instrument part $\boldsymbol{Y}^{\mathrm{pi}}$ and separated spectrograms $\boldsymbol{Y}^{\mathrm{ti}}$.

same problem of permutation. To address this problem, methods such as permutation invariant training (PIT) [6], and deep clustering [5] have been proposed recently.

PIT tackled the permutation problem by calculating a loss function for all possible pairs of predicted values and ground truth, while optimization is only conducted for the pair with minimum loss. Although its implementation is simple and it can be combined with other learning techniques, its computational complexity remains considerably high. In details, when N sources are included in the target mixture, $N!$ possible permutations must be calculated in their algorithm.

On the other hand, deep clustering avoids the permutation problem by optimizing an embedded representation of the desired output, so that the class separation can be conducted via clustering in the embedded space at inference time. Given a $X \times D$ matrix $\boldsymbol{A}$ as the embedded representation, where X is the time-frequency index and D is the embedding dimension, the affinity matrix $\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}}$ is calculated. In the same manner, the affinity matrix $\boldsymbol{B}\boldsymbol{B}^{\mathrm{T}}$ is obtained for the ground truth data $\boldsymbol{B}$ which is a $X \times N$ matrix, where N represents the number of speakers. The optimization is conducted to minimize the distance between the two affinity matrices $||\boldsymbol{A}\boldsymbol{A}^{\mathrm{T}} - \boldsymbol{B}\boldsymbol{B}^{\mathrm{T}}||_F^2$. Here, deep clustering succeeds in circumventing the permutation problem as $(\boldsymbol{A}\boldsymbol{P})(\boldsymbol{A}\boldsymbol{P})^{\mathrm{T}} = \boldsymbol{A}\boldsymbol{A}^{\mathrm{T}}$ for any $D \times D$ permutation matrix $\boldsymbol{P}$. Furthermore, since optimization is conducted on the transformed $X \times X$ matrix, the target data may include any number of sources. For these advantages, we adopt the deep clustering method in our framework as described in Section 3.

3. PROPOSED METHOD

This section describes our proposed clustering-based method for the transcription of arbitrary musical instrument parts (Figure 2). Our framework consists of three parts: a feature extraction part, a feature embedding part to obtain piano roll space and timbre space, and an esti-

mation part based on deep spherical clustering. We first pretrain the feature extraction part and the feature embedding part individually for the stabilization of early learning stages, then optimize both parts in conjunction through the entire learning.

3.1 Problem Configuration

Let $\boldsymbol{S} = \{\boldsymbol{s}_k \in \mathbb{R}^l\}_{k=1}^K$ be a set of mixture audio signals, where $l = 44.1$ [kHz] $\times$ 10 [sec] is a length of the signal, and K is the number of mixture audio signals. We assume that each $\boldsymbol{s}_n$ consists of three instrument parts. Let $\boldsymbol{Y}^{\mathrm{pi}} = \{\boldsymbol{y}_n^{\mathrm{pi}} \in [0,1]^{T \times C}\}_{n=1}^{N+1}$ be a set of pitchgrams of piano rolls, where T is the number of time frames, C is the number of constant-Q transform (CQT) frequency bins and N is the number of musical instrument parts. Our goal is to train a DNN f that maps $\boldsymbol{S}$ to $\boldsymbol{Y}^{\mathrm{pi}}$. Here, we incorporated two key ideas into f for the performance improvement and the stable training. Let $\boldsymbol{Y}^{\mathrm{ti}} = \{\boldsymbol{y}_n^{\mathrm{ti}} \in \mathbb{R}^{T \times F}\}_{n=1}^N$ be a set of corresponding spectrograms of the piano rolls, where F is the number of short-time Fourier transform (STFT) frequency bins. We train f that maps $\boldsymbol{S}$ to not only $\boldsymbol{Y}^{\mathrm{pi}}$, but also $\boldsymbol{Y}^{\mathrm{ti}}$ for improving the performance of a transcription. To achieve this with the stable training, we introduce an intermediate supervision, which consists of two semantic features. Let $\boldsymbol{X}^{\mathrm{pi}} \in [0,1]^{T \times C}$ and $\boldsymbol{X}^{\mathrm{ti}} \in \mathbb{R}^{T \times F}$ be a set of pitch characteristics and a set of timbral characteristics, respectively. We divided the f into two networks: feature extraction network g that maps $\boldsymbol{S}$ to $\boldsymbol{X}^{\mathrm{pi}}$, and feature embedding network h that maps the concatenation of $\boldsymbol{X}^{\mathrm{pi}}$ and $\boldsymbol{X}^{\mathrm{ti}}$ to $\boldsymbol{Y}^{\mathrm{pi}}$ and $\boldsymbol{Y}^{\mathrm{ti}}$. Firstly, the network g and h are trained individually for the stable training, and then our full network $f\ (= h \circ g)$ are jointly trained for the overall optimization.

3.2 Feature Extraction

In the feature extraction stage, a pitchgram and spectrogram are obtained from the input music signal, as pitch and timbral characteristics of each instrument are impor-

tant for estimating piano rolls of each musical instrument part. For pitch, we computed a condensed pitchgram of the given music signal, in a form similar to a logarithmic frequency spectrogram using an instrument-independent neural multi-pitch estimator [21]. This network receives harmonic constant-Q transform (HCQT) as its input and outputs a condensed pitchgram denoted by $\boldsymbol{X}^{\mathrm{pi}}$. A value of each pitchgram bin is proportional to its salience.

We computed an STFT spectrogram $\boldsymbol{X}^{\mathrm{ti}}$ of the given music signal. Although there are other possible representations for timbral characteristics, we use STFT following the original deep clustering [5]. To reduce variations in total volume of input signals, the STFT spectrogram is normalized so that each time-frequency bin has a mean of zero and a standard deviation of one. Details are in Section 4.1.

3.3 Feature Embedding

We adopt joint learning of piano roll transcription and sound source separation. They are known to have a complementary relationship and have been reported to improve performance when they are learned simultaneously [8–10]. Following this knowledge, we propose a network based on deep spherical clustering that allows joint learning of transcription and separation. To learn the obtained pitch and timbral feature at the same time, we concatenate them along each frequency axis. This input feature $\boldsymbol{X}^{\mathrm{in}} \in \mathbb{R}^{T \times (C+F)}$ is used as the input to our network. The network maps the input feature $\boldsymbol{X}^{\mathrm{in}}$ to two separate latent spaces: piano roll space $\boldsymbol{V}^{\mathrm{pi}}$ and timbre space $\boldsymbol{V}^{\mathrm{ti}}$. The structure of our network is shown in Figure 3, where D and D' are the embedded dimensions of piano roll and timbre space. It consists of a three layer Bidirectional Long short-term memory (BLSTM), a fully connected (FC) layer for each space with tanh activation, and finally L^2 normalization. L^2 Normalization is conducted so that the piano roll space and timbre space respectively form a D and D' dimensional hypersphere.

The binary masks are made from the two latent spaces and applied to the pitchgram and the spectrogram later. In order to generate masks by clustering, all time-frequency bins have to be located ideally on the spherical latent spaces, i.e., bins of the same source are close and bins of different sources are far apart. This can be achieved by constructing the affinity matrix of each space, $\boldsymbol{V}^{\mathrm{pi,ti}}\boldsymbol{V}^{\mathrm{pi,ti}\mathrm{T}}$. Since $\boldsymbol{V}^{\mathrm{pi,ti}}$ is L^2 normalized, $TC \times TC$ or $TF \times TF$ matrix $\boldsymbol{V}^{\mathrm{pi,ti}}\boldsymbol{V}^{\mathrm{pi,ti}\mathrm{T}}$ show cosine similarity of all time-frequency bins. Let $TC \times (N+1)$ matrix $\hat{\boldsymbol{M}}^{\mathrm{pi}}$ and $TF \times N$ matrix $\hat{\boldsymbol{M}}^{\mathrm{ti}}$ represent correct masks, where N is the number of musical instrument parts. We assume that each time-frequency bin is attributed to only one source. If more than one source share the same bin, the bin is assigned to the dominant source which has the largest volume (MIDI velocity) or the largest power spectrogram. $\hat{\boldsymbol{M}}^{\mathrm{pi,ti}}$ thus take binary value, one for assigned bin and zero for the opposite, and affinity matrix $\hat{\boldsymbol{M}}^{\mathrm{pi,ti}}\hat{\boldsymbol{M}}^{\mathrm{pi,ti}\mathrm{T}}$ also have binary value. We can train this network using $\hat{\boldsymbol{M}}^{\mathrm{pi,ti}}\hat{\boldsymbol{M}}^{\mathrm{pi,ti}\mathrm{T}}$ as target affinity matrix of $\boldsymbol{V}^{\mathrm{pi,ti}}\boldsymbol{V}^{\mathrm{pi,ti}\mathrm{T}}$.

Note that we prepare an extra dimension for $\hat{\boldsymbol{M}}^{\mathrm{pi}}$. Because the condensed pitchgram $\boldsymbol{X}^{\mathrm{pi}}$ is a prediction, $\boldsymbol{X}^{\mathrm{pi}}$ may include misestimations, i.e., false negatives and false positives. Among them, false positives should be treated as exceptions because they have no true instrumental attribution. We therefore prepare an additional dimension for bins which are silent in the ground truth, thus true negatives and false positives are put in this dimension. We also retain $\boldsymbol{X}^{\mathrm{ti}}$ bins whose magnitude is greater than the original maximum magnitude minus 40 dB. This prevents the network from considering about small power bins too much.

3.4 Training Strategy

Training of the multi-pitch estimator is conducted by minimizing the cross entropy loss shown in Eqn (1),

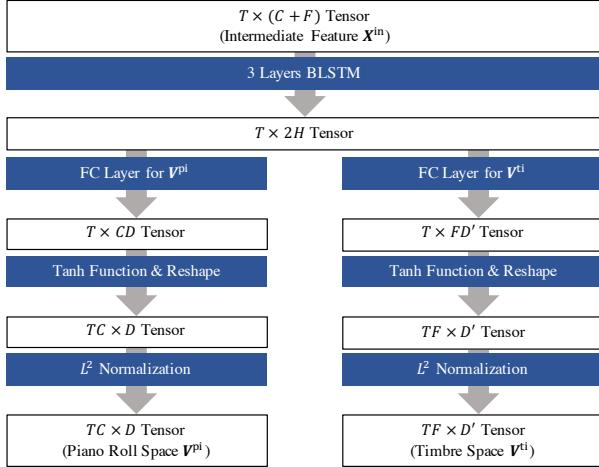
$$\mathcal{L}_{DS} = -\hat{\boldsymbol{X}}^{\mathrm{pi}} \log(\boldsymbol{X}^{\mathrm{pi}}) - (1 - \hat{\boldsymbol{X}}^{\mathrm{pi}}) \log(1 - \boldsymbol{X}^{\mathrm{pi}}) \quad (1)$$

where $\hat{\boldsymbol{X}}^{\mathrm{pi}}$ and $\boldsymbol{X}^{\mathrm{pi}}$ represent the ground truth condensed pitchgram and the estimated condensed pitchgram. Both have values ranging from zero to one. Training of simultaneous embedding part is conducted to minimize Eqn (2).

$$\mathcal{L}_{DC}{}^{\mathrm{pi,ti}} = ||\boldsymbol{V}^{\mathrm{pi,ti}}\boldsymbol{V}^{\mathrm{pi,ti}\mathrm{T}} - \hat{\boldsymbol{M}}^{\mathrm{pi,ti}}\hat{\boldsymbol{M}}^{\mathrm{pi,ti}\mathrm{T}}||_F^2 \quad (2)$$

To reduce computational costs, we used a variation of Eqn (2) in practice.

$$\mathcal{L}_{DC}{}^{\mathrm{pi,ti}} = ||\boldsymbol{V}^{\mathrm{pi,ti}\mathrm{T}}\boldsymbol{V}^{\mathrm{pi,ti}}||_F^2 - 2||\boldsymbol{V}^{\mathrm{pi,ti}\mathrm{T}}\hat{\boldsymbol{M}}^{\mathrm{pi,ti}}||_F^2$$
$$+ ||\hat{\boldsymbol{M}}^{\mathrm{pi,ti}\mathrm{T}}\hat{\boldsymbol{M}}^{\mathrm{pi,ti}}||_F^2 \quad (3)$$

Direct construction of the original affinity matrix is avoided in Eqn (3) because TC and TF are much greater than D and D' [5]. Using these two kinds of losses, the total loss function is described as Eqn (4).


$$\mathcal{L}_{total} = \mathcal{L}_{DS} + \alpha\mathcal{L}_{DC}{}^{\mathrm{pi}} + \beta\mathcal{L}_{DC}{}^{\mathrm{ti}} \quad (4)$$

α and β in Eqn (4) are parameters to decide weights of each loss. We set them both at 0.000001 in our experiment.

For the stabilization of early learning stage, we first pretrained multi-pitch estimator and simultaneous embedding network respectively using the loss in Eqn (1) and Eqn (3). After pretraining, global optimization was conducted through end-to-end training by Eqn (4). We used Adam optimizer [22] for every training.

3.5 Estimation

At inference time, we generate two binary masks $\{\boldsymbol{M}_i^{\mathrm{pi}}\}_{i=1,...,N+1}$ and $\{\boldsymbol{M}_j^{\mathrm{ti}}\}_{j=1,...,N}$ for $\boldsymbol{X}^{\mathrm{pi}}$ and $\boldsymbol{X}^{ti}$ respectively from learned latent spaces $\boldsymbol{V}^{\mathrm{pi}}$ and $\boldsymbol{V}^{\mathrm{ti}}$. Mask generation is conducted by clustering the embedded features. Here, since the two spaces are hyperspherical shaped, we execute clustering by means of spherical k-means [23] though original deep clustering simply uses k-means. Because spherical k-means groups features based

Figure 3. Details of simultaneous embedding part in Figure 2. $2H$ is the number of hidden nodes in BLSTM.

on their distance on a hypersphere, i.e. cosine distance, this should be applied for our purpose rather than k-means. Piano rolls of each musical instrument part and silent part $\{Y_i^{\mathrm{pi}}\}_{i=1,\ldots,N+1}$ are calculated by Eqn (5).

$$Y_i^{\mathrm{pi}} = X^{\mathrm{pi}} \otimes M_i^{\mathrm{pi}} \qquad (5)$$

Additionally, spectrograms of each part $\{Y_j^{\mathrm{ti}}\}_{j=1,\ldots,N}$ are obtained by Eqn (6), which can be converted to separated sounds of each instrument via inverse STFT.

$$Y_j^{\mathrm{ti}} = X^{\mathrm{ti}} \otimes M_j^{\mathrm{ti}} \qquad (6)$$

In Eqn (5) and Eqn (6), element wise product is described as $\otimes$. Since M_j^{ti} is only for retained bins of X^{ti}, other bins are shared with all sources.

4. EVALUATION

4.1 Data

We used the Slakh2100-orig dataset [24] for our evaluation. The dataset contains 1500 training tracks, 375 validation tracks, and 225 test tracks. Each track is composed of multiple instruments, and the dataset consists of both mixed and separated sound sources with their MIDI data. It contains twelve kinds of instruments: piano, bass, guitar, drums, strings, synth pad, reed, brass, organ, pipe, synth lead, and chromatic percussion. We eliminated drums and chromatic percussion from the data to focus on instruments where pitch is important, *i.e.*, we used the other ten instruments for the experiment. To demonstrate the capability of estimating the piano rolls of arbitrary musical instrument part, we only used seven instruments (piano, bass, guitar, strings, synth pad, reed, and brass) for the training and validation data. We evaluated the performance using test data; above seven for the closed condition (seen instruments), and ten for the open condition (unseen instruments).

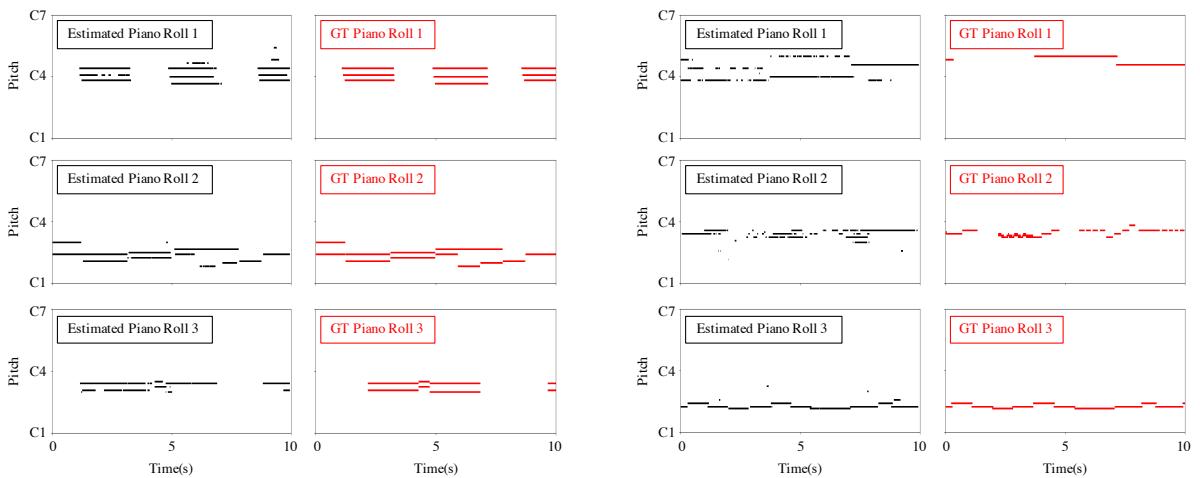
Training samples are constructed by cutting the tracks into ten seconds segments. Ground truth for condensed pitchgram is prepared by overlaying the MIDI data for the constituent sound sources. To make the mixture signal and the ground truth of condensed pitchgram, we overlaid both cut sound sources and MIDI data. Here, segments that do not have instrument sound for more than five seconds are omitted. The mixture MIDI data are binarized and gaussian blurred according to [21]. The musical recordings are mono-channel and their sampling rates are 44.1kHz. We computed STFT using Hann window with a size of 2048 time frames $\approx$ 50ms. The hop size is 512 frames $\approx$ 11ms for both STFT and HCQT. HCQT is computed for harmonics of {0.5, 1, 2, 3, 4, 5} with the minimum frequency 32.7Hz (C1) over six octaves. Our implementation uses the librosa library [25]. In total, 11 hours of training data and 3 hours of validation data were generated. For test data, 6 hours of data were generated for each condition.

4.2 Experimental Conditions

We evaluated the frame-level accuracy of transcriptions for each instrument part in the mixture. For the experiment, we fixed the number of mixed instruments to three, *i.e.*, $N = 3$. The transcription accuracy is evaluated by precision, recall, and F-measures. We count the pitchgram bin of a certain instrument as correct when binary values of estimation result and ground truth match with a correct part attribution. These metrics are calculated with Eqn (7),

$$P = \frac{TP}{TP + FP}, \ R = \frac{TP}{TP + FN}, \ F = \frac{2PR}{P + R} \quad (7)$$

where TP, FP, and FN are the number of true positive, false positive, and false negative, respectively. These values are calculated by the mir_eval [26] library.

To compare with the existing state-of-the-art classification-based method, we reimplemented [3] with eight output classes: the seven known instruments above and a non-instrument class. For a fair comparison between our clustering approach and the existing classification approach while considering the correctness of part attribution, we set evaluation conditions as follows:


1. In the clustering approach, part attribution is not conducted explicitly. Thus, clusters are assigned to each instrument source by optimizing the F-measure.

2. In the classification approach under the closed condition, estimated parts are directly used as part assignments.

3. In the classification approach under the open condition, by design, part attribution cannot be conducted for unknown instrument sources. Thus, estimated parts are reassigned to each instrument source included in the audio by optimizing the F-measure.

4.3 Experimental Results

The experimental results are shown in Table 1. Our proposed method outperformed the state-of-the-art classification-based method [3] in the transcription of unknown instruments under the open condition. Furthermore, the F-measure score of unknown instruments

| Instrument | Closed condition | | | | | | Open condition | | | | | |

Table 1. Comparative results of MI-MPE on the Slakh2100-orig dataset [24] with classification-based method by [3] and our method. P, R, and F are precision, recall and F-measure, respectively, defined in Eqn (7).

Figure 4. Transcribed piano rolls of each instrument part from the mixture signals. The left pairs are successful cases (Track01879) and the right pairs are failure cases (Track01878). The left column shows the estimated piano rolls (black) and the right column shows the ground truths (red). Each row shows the corresponding part, respectively.

was comparable to that of known instruments in our method, while the score significantly decreased in the classification-based method. Our method also succeeded in transcribing known instruments under both conditions at an accuracy equivalent to the classification-based method.

Examples of estimated piano rolls using our method are illustrated in Figure 4. In the successful cases, although some errors are present, it can be seen that our proposed method well-conducted pitch estimation and instrument assignment. In the failure cases, some notes which have to appear in piano roll two are transcribed in piano roll one around three seconds, in addition to many misestimations.

4.4 Discussion

Our method can obtain separated sounds of each instrument part in addition to their piano rolls; however, matching the estimated piano rolls and the instrument part labels still have to be done manually. One of the most interesting directions of this research is the automation of this process.

Also, we assume that each time-frequency bin is attributed to only one source as mentioned in Section 3.3 though different instruments may share the same bin in practice. To deal with this case, another direction is to introduce the von Mises-Fisher (vMF) distribution [27, 28] into the hyperspherical latent space and perform soft clustering based on this distribution.

5. CONCLUSION

This paper presented a method for transcription of arbitrary musical instrument parts based on deep spherical clustering. Timbral and pitch characteristics of the music signal are simultaneously considered in the transcription, through joint clustering of a pitchgram and a spectrogram. The experimental results showed that the proposed method is capable of transcribing musical pieces including musical instruments not in training data. We plan to automate the matching process and introduce the vMF distribution into the hyperspherical latent space for future work.

ABSTRACT

Accurate and flexible representations of music data are paramount to addressing MIR tasks, yet many of the existing approaches are difficult to interpret or rigid in nature. This work introduces two new song representations for structure-based retrieval methods: *Surface Pattern Preservation (SuPP)*, a continuous song representation, and *Matrix Pattern Preservation (MaPP)*, SuPP's discrete counterpart. These representations come equipped with several user-defined parameters so that they are adaptable for a range of MIR tasks. Experimental results show MaPP as successful in addressing the cover song task on a set of Mazurka scores, with a mean precision of 0.965 and recall of 0.776. SuPP and MaPP also show promise in other MIR applications, such as novel-segment detection and genre classification, the latter of which demonstrates their suitability as inputs for machine learning problems.

1. INTRODUCTION

This paper builds on the traditions of matrix representations of songs started by Foote [1]. Specifically, we are principally interested in the cover song identification task. Recent content-based approaches to this task include building objects that compare one recording against a second one [2, 3], comparing slices of recordings to each other [4], creating a graph of songs on which to perform clustering [5], and using deep learning [6].

Structure-based approaches to the cover song task begin by creating representations encoding songs' structural information. These structural representations do not always explicitly encode where repetitions occur (for example, [7]). In contrast, the aligned hierarchies encode every possible repeated structure's placement within a song [8]. Between

these approaches is recent work by McGuirl et al. [9] which develops start-end (SE) and start(normalized)-length (S_NL) diagrams. These structure-based musical representations seek to balance the amount of structural information provided by leveraging ideas from Topological Data Analysis (TDA), a field of applied mathematics.

We address issues of SE and S_NL diagrams, discussed in Section 2.2, by transforming S_NL diagrams into surface and matrix representations, called Surface Pattern Preservation (SuPP) and Matrix Pattern Preservation (MaPP). SuPP and MaPP are analogous to TDA persistence surfaces and persistence images [10], respectively. These novel representations can be thought of as two versions of the same concept, with SuPP as the complete representation containing all possible structural information, and MaPP as its down-sampled computationally friendly extension. MaPP can be embedded into Euclidean space [1] making calculations straightforward using distance functions. Thus, MaPPs are more usable for machine learning algorithms than their predecessors.

Additionally, SuPP and MaPP are both adaptable to varying MIR tasks, such as the cover song task, novel-segment detection, and genre classification, whereas the aligned hierarchies, SE diagrams, and S_NL diagrams were created specifically for the cover song task. We present ways in which SuPP and MaPP may be adapted for these different tasks with a larger focus on the cover song task and how these new methods compare with results from S_NL diagrams and another extension of the aligned hierarchies.

2. BACKGROUND

Continuing the work begun with the aligned hierarchies [8] and extended in S_NL diagrams [9], SuPP and MaPP are consecutive representations that are smoothings of S_NL diagrams. Additionally, MaPP combines the strengths of the aligned hierarchies and S_NL diagrams to build a representation that can be used in standard machine learning algorithms such as k-means clustering or support vector machines. In this section, we briefly review aligned hierarchies and S_NL diagrams while highlighting their limitations to motivate the novel representations proposed in this work.

---

[1] In fact, MaPP can be embedded into any inner product space.

2.1 Aligned Hierarchies

The aligned hierarchies representation encodes all possible hierarchical structure decompositions of a song on a single common time axis [8]. While this representation clearly shows the length of each repeated section, it does not visually emphasize the differences between the lengths of repeats using white space. Also, the distance measure for the aligned hierarchies is inefficient to compute and is quite coarse [8]. First, the distance measure notes only when two repeats of the same size line up exactly in terms of placement within the song. Second, comparisons between songs under this distance measure require both songs to be the same number of beats. This last limitation makes using the aligned hierarchies impractical for cover song detection.

2.2 SE and S_NL Diagrams

Motivated by TDA theory, SE and S_NL diagrams extend the aligned hierarchies and overcome the rigidity in comparing songs with aligned hierarchies. While SE and S_NL diagrams are more flexible and computationally efficient than their predecessor, they were built with the cover song task in mind and are difficult to adapt for other MIR tasks. Furthermore, they are not suitable to use with machine learning algorithms.

2.2.1 Topological Data Analysis Inspiration

Broadly, TDA is concerned with extracting quantifiable shape features from large, complex datasets [11–14]. Though not extracting topological information typically sought by TDA methods, SE and S_NL diagrams draw their inspiration from persistence diagrams [11, 12] which track how topological features persist across an increasing sequence of spatial scales. Just as persistence diagrams are a collection of 2-D points whose x- and y-coordinates represent the length scales at which the topological features appear and disappear, SE and S_NL diagrams are collections of 2-D points whose x- and y-coordinates represent the start and end (or length) times, respectively, of repetitive sections in a song. An advantage of the correspondence between persistence diagrams and SE and S_NL diagrams is that rich mathematical theory from TDA can be extended to the musical representations for computational tasks.

2.2.2 Structure of SE and S_NL

SE and S_NL diagrams extend the aligned hierarchies by transforming them into a representation consisting of a finite collection of points [9]. Specifically, the SE diagram for a song is defined as $\{(s_i, e_i)\}_{i=1}^{N} \subset \mathbb{R}_+^2$, where s_i and e_i are the start and end times, respectively, of the ith repeated structure. Similarly, the S_NL diagram for a song is defined as $\{(\alpha(s_i/M), e_i - s_i)\}_{i=1}^{N} = \{(\bar{s}_i, \ell_i)\}_{i=1}^{N}$, where $\alpha > 0$ is a scaling factor and M is a normalization term related to the length of the song, with s_i and e_i as above. Figure 1 shows the transition from the aligned hierarchies to the S_NL diagram for Chopin's Mazurka Op. 6, No. 1. Both the SE and S_NL diagrams add visual emphasis for the differences between the lengths of the repetitions, but lose the visual width of each repetition.

2.2.3 Shortcomings of Previous Work

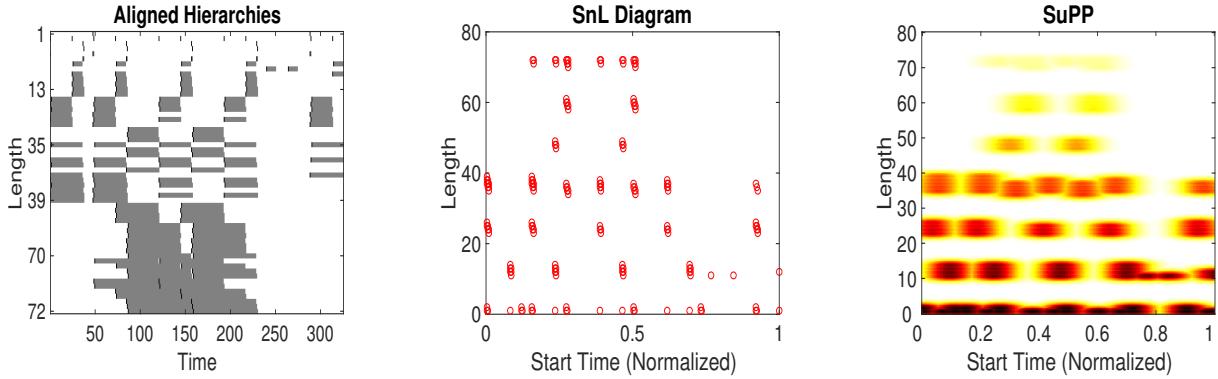
Similar to persistence diagrams, the complex structure of SE and S_NL diagrams makes them unsuitable inputs for most statistical analyses and machine learning tasks. For example, these diagrams do not live in an inner product space and simply computing averages in the space of persistence diagrams, and therefore in the spaces of SE and S_NL diagrams, remains a challenge. The notion of an average persistence diagram is defined through the Fréchet mean, which views the space of persistence diagrams as a probability space [15]. The Fréchet mean is computed as the solution of a minimization problem and is not guaranteed to be unique. Moreover, it is non-trivial to compute.

Without a unique and easy-to-compute mean or an inner product structure, the utility of SE and S_NL diagrams for MIR tasks is limited. In particular, SE and S_NL diagrams cannot be used as inputs for most classification and regression models, such as support vector machines, which would otherwise be useful for tasks like genre classification.

2.3 SuPP and MaPP Inspiration

This work continues to leverage TDA theory in the creation of two new structural representations, SuPP and MaPP. Just as persistence diagrams are transformed into persistence surfaces and persistence images [10] through a weighted sum of Gaussian functions centered at each point in a given persistence diagram, here we transform SE and S_NL into SuPP and MaPP. The mathematical details of this transformation are provided in Section 3. Like persistence images, MaPPs can be embedded into an inner product space, such as Euclidean space, and can therefore be used as inputs for machine learning algorithms.

3. METHODS

In this section, we define Surface Pattern Preservation (SuPP) and Matrix Pattern Preservation (MaPP). SuPP is a surface representation of S_NL diagrams [9] that allows similar repeated sections to be viewed as a single structure. Since comparing surfaces computationally is difficult, we introduce MaPP, the discrete matrix version of SuPP. As a matrix, MaPP allows for pairwise comparisons using common distances such as the Euclidean and Frobenius metrics. The procedure [2] for creating SuPP and MaPP from S_NL diagrams is outlined below and summarized in Algorithm 1.


3.1 Surface Pattern Preservation (SuPP)

SuPP is a smoothing of a song's S_NL diagram that maintains structural information of the song. This smoothing is achieved by placing a 2-D Gaussian at each point in a song's S_NL diagram and aggregating overlapping Gaussians.

3.1.1 Defining Repeats as Gaussians

Defining the Gaussians that represent the repeated structures of the piece is the heart of the transformation from

---

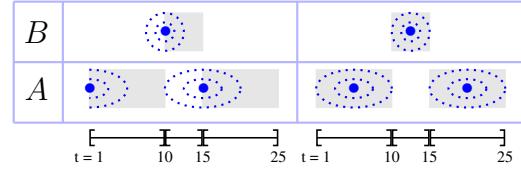
[2] Code is available on GitHub: `https://github.com/cgsavard/ICERM_compare_songs`

Figure 1: From left to right, the aligned hierarchies, S_NL diagram, and SuPP corresponding to the score of Mazurka Op. 6, No. 1 by Chopin. The weights applied to SuPP are the weights used for the cover song task found in Section 4.2.1.

the S_NL diagram to SuPP. In general, given a S_NL diagram $\{(\bar{s}_i, \ell_i)\}_{i=1}^N$, we first place a Gaussian (g) over each repeated structure so that $(\bar{s}_i, \ell_i) \rightarrow g_i(\bar{s}, \ell)$ where

$$g_i(\bar{s}, \ell) = \frac{1}{2\pi\sigma_s\sigma_\ell} e^{-\left(\frac{(\bar{s}-T_s(\bar{s}_i))^2}{2\sigma_s^2} + \frac{(\ell-T_\ell(\ell_i))^2}{2\sigma_\ell^2}\right)}, \quad (1)$$

$T = (T_s, T_\ell) : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ defines the center of each of the Gaussians, σ_s is the standard deviation in the start direction, and σ_ℓ is the standard deviation in the length direction.

The Gaussians can either be centered at the beginning of a repeated structure, so that $T(\bar{s}_i, \ell_i) = (T_s(\bar{s}_i), T_\ell(\ell_i)) = (\bar{s}_i, \ell_i)$ is the identity, or in the middle of a repeated structure, so that $T(\bar{s}_i, \ell_i) = (T_s(\bar{s}_i), T_\ell(\ell_i)) = (\bar{s}_i + \frac{\ell_i}{2}, \ell_i)$. This choice is based on the task at hand as well as user preference. Midpoints correspond to the central beat in each repeated section, and are therefore a good indicator for where these structures are occurring, on average, in the song. For our cover song task experiment, we adjust the S_NL diagrams by choosing to center each Gaussian about the repeated structures' midpoints rather than their start times (i.e., $T(\bar{s}_i, \ell_i) = (\bar{s}_i + \frac{\ell_i}{2}, \ell_i)$). Figure 2 illuminates how using the start or midpoint of the repeated section for the Gaussians compares visually for the repetitions in aligned hierarchies. Other distributions aside from a Gaussian can also be used and may be preferable for certain MIR tasks.


After determining the appropriate placement of the Gaussians, the next step is to set the two standard deviation parameters that govern the shape of these Gaussians. The standard deviation σ_s determines the width of the Gaussians with respect to the start (or time) axis; that is, the axis representing where each repeat in the song - now represented as a Gaussian - exists. The standard deviation σ_ℓ determines the width of the Gaussians with respect to the length axis. These standard deviations control the extent to which nearby Gaussians will overlap.

Figure 2: How 2-D Gaussians relate to repeated structures of aligned hierarchies when using the S_NL diagram (left) or the altered S_NL diagram with midpoints (right).

3.1.2 Creating the Surface

The next step in the SuPP creation is to aggregate the collection of Gaussians to create a surface. When two or more Gaussians intersect, which occurs when points in the S_NL diagram are close together, the SuPP value at the intersection is set to the maximum of the Gaussians rather than the sum of the Gaussians as is done for persistence surfaces [10]. That is, for any S_NL diagram $\{(\bar{s}_i, \ell_i)\}_{i=1}^N$, we define SuPP as the surface SuPP : $\mathbb{R}^2 \rightarrow \mathbb{R}$, where

$$\text{SuPP}(\bar{s}, \ell) = F(\bar{s}, \ell) * \max_{i \in [1, N]} g_i(\bar{s}, \ell), \quad (2)$$

for some weighting function $F(\bar{s}, \ell) : \mathbb{R}^2 \rightarrow \mathbb{R}$ and $g_i(\bar{s}, \ell)$ defined in Eqn. 1. Combining the Gaussians over all repeats allows repetitive structures that are similar in length and start time to be perceived as the same repeated section. We use the maximum instead of other aggregators because we want these similar structures to be treated as one section. We do not want sections to be more highly weighted if there are many similar structures in that section. The choices of σ_s and σ_ℓ determine how close points in S_NL need to be for their Gaussians to substantially blur together.

Algorithm 1 Algorithm for constructing SuPP and MaPP

Input: Song's S_NL diagram $\{(\bar{s}_i, \ell_i)\}_{i \in I}$
for $i \in I$ **do**
    • Replace $(\bar{s}_i, \ell_i)$ with 2-D Gaussian defined by
      $\mu = (\bar{s}_i, \ell_i)$ and $\sigma = (\sigma_s, \sigma_\ell)$
end for
    • Aggregate all Gaussians to create a surface by using
      the maximum function
    • Apply weighting function to surface to create SuPP
    • Discretize SuPP to create gridded surface
    • Integrate the area under each gridded unit and store
      resulting values in a matrix to create MaPP
Outputs: SuPP, MaPP

The weighting function $F(\bar{s}, \ell)$ governs which type of repeated structures are emphasized in the resulting surface. This weight controls the heights of the Gaussians in SuPP, lifting important sections of the song and suppressing other sections. The surface weight can be varied by the user based on the MIR task at hand. In Section 4, we provide an example of how one may want to set the weighting function.

3.2 Matrix Pattern Preservation (MaPP)

SuPP is a continuous representation carrying all information found in S_NL diagrams. Beyond this, user-specified parameters can be set to emphasize various parts of a song. However, using a continuous surface representation is computationally complex and thus not feasible for many computing tasks. To address this challenge, a transformation of SuPP into a discrete representation with a natural embedding and metric for comparison, such as MaPP, is necessary.

To create MaPP, SuPP is first sectioned by placing a grid over the $\mathbb{R}^2$ plane over which SuPP is defined. This discretization is based on a user-defined resolution. Then, the volume beneath each grid unit of SuPP is computed using numerical integration. These volumes are recorded as entries in a matrix with the same dimensions as the gridded SuPP, resulting in MaPP.

Namely, for a S_NL diagram $\{(\bar{s}_i, \ell_i)\}_{i=1}^{N}$, the corresponding MaPP is a $P \times P$ matrix such that:

$$\text{MaPP}(\text{SuPP})_{jk} = \int_{\beta_k}^{\beta_{k+1}} \int_{\alpha_j}^{\alpha_{j+1}} \text{SuPP}(\bar{s}, \ell) d\bar{s} d\ell \quad (3)$$

where $\alpha_j = j\frac{R_{\bar{s}}}{P}$ and $\beta_k = k\frac{R_\ell}{P}$ are the individual grid widths and heights given by the user-defined resolution P and the ranges $R_{\bar{s}}$ and R_ℓ of the respective axes in the SuPP.

3.3 Embedding MaPP Representations

Since the MaPP representations are matrices, they can be embedded into various metric spaces. There are many pre-existing metrics with strong mathematical theory that can be applied to compute distances between matrices. We use the Frobenius norm. The Frobenius distance between two MaPPs A and B is defined as:

$$d_F(A, B) = \sqrt{\text{Tr}((A - B) * (A - B)^T)}, \quad (4)$$

where Tr indicates the trace [16]. The Frobenius norm measures the "average" value within the difference matrix $A - B$.

With any suitable embedding, we inherently define a classification space for MaPP representations and the songs that they represent. Thus, we can employ various computational techniques to compare songs. We also note that not all MIR tasks rely on song comparisons, and MaPP can also be used for exploration within a song.

4. APPLICATION TO COVER SONG TASK

SuPP and MaPP can be used in structure-based retrieval methods for a variety of MIR tasks. In this section, we show how these representations can address the cover song task, and compare our methods with some previous methods.

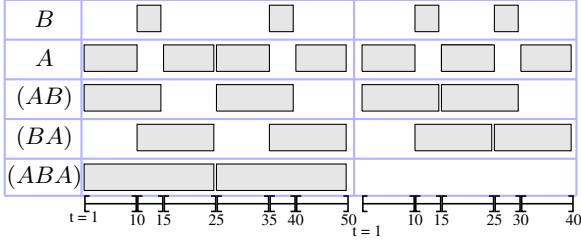
4.1 Dataset

To test the efficacy of SuPP and MaPP, we use a collection of Chopin's Mazurka scores as **kern files from the KernScore online database [3] [17]. There are 52 scores in the Mazurka dataset, and we extract two versions for each score. The first version of each piece, referred to as the "expanded" score, plays each repeated section as marked in the score. The second version, referred to as the "non-expanded" score, does not respect these repetition markers and plays marked repeated sections once. As a result, the data consists of 104 songs with pairs of expanded and non-expanded versions for each Mazurka piece.

Each score is initially represented as a thresholded self-dissimilarity matrix (SDM). Following the procedure from [8, 18], we first extract a chroma vector for each beat in the score using the Python library music21. We then build audio shingles [4] for each beat [19–21] by concatenating S number of consecutive chroma vectors, encoding local information for each beat. We set the shingle width to $S = \{6, 12\}$ and then compute the cosine-dissimilarity measure between each pair of audio shingles. We finally create the SDM by thresholding the matrices using $\mathcal{T} = \{0.01, 0.02, 0.03, 0.04, 0.05\}$. This SDM is converted to the aligned hierarchies [8], and then to S_NL diagrams [9]. From the S_NL diagram, we create a SuPP which is then discretized to become a MaPP, as described in Section 3.2.

4.2 Experiment

The cover song identification task, or version detection task, aims to identify recordings that are performances of the same piece of music. We address this task by creating SuPP and MaPP representations for each song and calculating pairwise Frobenius distances between MaPPs. The distance between two MaPPs is a measurement of structure dissimilarity, which is used alongside a clustering technique to deem whether songs are covers of the same work.

4.2.1 Setting SuPP Parameters


As discussed in Section 3.1, to create the SuPP representation we start by defining where the Gaussians representing each repetition are centered. For addressing the cover song task, the S_NL diagram is adjusted so the horizontal axis reflects the midpoints of the repeated structures instead of their start times. [5] We next define σ_s, σ_ℓ, and the weighting function to determine the size, shape, and height of the 2-D Gaussians placed over each point in the S_NL diagram.

For these experiments, we use a normalized constant standard deviation for σ_s, which determines the width of the Gaussians on the time axis. Recall that the time axis is normalized in the S_NL diagrams so that all songs are placed within the same range. We set $\sigma_s = \frac{1}{M}$ beats for each song, where M is the normalization constant, or the total

---

Figure 3: These aligned hierarchies represent songs of structure ABAABA (left) and ABABA (right). By omitting a middle "A" section in ABAABA, the longer repetitive sections break down while the shorter ones are preserved.

song length, inherited from the $S_N L$ diagram for a given song. This means that repeats of the same length that start within two beats ($2\sigma_s$) of each other will overlap, and thus combine to form a single structure in the SuPP.

The second parameter is σ_ℓ, which determines the width of the Gaussians in the length direction. We use a constant value for this parameter, setting $\sigma_\ell = 1$. Since the songs are not normalized along this dimension in the $S_N L$ diagrams, no normalization term is needed here. This means that there will be overlap between repeats centered at the same beat and those whose lengths differ by up to two beats.

Lastly, we choose a weighting function to apply to our surface that will give more importance to shorter structures than longer structures, due to longer repetitive structures having more variance between cover songs than shorter ones. An example of this phenomenon can be seen in Figure 3; a slight change in the overall song pattern, such as repeating the chorus one fewer time, breaks down the largest structures while maintaining the shorter repeats. To encode this importance on smaller-sized structures, we choose the following piece-wise linearly decreasing function:

$$F(\bar{s}, \ell) = \begin{cases} 1 & \ell \leq \ell_{min} \\ 1 - \frac{\ell - \ell_{min}}{\ell_{max} - \ell_{min}} & \ell_{min} \leq \ell \leq \ell_{max} \\ 0 & \ell \geq \ell_{max} \end{cases} \quad (5)$$

where ℓ_{min} and ℓ_{max} are user-specified bounds on the lengths of repetitive structures included in SuPP. We set $\ell_{min} = 0$ beats and $\ell_{max} = 80$ beats in order to include 98% of structures seen in our data. As the length increases from ℓ_{min} to ℓ_{max}, the weight decreases from one to zero.

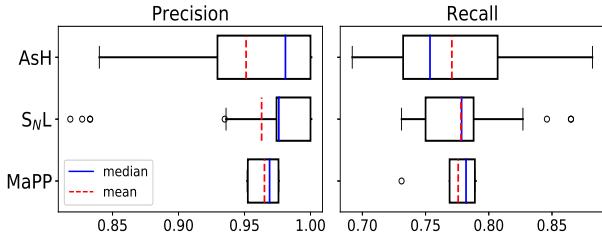
4.2.2 Comparing MaPPs

For the cover song task, we set the MaPP resolution to $P = 200$, yielding a 200 x 200 matrix. This choice of resolution follows the work in [10, 22], which shows that this parameter value is robust, though other resolutions may be applied. This process is analogous to the resampling in [7] but is an aggregation within SuPP instead of a sampling.

After creating a MaPP for each song, we compute pairwise Frobenius distances and apply a clustering algorithm. Noting that MaPP encodes a notion of musical structure, the Frobenius distance offers a measure of the dissimilarity between the musical structures of two different pieces. For cover songs, we expect this distance to be low because

songs that cover the same piece of music will likely have similar repeated musical structures.

For the Mazurka scores dataset, each song has exactly one match, namely the expanded version with repeat markers honored and the non-expanded version where the repetition markers are ignored. Therefore, we use mutual k-nearest neighbors with $k = 1$ to pair the songs. Under this technique, two songs are only labeled covers of the same piece if they both claim each other to be their closest "neighbor," corresponding to the smallest distance computed. If there is no mutual nearest neighbor, then that song is not matched to any other in the dataset.

4.2.3 Results


Ten experiments were performed with varying thresholds and shingle numbers applied to the SDMs. Overall, precision and recall values across these experiments were consistent (see Table 1) with mean precision of 0.965 and mean recall of 0.776. Figure 4 shows these results to be comparable to similar experiments on average using $S_N L$ diagrams [9] and aligned sub-hierarchies [6] (AsH) [18]. However, MaPP results have less variability among the ten experiments and thus show more stability. Additionally, MaPP is more flexible in its creation, allowing for more user creativity, and it is more computationally efficient to compare MaPPs than $S_N L$ or AsH representations, as the latter two include optimal matching steps in their comparisons.

We found that songs with few repetitive structures (and thus a scarce $S_N L$ diagram) make up the majority of the songs left without a match or improperly matched. Therefore, our method works best when analyzing songs with ample repetitive structures. An example of expanded and non-expanded versions of a score that were not matched together is shown in Figure 5, visibly due to scarce amounts of repeated structures in the non-expanded $S_N L$ diagram.

---

[6] AsH are extensions of aligned hierarchies that make aggregate comparisons using sections of songs instead of one cohesive structure representation as with aligned hierarchies.

Threshold ($\mathcal{T}$)	Shingle (S)	Precision	Recall
0.01	6	0.952	0.769
	12	0.975	0.778
0.02	6	0.974	0.731
	12	0.964	0.786
0.03	6	0.952	0.769
	12	0.976	0.789
0.04	6	0.952	0.769
	12	0.976	0.789
0.05	6	0.976	0.789
	12	0.954	0.789

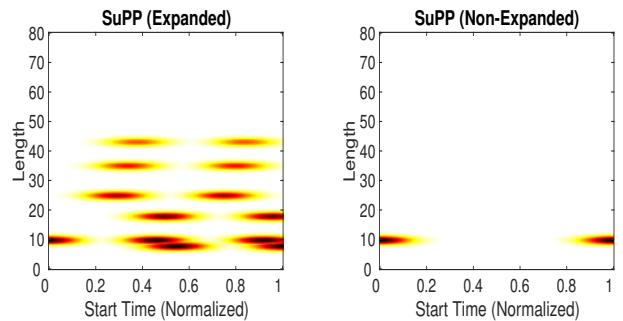
Table 1: Experimental results for the cover song task using midpoint versions of $S_N L$ diagrams, normalized constant σ_s, constant σ_ℓ, and linearly decreasing weight along the length axis from Eqn. 5.

Figure 4: A comparison of precision and recall values for varying threshold and shingles for three different methods: MaPP, S_NL diagrams, and AsH. The AsH results do not include the songs which were left unmatched due to empty AsH representations (which varied between 14% and 65% of the dataset) as error, thus inflating the results compared to the other two methods.

Figure 5: Mazurka Op. 68 No. 4 expanded (left) and non-expanded (right) do not match using k-mutual nearest neighbors with $k = 1$ on their corresponding MaPPs due to scarce repeated structures in the non-expanded S_NL diagram.

5. OTHER APPLICATIONS

Following are two additional examples of how SuPP and MaPP can be used to address other MIR tasks: novel-segment detection and genre classification. Preliminary experimental results show promise with both tasks, and future work will include a full analysis of these experiments.

5.1 Novel-Segment Detection


We define novel-segment detection to be finding the boundaries between repeated segments and novelty sections. This is a combination of both the novelty detection and segmentation tasks in MIR [23–25]. These boundaries often distinguish between typical segments within a musical piece, like a verse or a coda, making the segmentation task a natural application of such detection [23, 24].

For this task, we extend the analysis of MaPP from Section 4 by transforming the matrix into a vector; that is, given a MaPP, we create a 1-D vector by taking the sum of each column. This projection yields a time-dependent vector whose entry at a given time step corresponds to the sum of the structure activity measured by MaPP at that time. Global and local minima (as specified by user-specific constraints) of this projection correspond to regions between large amounts of structure. Outliers within the collection of minima correspond to novelty sections, where no repetitive structure is present for a long period of time. Preliminary work using this methodology of locating the minima of the summation projection of MaPP shows promising results, highlighting the flexibility of MaPP in other MIR tasks.

5.2 Genre Classification

In genre classification, we seek to classify songs by the genres assigned to them by their recording company. We use the collection of 104 Chopin's Mazurkas along with a selection of 676 Jazz lead sheets [26] from the *iRb Corpus* in the `**jazz` format to have two genres.

Given that MaPP representations embed into inner product spaces, we can use machine learning algorithms for MIR tasks. MaPP matrix elements become the features for each song with the number of features set by the resolution parameter. Various machine learning algorithms, implemented in sklearn,[7] are applied to our set of MaPPs as constructed in Section 4, representing 104 Mazurka scores and 676 jazz lead sheets. Logistic regression, a Gaussian kernel support vector machine (SVM), and a polynomial kernel SVM distinguish between the Mazurka and jazz pieces with high accuracy of above 94% for each classifier.

6. CONCLUSION

In this paper, we introduce SuPP and MaPP, two musical representations influenced by TDA theory. We describe how SuPP and MaPP are built and give intuition into how parameters may be chosen when applying these representations to the cover song task. Our accuracies using MaPP for this task are comparable to previous studies on average but indicate greater stability among various SDM thresholds and shingles. Preliminary experiments applying SuPP and MaPP to novel-segment detection and genre classification are plausible, demonstrating the adaptability of these representations for distinct MIR tasks.

We discuss how SuPP and MaPP overcome limitations of the aligned hierarchies [8] and S_NL diagrams [9], and how they are adaptable with user-specified parameters allowing for task-specific representations. Unlike its predecessors, MaPP is well suited for machine learning. Future work will demonstrate this through various MIR tasks, such as genre classification, and by applying similar methods to additional datasets including audio data, such as the Da-TACOS dataset [27]. A drawback of SuPP and MaPP is the necessary manual selection of parameters, requiring a deep understanding of the task at hand.

SuPP and MaPP, alongside SE and S_NL diagrams [9], offer inspiring insights and open up a realm of opportunities in the intersection of TDA and MIR. These methods are both grounded in mathematical theory and have practical applications to the field of MIR, as seen by the effective use of MaPP for the cover song task. The experiments in this paper further highlight the utility of TDA-based methods and explore new opportunities for future experimentation in the intersection of TDA and MIR.

ABSTRACT

While common approaches to automatic structural analysis of music typically focus on individual audio files, our approach collates audio features of large sets of related files in order to find a shared musical temporal structure. The content of each individual file and the differences between them can then be described in relation to this shared structure. We first construct a large similarity graph of temporal segments, such as beats or bars, based on self-alignments and selected pair-wise alignments between the given input files. Part of this graph is then partitioned into groups of corresponding segments using multiple sequence alignment. This partitioned graph is searched for recurring sections which can be organized hierarchically based on their co-occurrence. We apply our approach to discover shared harmonic structure in a dataset containing a large number of different live performances of a number of songs. Our evaluation shows that using the joint information from a number of files has the advantage of evening out the noisiness or inaccuracy of the underlying feature data and leads to a robust estimate of shared musical material.

1. INTRODUCTION

Automatic analysis of musical structure from audio is one of the more challenging tasks in music information retrieval (MIR) [1–3]. Reasons for this are the relatively high-level nature of the problem and its dependence on lower-level audio descriptors, which have a tendency to be noisy, as well as the restricted availability of annotated collections in a limited number of musical genres, which are necessary for tackling the problem with solutions based on machine learning. However, the growing number of large

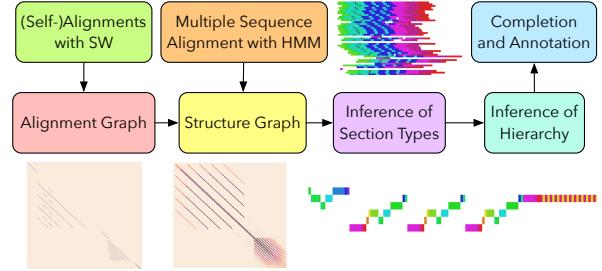
public and online music collections, which are usually annotated with user-curated metadata (song titles, artists, recording information, or dates), can potentially be used for unsupervised structural analysis which may be of considerable musicological value.

This paper introduces an approach for the detection of temporal structure in large collections of musical audio recordings where information from a number of related recordings is combined to improve the quality of results. From a given set of input audio recordings, e.g. different performances of the same song, our method identifies the most commonly occurring sequential structures, relates them to each other and organizes them hierarchically. The individual files can then be described, compared and aligned with each other by referencing this shared structure. Inspired by techniques used in genetic sequencing, we combine the use of different alignment methods, including dynamic programming (DP) and multiple sequence alignment (MSA) with graph representations and search methods. We evaluate our method on a subset of the Live Music Archive (LMA) of the Internet Archive and analyze the harmonic content of a large number of performances of a selection of songs. We compare the harmonic essence thus obtained with existing lead sheets and illustrate the differences between individual performances in a few qualitative comparisons. Although the examples in this paper focus on formal structure determined by harmonic progressions, the method can easily be used for structure determined by other musical aspects.

2. RELATED WORK

With the omnipresence of large digital audio collections of music, the automatic analysis of large corpora is becoming an increasingly central task in music information retrieval. Recent research in this area has mainly focused on large-scale statistical analysis of audio features [4–6], as well as making these accessible using interactive browsing tools [7–9]. While the analysis of temporal structure, including the identification of musical patterns, motifs, harmonic progressions, or form across corpora, are relatively well established for collections of symbolic music [10–12], only a

few have attempted to use similar analysis methods for audio collections [13–15]. Potential reasons for this are often discussed and may be due to common problems with audio collections, including mislabeling, duplication, differing recording quality, or noisy audio features [4, 6, 16, 17].

Many of the methods used jointly in this paper have previously been applied in different musical contexts. Dynamic programming is often used to align audio recordings of different performances of the same material, either audio-to-score or audio-to-audio [18–20], sometimes considering musical variations and structural differences [21]. While immediate uses include score following, automatic accompaniment, and computer-assisted production, some have used alignment methods for classification tasks such as cover song identification [22] and plagiarism [23].


While the alignments methods most commonly used in MIR are pairwise, i.e. applied to align pairs of sequences, such as the Smith-Waterman or the Needleman-Wunsch algorithm [24], there are many methods for directly aligning multiple sequences commonly used in bioinformatics, but only a few have so far been applied to musical data. [25] used *multiple sequence alignment (MSA)* to eliminate conflicts and typos in song lyrics retrieved from the Web. [20] used their own progressive MSA method as well as *Profile HMMs* (Hidden Markov Models) to align different recordings of performances of classical music and found the two methods to lead to comparable results. In [26, 27], which comes closest to the present work, different MSA libraries were used along with pattern mining to detect harmonic patterns in symbolic transcriptions of a set of 138 songs. The authors were able to identify cover songs as well as genre clusters with their most characteristic progressions.

There are generally three common approaches to automatically discovering musical structure in sequences of feature vectors from individual recordings, via repetition, novelty, or homogeneity [1]. The first identifies repeating subsequences whereas the other two identify abrupt changes or comparatively stable areas. Sections often reappear in slightly varied forms, which has been addressed in [28]. Recent methods often use combined approaches using both harmonic and timbre features in order to improve results, e.g. [29]. While music is inarguably organized hierarchically [2], few approaches enable the detection of hierarchical structure [30].

Our approach is purely repetition-based, however, not only in individual recordings, but in the entire collection of interest. This allows the identification of sections occurring only once in a given piece and leads to more robust descriptions of the found sections. Similar to our approach, [31] used automatically detected musical structure to improve chord label quality for individual pieces.

3. METHOD

Our method consists of a five-step process. Given a set of recordings, we create an alignment graph based on a number of self-alignments and pairwise alignments. Then, we use an MSA to partition the alignment graph and create a structure graph. We then search the structure graph for

Figure 1. Overview of the five-step process.

commonly occurring sections and classify them into section types. These section types are then grouped into a hierarchical structure, based on their co-occurrence. Finally, we complete the structure graph with material from the individual recordings that was left out by the MSA and annotate the recordings with section types. Figure 1 shows an overview of the process.

3.1 Alignment Graph

Given a collection A of K related audio recordings we obtain a *feature sequence* $A^k = (a_1^k, ..., a_{N_k}^k)$ of length N_k for each recording $k = 1, ..., K$. Each element a_i^k represents a time segment, such as a beat, bar, or onset, with corresponding feature information, such as chroma vectors or chord labels.

A *local alignment* between two such sequences A^s, A^t is commonly defined as a sequence of pairs $p = (p_1, ..., p_L)$ with $p_l = (s_l, t_l) \in [1, ..., N_s] \times [1, ..., N_t]$ with a monotonicity constraint $1 \leq s_1 \leq ... \leq s_{N_s} \leq N_s$ and $1 \leq t_1 \leq ... \leq t_{N_t} \leq N_t$ and a step condition $p_{l+1} - p_l \in \{(0,1),(1,0),(1,1)\}$. A local *self-alignment* can be defined accordingly with $A^s = A^t$.

In our situation it is advantageous to only consider *diagonal local alignments* in order to reduce ambiguity and noise in the alignment graph. We can achieve this with a more strict step condition $p_{l+1} - p_l = (1,1), \forall l = 1, ..., L\text{-}1$.

Due to repetition and variation in the given musical material, many sensible local alignments may exist between each pair of recordings. For example, if in one recording the first of a pair of musical sections is expanded or another is inserted between the two sections, two independent local alignments are still able to capture the commonality between the two recordings. The same is true for self-alignments, which are able to characterize repetition at different temporal intervals within recordings.

From a large number of such alignments and self-alignments we can then create an *alignment graph* $G_A = (N_A, E_A)$ for collection A with a node for each segment a_i^k and an edge between each aligned segment pair p_l. Due to the alignments being local, not every node in the graph is necessarily connected, and some nodes may have many incident edges.

Due to the large size of many audio collections of interest and the time complexity of alignment algorithms, it may not be feasible to calculate the alignments between ev-

ery possible pair of recordings. However, for our method it has proven to be sufficient to select a small subset of all possible pairings, e.g. n random pairings per recording ($n * K$ alignments) plus all K self-alignments.

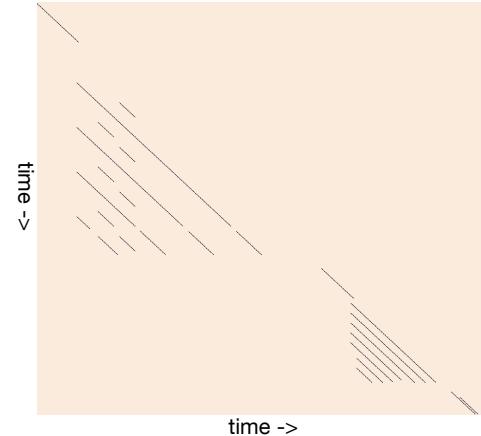
3.1.1 Alignment and Self-Alignment Methods Used

Common approaches to alignment are usually designed to find a single global or local alignment for a pair of given sequences. For the reasons outlined above we are more interested in finding multiple local diagonal alignments of reasonable length. Many common approaches can be modified for this purpose. Here we discuss the *Smith-Waterman* algorithm, which we use in our experiments.

Smith-Waterman is a dynamic programming algorithm developed in the context of genetic sequence alignment [32]. For two given input sequences A^s, A^t, the simplest variant with a linear gap penalty generates a scoring matrix $H_{i,j}$ with dimension $N_s + 1 \times N_t + 1$ and with $H_{i,0} = H_{0,j} = 0$. Each $H_{i,j}$ with $i, j > 0$ is then determined as follows:

$$H_{ij} = \max \begin{cases} H_{i-1,j-1} + sim(a_j^s, a_j^t), \\ H_{i-1,j} - P_G, \\ H_{i,j-1} - P_G, \\ 0 \end{cases} \quad (1)$$

where sim is a similarity function between feature vectors and P_G is a gap penalty. [1] Depending on the nature of the feature vectors, one may choose sim to be a simple cosine similarity, or a function that returns a match score for identical vectors and else a lower mismatch score.

Starting from the highest score in the matrix, the algorithm then finds the most likely alignment path by tracing back the origins of the score and ending at a position with a score of 0. Our modification of the algorithm finds diagonal paths by limiting trace-back to matching pairs containing a maximum number of $\gamma \geq 0$ subsequent diagonal gaps (mismatches). With one iteration of Smith-Waterman, several of these paths may be extracted by gradually removing found paths from the matrix and setting their values to 0.


Furthermore, due to the fact that some potential paths can be covered up by higher-rated paths nearby, we propose an *iterative variant* of Smith-Waterman where every element in the neighborhood of a previously found alignment path p is set to zero, i.e. $\forall p_l \in p$ we set $H_{ij} = 0$ for $s_l - \delta \leq i \leq s_l + \delta$ and $t_l - \delta \leq j \leq t_l + \delta$. The parameter $\delta \geq 0$ controls the minimum distance between alignments, which can be used for limiting the number of results. [2]

Additional ways of improving the performance of the algorithm and the quality of the resulting alignments that have proven useful are limiting the number of iterations, setting a score threshold below which alignments are no longer considered, or setting a minimum segment length.

Many of the existing methods can also be modified for *self-alignment*. With Smith-Waterman, we simply treat the

Figure 2. The matrix resulting from a diagonal self-alignment of a recording of *China Doll* from the dataset used in Section 4 (10 longest segments).

trivial diagonal alignment as a previously found path p. Figure 2 shows an example diagonal self-alignment.

3.2 Structure Graph

The next step is to construct a *structure graph* that encapsulates the most common structural characteristics found in the given collection. The goal is to identify a large subgraph G'_A of G_A that can be partitioned into a sequence of partitions $P_1, \ldots, P_M$ of corresponding nodes in G'_A, i.e. $P_m \subset N_A$. Each partition contains at most one segment of each recording, i.e. $k \neq l, \forall a_i^k, a_j^l \in P_m$, and the partitions are strictly ordered temporally, i.e. $i < j, \forall a_i^k \in P_m, a_j^l \in P_{m+1}$. For example, if the nodes of G_A represent bars in A, each partition contains bars of different recordings that can be considered equivalent. Subsequent partitions may be thought of as recurring sequences, although there may be gaps in individual or all recordings between to adjacent partitions. Note that $\cup P_m$ may likely not include all nodes of G_A due to significant structural differences between the individual recordings, hence the definition of G'_A. Figure 3 shows the connection matrix of an example partition where the z-axis shows the number of connections between partition pairs.

We can infer such a partition directly from the connections in G_A in an iterative manner. We experimented with various graph search approaches, e.g. searching for the most densely connected components with at most one node per recording and aligning these components temporally, or with beam search with various partition improvement and modification methods based on functions that rate the clarity of the connection matrix of the partition.

However, while these methods work well for relatively similar input sequences, we obtained better and faster results for more diverse input material with multiple sequence alignments using *Profile HMMs* [24], a method common in genetic sequencing where a reasonable simultaneous alignment is found for all sequences. A Profile HMM is a particular type of Hidden Markov Model with three types of states and a given length L. *Match states* M_j

---

[1] In genetic sequence alignment it is generally more appropriate to replace P_G with a gap penalty function that distinguishes between opening and closing a gap and decreases for longer gaps.

[2] A similar iterative ('recursive') variant was introduced in [19]. However, there each sequence element is involved in at most one pair.

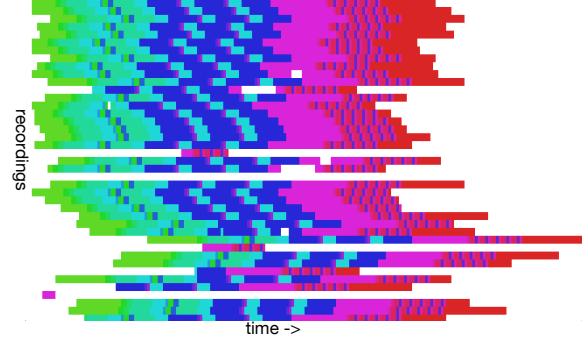
Figure 3. Connection matrix of the partitioned alignment graph of *China Doll* (65 recordings). The z-axis shows the number of connections between the nodes of each partition pair. The beginning of the song features a regularly repeating section (verses and solos), followed by a section that occurs only once but in most versions (interlude and chorus), followed by a short repeated ostinato (outro).


Figure 4. Transition structure of a Profile HMM [24].

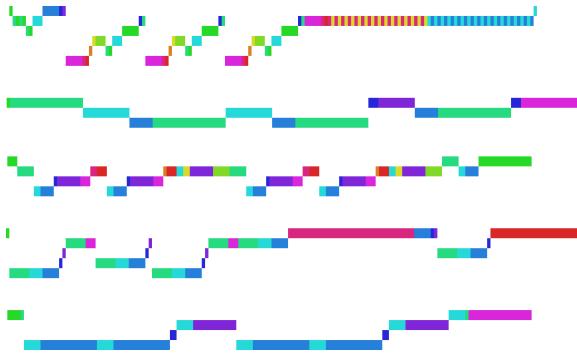
represent segments shared between sequences, *insert states* I_j represent possibly multiple consecutive segments particular to an individual sequence, and *delete states* D_j represent segments missing in a particular sequence (the segment represented by the corresponding match state), where $j = 1, \ldots, L$ (see Figure 4).

There are L match and L delete states, as well as $L + 1$ insert states. The emission distributions for the match and insert states are chosen depending on the input feature sequences, e.g. 12-dimensional multivariate gaussian for chroma vectors, or multinomial discrete distributions for chord labels. The model is trained with a number of related sequences, in our case the A^k, using the expectation maximization variant of Baum-Welch. L is usually chosen based on the lengths of the input sequences, e.g. their maximum, median, mean, or minimum length. Individual state sequences for each input sequence can be decoded using the Viterbi algorithm, i.e. we obtain a state label for each a_i^k. We can then infer the M partitions from the segments associated with the L match states ($M \le L$), for example by only keeping the match states that appear in a proportion of at least $0 \le \lambda \le 1$ of all the sequences.

We now define a *structure graph* $G''_A = (N''_A, E''_A)$ whose nodes correspond to the partitions P_m and whose edges are determined by the most common mutual connections in G'_A between the elements of different partitions. More precisely, we add an edge for each node pair $P_m, P_n \in N''_A$ where $P_m \in con(P_n, \mu)$ and $P_n \in$

Figure 5. Juxtaposition of different recordings of *China Doll* where colors represent segment types. The different horizontal offsets illustrate varying lengths of introductory tuning or announcements. The empty lines are mislabeled recordings of different songs.

$con(P_m, \mu)$. The function $con(x, \mu)$ returns the set of $\mu > 0$ nodes in N''_A most strongly connected to x:


$$con(x, \mu) = \underset{y \in N'_A \setminus x}{\text{argmax}} \; |\{e \in E_A \mid a, b \in e, a \in x, b \in y\}| \\ \mu$$

(2)

where argmax_μ returns the set of μ arguments for which the function is maximized. The parameter μ should be relatively small for best results, e.g. $0 < \mu \le 5$. For illustration, the resulting graph is a pruned simple-graph version of the multigraph of which a connection matrix is shown in Figure 3. The pruned graph contains only nodes representing significantly large partitions are kept and simple edges are established wherever the multigraph has many edges.

3.3 Inference of Section Types and Hierarchies

The structure graph can then automatically be decomposed in order to find *types of sections* recurring in the collection and within single recordings. The connected components C_j in G''_A represent sets of equivalent partitions of segments recurring at different points in time. We sort these components by their lowest partition index $\min_m(P_m \in C_j)$ and group temporally adjacent ones where $P_m \in C_j \iff P_{m+1} \in C_{j+1}$ into sequences. For each of these sequences we can retrieve the corresponding recurrent sections by simply transposing the two-dimensional arrays of indexes, i.e. $(C_{j1}, \ldots, C_{jJ})^T$ with $j1, \ldots, jJ$ being the sorted indexes of the components in a given group. Finally, we merge temporally adjacent groups of sections G, H if for each section in G there is a directly temporally adjacent section in H and vice versa. Figure 5 shows a visualization of the section types thus obtained for the partitioned graph shown in Figure 3.

For music with no recurring sections the above procedure may result in only a few or no section types. We therefore suggest an additional step of inferring boundaries between adjacent connected components C_j, C_{j+1}. Let $\Delta_{j,j+1} = avg_k(n_k - m_k)$ be the average difference in index over all recordings k appearing C_j, C_{j+1}, where m_k, n_k are the indexes of the segments of k, i.e. $a_{m_k}^k \in C_j, a_{n_k}^k \in C_{j+1}$. If $\Delta_{j,j+1} \ge \tau$ for a given thresh-

Figure 6. Visualization of the structural hierarchies of five different songs from the dataset from Section 4.1. The top-most is the unflattened hierarchy of *China Doll* (Figures 3 and 5), all others are flattened. The colors indicate section types, the vertical axis nesting level.

old $\tau > 1$, we introduce a section boundary between C_j and C_{j+1}. For example, for $\tau = 5$ we add a section boundary between any two subsequent components where there are on average 4 segments missing per recording.

Finally, we can simplify the structure by inferring a *hierarchy* from the obtained section types. This can be done using a simple recursive search method that identifies the most frequently recurring adjacent section types and either combines them into a new type or concatenates them if they always co-occur. This hierarchy can then be simplified by further merging adjacent types that always appear together, and finally flattening nested types if their parts only occur within them. Figure 6 shows a few visualizations of example hierarchical structures.

3.4 Annotation of Individual Structures

In a final step of the process, each individual recording in the collection can be annotated using the found shared structure. First, we label each segment in the structure graph with a corresponding section type identified as described in the previous section. Then, using the alignment graph G_A we can infer section types for segments that are not in the structure graph, which may for example be the case if some recordings contain additional repetitions of sections. We consider for each segment a_i^k in $G_A \setminus G'_A$ and check which partition P_m in G''_A it is most strongly connected to, i.e. which partition contains the most segments connected to a_i^k. Note that some segments, sections, or entire recordings may remain unlabeled, if they were not aligned or self-aligned in the first step of the process (Section 3.1), due to being entirely unrelated or their features being too noisy (see Figure 5 for some examples).

Finally, we can annotate each segment that received a section type with a *feature value* derived from the shared structure. We determine a value for each position of every section type by summarizing the original features of all segments associated with that position. For example, we may label the first beat of a section type with the chord label most frequently occurring among all associated beats.

All corresponding segments in individual recordings can then be annotated with that label.

4. EXPERIMENTS

We tested our approach on material from the Grateful Dead collection of the Live Music Archive,[3] which holds more than 13,000 recordings of over 2,000 shows spanning the years 1965 to 1995. The large number of recordings of individual songs and the improvised nature of Grateful Dead's performances make this collection particularly interesting for our work.

4.1 Dataset and Preparations

We created a *dataset*[4] with all performed versions of 15 songs from this collection, selected based on the criteria that a large number of versions exist and that a corresponding studio recording by the Grateful Dead is available that could potentially be used as a reference in the future. The fact that these recordings are live recordings poses additional challenges to the ones outlined in Section 2. Many of them contain a considerable amount of crowd noise which may lead to noisy audio features, and most of these recordings were made by amateurs using their analog tape equipment, which means that many of them are out of tune due to varying tape speed. We addressed the second of these problems and *resampled* the audio files after comparing their rotated chroma features with the ones of the respective studio version. For a ground truth, we *transcribed* the chord progressions beat-by-beat and grouped them into bars and sections for each of the songs with the help of existing lead sheets.[5] This level of granularity is particularly important due to the fact that many of these songs are based on odd meters (e.g. 7/4 in *Estimated Prophet*) or contain metrical changes (e.g. abbreviated 2/4 bars in *China Cat Sunflower*). Tuning ratios, a script for downloading and resampling, and transcriptions are published with the dataset.

The experiments described here[6] are based on a *subset* of the dataset with at most 100 versions of every song. We extracted triadic chord features using [33] (root notes and one of the four qualities major, minor, diminished, and augmented) and summarized them to beats extracted using Madmom.[7] The summarization process is based on the statistical mode of the chords in each temporal segment, i.e. for each segment the chord that was played for the longest. In order to be comparable with the features, we simplified the transcribed chords to triads as well.

We used our own implementation of a Profile HMM and initialized it with L = median input length and with uniform distributions and transition probabilities, except match-match 0.999 and delete-insert 0.01. Our Smith Waterman implementation led to the quickest and best results

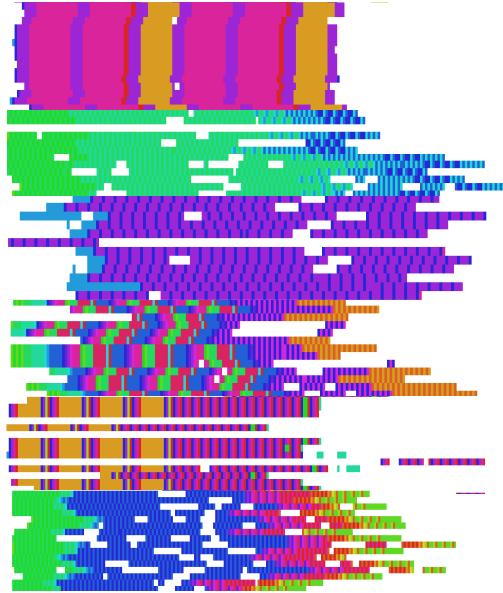
with the following parameter settings: a single iteration, 10 longest alignment segments, minimum segment length 16, $\gamma = 4$, $\delta = 4$, $\lambda = .1$, $\mu = 1$, $\tau = 2$.


4.2 Results

Due to the fact that there is no previous work with which to compare our method, we chose to perform an evaluation similar to [31] where structural information is used to improve chord prediction accuracy. [8] We used Smith Waterman to align the following sets of sequences with the ground truth transcriptions: (a) the original extracted chord sequences as a baseline (b) the sequences annotated by our method according to Section 3.4 and (c) the shared harmonic structure identified by our method according to Section 3.3. We then calculated two measures for each of the sets of sequences: the proportion of correctly matched ground truth segments p_G as well as the proportion of correctly matched segments in the output p_O, i.e.

$$p_G = \frac{\text{matches in alignment}}{\text{length of groundtruth}}, \ p_O = \frac{\text{matches in alignment}}{\text{length of output}} \tag{3}$$

Table 1 shows the overall values and Figure 7 shows distributions of p_G per song. p_O is lower than p_G due to for example additional repetitions of sections in performances or the high degree of variation and improvisation in many of the songs, i.e. there are deviations from the 'lead sheet' in individual recordings. However, the fact that on average the shared harmonic structure matched with the lead sheet content with an average probability of 82.5% is promising.

---

[8] Note that instead of evaluating the hierarchical structures, which necessitates a non-trivial generalization of the method suggested in [34] and will be done in future work, we evaluate the flattened annotations, which nevertheless result from the process described in sections 3.1 through 3.4.

Figure 8. Visualisation of the segment types for 6 songs (*Box of Rain*, *Eyes of the World*, *Franklin's Tower*, *Sugar Magnolia*, *Casey Jones*, and *China Cat Sunflower*), around ten recordings each.

4.3 Application

As a more qualitative investigation of the potential of our approach we created a simple Web application for the interactive exploration of annotations and alignments along with the underlying recordings. Users can hear the corresponding segments of the recordings by clicking on the colored blocks. Figure 8 compiles six screenshots for different songs that illustrate different shared structures and individual deviations from them. Whereas *Box of Rain* has a very even and simple $AABAAB$ structure with tiny insertions, other songs, such as *Eyes of the World* or *Franklin's Tower*, feature longer more open-ended yet highly repetitive sections. *Casey Jones* is a combination of both with four verse/chorus repetitions followed by an extended jam over part of the chorus.

5. CONCLUSION

We have presented a new method for the extraction of shared temporal structure from a number of related audio recordings and shown with both quantitative and qualitative results how such a method could be useful. For example, it could provide musicologists a way to systematically study and explore larger archives of related recordings, or yield more reliable estimates of audio features for noisy live music recordings. Besides a more extensive evaluation and application, future work could include an expansion of the method for joint use of different kinds of feature vectors, either to improve the inference of sections and hierarchies for less repetition-based music (analogous to other approaches to structure inference) or for a more multidimensional analysis of the musical material.

A CHORUS-SECTION DETECTION METHOD FOR LYRICS TEXT

Kento Watanabe   **Masataka Goto**

National Institute of Advanced Industrial Science and Technology (AIST), Japan

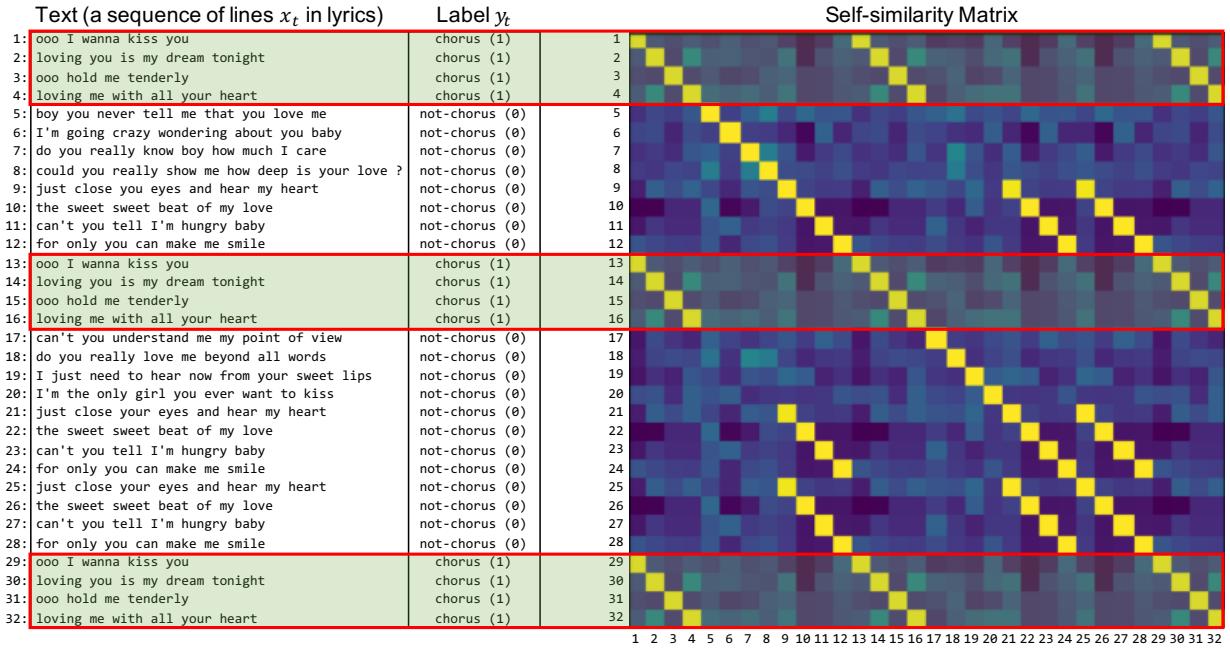
{kento.watanabe, m.goto}@aist.go.jp

ABSTRACT

This paper addresses the novel task of detecting chorus sections in English and Japanese lyrics text. Although chorus-section detection using audio signals has been studied, whether chorus sections can be detected from text-only lyrics is an open issue. Another open issue is whether patterns of repeating lyric lines such as those appearing in chorus sections depend on language. To investigate these issues, we propose a neural network-based model for sequence labeling. It can learn phrase repetition and linguistic features to detect chorus sections in lyrics text. It is, however, difficult to train this model since there was no dataset of lyrics with chorus-section annotations as there was no prior work on this task. We therefore generate a large amount of training data with such annotations by leveraging pairs of musical audio signals and their corresponding manually time-aligned lyrics; we first automatically detect chorus sections from the audio signals and then use their temporal positions to transfer them to the line-level chorus-section annotations for the lyrics. Experimental results show that the proposed model with the generated data contributes to detecting the chorus sections, that the model trained on Japanese lyrics can detect chorus sections surprisingly well in English lyrics and that patterns of repeating lyric lines are language-independent.

1. INTRODUCTION

The digitization of lyrics collections has opened various areas of lyrics-based research in the Music Information Retrieval (MIR) community, such as research on lyrics browsing [1–3], lyrics genre classification [4–6] and lyrics-to-audio synchronization [7–17]. Lyrics are usually plain text without any annotations, and some researchers have analyzed their structure, such as paragraph structure and topic transitions between paragraphs [18–22]. For example, Fell et al. [18] and Watanabe et al. [19] estimated section boundaries in lyrics text without empty lines but were not able to assign a section label such as verse or chorus to each estimated section. Chorus sections were not detected in lyrics text.

The goal of this paper is to achieve automatic chorus-section detection for lyrics text. This task has not been studied, though chorus-section detection, as well as music structure analysis, for audio signals has been a popular topic of research in the MIR community [23–41]. Since whether chorus sections can be detected from text-only lyrics is an open issue, it is worth investigating this issue from academic viewpoints. Moreover, a chorus-section detection method for lyrics text has potential applications. For example, when listeners want to find lyrics with a chorus section having a particular phrase such as "I love you" for the purpose of singing, reusing its chorus section in a short video clip, etc., it is necessary for a lyrics search system to automatically detect which lines of the lyrics are included in chorus sections. The detected lyric lines of chorus sections could be used in a lyrics viewing function of music services displaying lyrics with those lines highlighted by a different color or typeface. Automatic lyric video generation technologies could give those lines more vivid animations.


Chorus sections are the most repeated and memorable portions of a song [39]. Since it is not easy to explore heuristic rules to find such sections, most existing chorus-section detection methods for audio signals have leveraged repetitive patterns of those sections within a song. In this paper, we propose a supervised model that can detect chorus sections in English and Japanese lyrics. Our model uses both structural features that represent patterns of repeating lyric lines and linguistic features that are calculated from word2vec [42] and context2vec [43]. To detect chorus sections using only plain text without any labels or even empty lines (i.e., section boundaries), we investigate a model and features effective for chorus-section detection. Experimental results show that our proposed model outperforms alternative baseline models and that combining structural and linguistic features contributes to better performance.

Although such a supervised model needs a large dataset of lyrics with line-level chorus-section annotations for its training, there was no such dataset as there was no prior work on chorus sections in lyrics text. To address this issue of lacking training data, we generated a dataset consisting of 9,313 English and 91,459 Japanese lyrics with chorus-section annotations by utilizing pairs of musical audio signals and their corresponding manually time-aligned lyrics. We first automatically detected chorus sections in audio signals of a song [39]. Then, since each lyric line had the corresponding start time within the song, we could find lyric lines that temporally correspond to the duration of each detected chorus section. We thus obtained the annotated dataset by assigning a `chorus` label to those lyric

Text (a sequence of lines x_t in lyrics)	Label y_t		Self-similarity Matrix
1: ooo I wanna kiss you	chorus (1)	1	
2: loving you is my dream tonight	chorus (1)	2	
3: ooo hold me tenderly	chorus (1)	3	
4: loving me with all your heart	chorus (1)	4

26: the sweet sweet beat of my love	not-chorus (0)	26	
27: can't you tell I'm hungry baby	not-chorus (0)	27	
28: for only you can make me smile	not-chorus (0)	28	
29: ooo I wanna kiss you	chorus (1)	29	
30: loving you is my dream tonight	chorus (1)	30	
31: ooo hold me tenderly	chorus (1)	31	
32: loving me with all your heart	chorus (1)	32	

Figure 1. Example of lyrics with chorus-section annotations and corresponding self-similarity matrix in which each cell represents the similarity between two lyric lines. These lyrics are from "How Deep Is Your Love?" (RWC-MDB-P-2001 No. 81 in the RWC Music Database [44]).

lines and a `not-chorus` label to the other lines. Experimental results show that the model trained with this large automatically generated dataset performs better than the model trained with a smaller manually annotated dataset and that the model trained on Japanese lyrics can detect chorus sections surprisingly well in English lyrics.

2. LYRICS CHORUS-SECTION DETECTION TASK

The left side of Figure 1 shows an example of lyrics with chorus-section annotations (labels). The lyrics of a song are a sequence of lyric lines, each line having a sentence or phrase. In this example there are three highlighted chorus sections that have exactly the same four lines, though in other songs, lyrics of chorus sections are repeated with some modifications. To maximize the applicability, as shown in this example, we assume that the input text of lyrics does not have any section boundaries. Even though some lyrics contain empty lines at those boundaries, those lines are deleted in advance. We also assume that the input text does not have explicit chorus labels such as "(chorus)" at the beginnings of chorus sections. Even though some lyrics contain those labels, they are deleted as well. When lyrics contain a repetition label such as "(* repeat)", it is manually replaced with the corresponding lyric lines.

We formulate this chorus-section detection task as a sequence labeling problem: predicting the `chorus` or `not-chorus` status for each lyric line. Let X_s be the lyrics of a song s composed of T lines of text: $X_s = \{x_1, ..., x_t, ..., x_T\}$. Each lyric line x_t has a binary label y_t. If $y_t = 1$, x_t is in a chorus section. If $y_t = 0$, x_t is not in a chorus section. Y_s denotes a sequence of labels correspond-

ing to X_s: $Y_s = \{y_1, ..., y_t, ..., y_T\}$. In the training step, the model learns the conditional probability $P(Y_s|X_s)$. In the validation/testing step, the trained model has to predict labels Y_s for given lyric lines X_s.

Chorus sections cannot be detected by simply extracting repeated lines since those lines often correspond to non-chorus sections. For example, lyric lines 9–12 and 21–24 in Figure 1 are exactly repeated, but those lines are not in chorus sections. It is also difficult to manually define a set of rules to find various chorus sections. We therefore prepare various features that could be useful for machine learning to deal with various types of chorus sections.

3. COMPUTATIONAL MODELING OF CHORUS SECTIONS IN LYRICS

We propose a neural network-based model for sequence labeling by using structural features that are self-similarity matrix (SSM) representations. SSM representations are widely used in computational music structure analysis, but we use different representations for lyrics. In addition to structural features, our model utilizes linguistic features such as word vectors and sentence vectors calculated from word2vec [42] and context2vec [43], which are widely used in natural language processing.

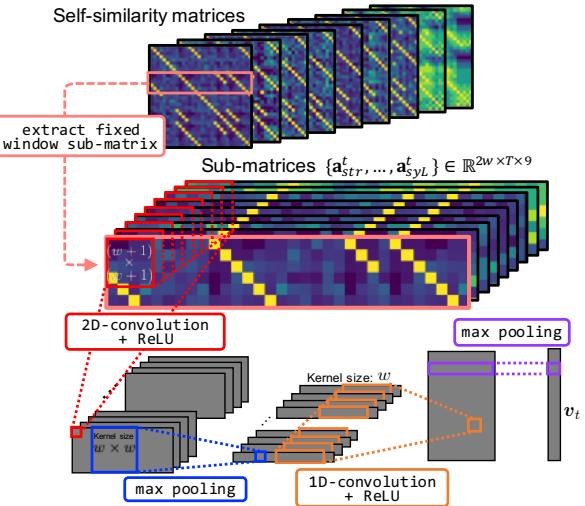
In the following sections, we first describe nine SSMs for capturing patterns of repeating lyric lines and explain how to encode the SSMs for neural networks (Section 3.1). We then describe the linguistic features obtained by vectorizing the semantic/syntactic information of lines using word2vec and context2vec (Section 3.2). Finally, we describe a neural-network-based sequence labeling model with these structural and linguistic features (Section 3.3).

3.1 Structural Features

Most previous work on music structure analysis for audio signals [23–41] identifies repeated musical sections by using a SSM like that shown in Figure 1. Repeated sections lead to high values in diagonals of the matrix, and those patterns are used to identify the structure. To capture repeated lyric lines that often appear in chorus sections, we also compute the SSM from lyrics text, but the design of the similarity measure to compute each cell of the SSM is important. We propose to use the following nine variations of similarity measures sim_m, where m denotes the variation. Some of the similarities are based on previous studies [18, 19].

String similarity (sim_{str}): a normalized Levenshtein edit distance [45] between the characters of two lyric lines.

Head similarity (sim_{head}): a normalized Levenshtein edit distance between the characters of the first two words of two lyric lines.

Tail similarity (sim_{tail}): a normalized Levenshtein edit distance between the characters of the last two words of two lyric lines.


Phonetic similarity (sim_{phone}): To capture rhymes in the lyrics, we calculate a normalized Levenshtein edit distance between the phonetic transcriptions of two lyric lines. We use the CMU pronunciation dictionary [1] to extract the phonetic transcription. For example, the phonetic transcription of "I love you" is [AY1, L, AH1, V, Y, UW1].

Part-of-speech similarity (sim_{pos}): To capture similarities in grammatical structure, we calculate a normalized Levenshtein edit distance between the part-of-speech (POS) sequences of two lines. We use the default POS tagger in the NLTK package [46].

Word vector similarity (sim_{w2v}): To capture the semantic similarity between two lyric lines, we simply average vectors of the words of each lyric line by using pre-trained word2vec [42] and compute their cosine similarity. This "bag of words" representation does not differentiate "dog bites person" from "person bites dog".

Context vector similarity (sim_{c2v}): To consider the word order, we vectorize the lyric lines using pre-trained context2vec [43], an extension of word2vec, which encodes a sequence of words by using Long Short-Term Memory (LSTM) networks [47]. We then compute their cosine similarity to obtain sim_{c2v}.

Word syllable count similarity (sim_{syW}): Since repeated phrases sometimes have the same number of syllables even if their words are different, we use a sequence of word syllable counts on each lyric line. For example, the word syllable counts of the two lyric lines *"Sometimes you lost yourself away"* and *"Everytime you just close your eyes"* [2] are {2, 1, 1, 2, 1} and {2, 1, 1, 1, 1, 1}, respectively. When successive lyric lines have similar syllable count sequences, they are likely to correspond to the repetition of sections. We use dynamic time warping (DTW) [48] to calculate the similarity between syllable count sequences.

Figure 2. Convolutional neural network for SSMs.

Lyric Line syllable count similarity (sim_{syL}): We can also use the total syllable count of all words in each lyric line. For example, in all the chorus sections shown in Figure 1, the total syllable count of the first lyric line is 6 and that of the second line is 8. We calculate the similarity of such total syllable counts of each pair of lyric lines by using the following procedure. (1) We extract a window of four lyric lines $L_t = \{x_t, x_{t+1}, x_{t+2}, x_{t+3}\}$ and shift it over the entire lyrics of a song. (2) The similarity between the lyric lines x_t and $x_{t'}$ is calculated by DTW of L_t and $L_{t'}$.

We thus calculated nine SSMs $\mathbf{A}_m \in \mathbb{R}^{T \times T}$, where each cell is a sim_m explained above. Then, to calculate feature vectors from the above nine SSMs, we exploit a convolutional neural network (CNN) architecture to detect textual macro structures from various patterns in SSMs regardless of their locations and relative sizes in SSMs. Except for network parameters, this CNN architecture is the same as that of Fell et al. [18], as we share the same motivation: to extract translation, scaling and rotation invariant features from the input image (in our case, nine SSMs).

Figure 2 illustrates the CNN structure. After calculating the nine SSMs, we extract fixed-size elongated-rectangle sub-matrices centered on the target lyric line: $\mathbf{a}_m^t = \mathbf{A}_m[t - w + 1, ..., t + w; 1, ..., T] \in \mathbb{R}^{2w \times T}$, where w is a fixed window size. The input of the CNN is nine sub-matrices $\{\mathbf{a}_{str}^t, ..., \mathbf{a}_{syL}^t\} \in \mathbb{R}^{2w \times T \times 9}$, where the number of channels corresponds to the number of SSMs. The kernel size of the first 2D-convolutional layer is $(w + 1) \times (w + 1)$ so that each feature can capture a prospective chorus section. Each resulting tensor is downsampled by max-pooling with $w \times w$ kernel size. We then apply the 1D-convolutional layer with a kernel size of w and the last max-pooling layer downsamples the resulting vector to a scalar. In this network, all convolutional layers employ the ReLU function. We can perform the above procedure independently for each lyric line x_t and obtain the CNN-based feature vector $\boldsymbol{v}_t$.

3.2 Linguistic Features

Some expressions tend to appear in chorus sections. To quantify this tendency, we calculate the difference between

Tri-gram	$P_c - P_n$	Tri-gram	$P_n - P_c$
I'm	0.12%	there's	0.04%
don't	0.11%	I've	0.03%
oh oh oh	0.05%	's a	0.03%
I'll	0.05%	I'd	0.02%
we're	0.04%	but I'	0.02%
you're	0.04%	's not	0.01%
'll be	0.04%	what's	0.01%
I don'	0.04%	na na na	0.01%
Let's	0.03%	yeah yeah yeah	0.01%
you got ta	0.03%	've been	0.01%
I can'	0.03%	't take	0.01%
can't	0.03%	didn't	0.01%

Table 1. Frequent word tri-grams in chorus and non-chorus sections. An apostrophe is regarded as a word.

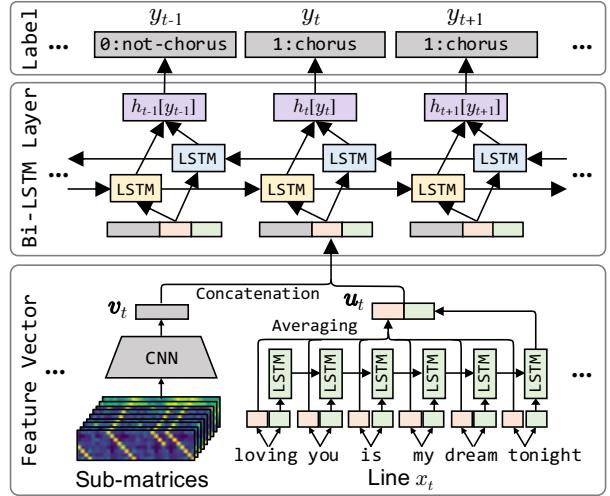
word tri-gram probabilities in the chorus and non-chorus sections. Table 1 shows the word tri-grams that frequently appear in both of the sections. Here, P_c and P_n denote word tri-gram probabilities in the chorus and non-chorus sections, respectively. As shown in this table, we found that phrases about the future (e.g., *"I'll"* and *"Let's"*) tend to appear in chorus sections more often than do phrases about the past (e.g., *"have been"* and *"didn't"*). To exploit such tendencies, we propose two linguistic features.

Average of word vectors ($ling_{ave}$): We use the average of word vectors of a given lyric line as a feature. The word vectors are obtained using pre-trained word2vec [42], skipping out-of-vocabulary words.

Vector representations for word sequences ($ling_{seq}$): To consider the word order that cannot be modeled by $ling_{ave}$, we use pre-trained context2vec [43] that enables vectorization of a lyric line by putting a sequence of word vectors into the LSTM.

We calculate the above linguistic feature vectors for each lyric line x_t and obtain their concatenated vector $\boldsymbol{u}_t$.

3.3 Neural Network-based Sequence Labeling Model

To solve the sequence labeling problem, we use the standard Bidirectional Long Short-Term Memory (Bi-LSTM) networks [49] to compute the conditional probability $P(Y_s|X_s)$. The neural network structure is illustrated in Figure 3.


The input to the Bi-LSTM layer at each time step t (lyric line) is a concatenation of two different types of feature vectors: (1) structural feature vectors $\boldsymbol{v}_t$ encoded from nine variations of SSMs in Section 3.1 and (2) linguistic feature vectors $\boldsymbol{v}_t$ encoded in Section 3.2. Formally, the conditional probability $P(Y_s|X_s)$ is calculated by using a softmax function:

$$P(Y_s|X_s) = \frac{\exp(\text{Score}(X_s, Y_s))}{\sum_{Y_s'} \exp(\text{Score}(X_s, Y_s'))}. \quad (1)$$

The Score() is defined as

$$\text{Score}(X_s, Y_s) = \sum_t \text{BN}(h_t[y_t]), \quad (2)$$

where $h_t[y_t]$ is the output of the Bi-LSTM for each time step t and BN() denotes batch normalization [50]. In the model training step, we use a binary cross-entropy loss.

Figure 3. Neural-network-based sequence labeling model for chorus-section detection.

4. EXPERIMENT

Inspired by audio-based chorus-section detection [39], we evaluated the proposed method by using the F-measure (F) that is a harmonic mean of precision (P) and recall (R), $F = (2 \cdot R \cdot P)/(R + P)$, where

$$P = \frac{\text{\# of lyric lines in correctly detected chorus sections}}{\text{\# of lyric lines in detected chorus sections}}.$$

$$R = \frac{\text{\# of lyric lines in correctly detected chorus sections}}{\text{\# of lyric lines in correct (annotated) chorus sections}}.$$

We also used the pair-wise F-measure (p-F), normalized conditional entropy F-measure (n-F) and V-measure (V) that are provided by the Python module `mir_eval` and commonly used to evaluate computational music structure analysis [51].

4.1 Methods Compared

To confirm the effectiveness of our Bi-LSTM method based on the Bi-LSTM model that can learn dependencies between adjacent lyric lines, we compared its performance with that of with two baseline methods:

(1) Heuristic: We implemented the heuristic that "if lines at the end of the lyrics are repeated with small modifications, all those repeated lines are chorus sections" by the following procedure: (i) From the SSM that is the average of the nine SSMs, we extracted diagonals whose cells had values higher than a threshold λ, which was tuned on a development set to be $\lambda = 0.62$. (ii) From the extracted diagonals, we selected the shortest diagonal among diagonals placed at the bottom of the SSM (e.g., the diagonal starting at the cell $\text{SSM}[29; 1]$ in Figure 1). (iii) Successive lines corresponding to the rows where the selected diagonal was located (e.g., lyric lines 29–32 in Figure 1) were assigned the label `chorus`. (iv) Other successive lines that were similar to the `chorus` lines (e.g., lyric lines 1–4 and 13–16 in Figure 1) were also assigned `chorus` labels.

(2) Multi-Layer Perceptron (MLP): Like the Bi-LSTM method, but with the Bi-LSTM model replaced by a standard MLP model. This method ignores transitions between adjacent lyric lines and predicts y_t from x_t only.

We chose the number of kernels for the first and second CNNs to be 200 and 400, respectively. We used $w = 3$ for the window size. In the MLP and Bi-LSTM methods, we chose the dimension of the hidden state to be 600. The word2vec [42] and context2vec [43] were pre-trained on lyrics and were not updated in the model training step of our method. The dimension of their output vectors was 300. We used AdamW for parameter optimization [52]. The initial learning rate was 0.001 with an exponential decay. We used a mini-batch size of 64. Training was run for 100 epochs, and the model used for testing was the one that achieved the best F-measure on the development set.

4.2 Dataset

To train our computational model that predicts whether the label of each lyric line is `chorus` or `not-chorus`, we needed a large amount of lyrics data with line-level chorus-section annotations like those illustrated in Figure 1. Since there was no dataset for this, we generated a large amount of such lyrics data by the following procedure:

(1) We prepared 100,772 pairs of musical audio signals and their corresponding manually time-aligned (temporally synchronized) lyrics [3] . To avoid unreliable lyrics, we confirmed that all lyrics had more than eight lines and less than 120 lines.

(2) We detected chorus sections of every song automatically by using its audio signals. In our experiments, we used the RefraiD method [39] to obtain the start and end times of each chorus section, but other methods could also be used.

(3) If the start time of a lyric line was within any chorus section detected in audio signals, that line was labeled `chorus`; otherwise, it was labeled `not-chorus`.

Of course, not all generated annotations were correct, but by using over 100,000 training data, the model could be robustly trained without being influenced by errors or outliers. The generated training data consisted of 9,313 English and 91,459 Japanese songs, and we called them EN_auto and JA_auto, respectively. [4]

Furthermore, we manually annotated three sets of lyrics data with more reliable line-level chorus-section annotations for three different purposes:

(a) For training comparison: We annotated 1,103 Japanese lyrics and called them JA_man [5] . By comparing the performance of the model trained on JA_auto with that of the model trained on JA_man, we could confirm that our generated data is reliable enough for training purposes.

(b) For tuning model parameters: We annotated the lyrics of 21 English and 79 Japanese songs from RWC-MDB-P-2001 and called them EN_RWC and JA_RWC,

| Method | Training data / Testing data | | | | | | | |
| | EN_auto / EN_test | | | | JA_auto / JA_test | | | |
	F	p-F	n-F	V	F	p-F	n-F	V
Heuristic	57.8	73.8	43.0	35.8	57.1	73.2	43.6	36.3
MLP	74.2	76.8	47.7	43.0	80.6	82.8	62.6	59.1
Bi-LSTM	**78.1**	**77.7**	**50.8**	**47.3**	**83.4**	**83.5**	**64.9**	**61.4**

Table 2. Experimental result: Comparison of different methods (the unit is %).

| Feature | Training data / Testing data | | | | | | | |
| | EN_auto / EN_test | | | | JA_auto / JA_test | | | |
	F	p-F	n-F	V	F	p-F	n-F	V
sim_{all}	77.9	76.1	48.6	45.5	81.2	82.7	63.6	59.6
$ling_{all}$	57.4	59.9	16.5	6.9	55.2	61.8	22.1	16.7
both	**78.1**	**77.7**	**50.8**	**47.3**	**83.4**	**83.5**	**64.9**	**61.4**

Table 3. Experimental result: Importance of using both structural and linguistic features.

respectively. These were used to tune model parameters. **(c) For testing**: We annotated the lyrics of 118 other English songs and 128 other Japanese songs and called them EN_test and JA_test, respectively [6] . These were used to test the chorus-section detection methods.

4.3 Comparison of Different Methods

Table 2 summarizes the evaluated performances of Heuristic, MLP and the proposed Bi-LSTM. We found that MLP and Bi-LSTM performed better than Heuristic. This indicates that methods based on supervised learning are better than a rule-based method. We also found that Bi-LSTM was better than MLP and thus confirmed the importance of learning dependencies between adjacent lines. Since we concluded from these results that the proposed Bi-LSTM is the best for the chorus-section detection task, in the subsequent experiments reported here we used only Bi-LSTM.

4.4 Importance of Using Both Structural and Linguistic Features

To investigate the effectiveness of structural and linguistic features, we compared their use individually and in combination. Table 3 summarizes the results. We found that the model with only the structural features sim_{all} greatly outperformed the model with only the linguistic features $ling_{all}$. Using both kinds of features further improved the performance. This not only confirms the importance of using SSMs, as had been shown for the audio-based detection of chorus sections, but also confirms that the additional use of linguistic features is helpful for detecting chorus sections, which has not been shown before.

4.5 Reliability of Generated Annotations

As stated in Section 4.2, we used JA_man for the proposed training comparison. Table 4 clearly shows that the model trained using JA_auto, automatically generated data the amount of which can be large, outperformed the model trained using JA_man, manually annotated data, the amount

---

[3] In our experiments, English and Japanese lyrics text as well as the start time of every lyric line were provided by a lyrics distribution company. Automatic lyrics-to-audio synchronization [7–17] could also be used to estimate such start times.

[4] The main genres are Rock (33%), Pop (25%) and Alternative (12%) for EN_auto, and J-Pop (53%), Rock (20%) and Anime (9%) for JA_auto.

[5] To investigate the accuracy of the automatic annotation method we used for generating EN_auto and JA_auto, we applied the same method to the songs (audio signals and corresponding manually time-aligned lyrics) in JA_man. The accuracy of the generated annotations was $F = 68.0\%$, thus the automatic annotation method seems to work decently well.

[6] The `chorus` and `not-chorus` labels were annotated only on the lyrics. No audio signal is available for these test data.

Training data	F	p-F	n-F	V
JA_auto (91,459 songs)	**83.4**	**83.5**	**64.9**	**61.4**
JA_man (1,103 songs)	80.3	77.3	53.3	50.4

Table 4. Experimental result: Reliability of automatically generated annotations.

Training data	Testing data	F	p-F	n-F	V
EN_auto (9,313 songs)	EN_test	77.9	76.1	48.6	45.5
JA_auto (91,459 songs)	EN_test	80.3	80.6	58.1	54.4
EJ_auto (100,772 songs)	EN_test	**81.0**	**82.3**	**60.7**	**57.4**

Table 5. Experimental result: Can the Japanese model detect English chorus sections?

of which is usually very limited because of the laborious manual effort its creation requires. The results also confirm that even if annotations generated automatically are not perfect they are reliable enough for training the model.

4.6 Training Data Size and Language Dependency

Tables 2 and 3 also show that the performances for English lyrics were worse than those for Japanese lyrics. Since the amount of Japanese training data was about 10 times than that of English training data, we think that the amount of training data greatly affects the performance of the proposed model. We are thus interested in answering the question "Can a model trained on a large amount of Japanese data detect English chorus sections?" In fact, although linguistic features are language dependent and the process of computing SSMs is also language dependent, structural features based on the resulting SSMs can be language independent because our SSMs simply represent patterns of repeating lyric lines, which could be universal in music.

As shown in the upper half of Table 5, which shows results obtained without using linguistic features, we found that the structural-feature-based model trained on Japanese data JA_auto succeeded in detecting English chorus sections in EN_test and its performance was better than that of the model trained on the smaller dataset EN_auto. This result indicates that the SSM-based model trained on a large amount of data can detect chorus sections regardless of the language of the test set. Moreover, this result is further evidence that Japanese and English SSMs (i.e., patterns of repeating lyric lines) have similar structures.

Obviously, the above result raises another question: "Can a model trained on both EN_auto and JA_auto perform better than one trained on only EN_auto or JA_auto?" To answer this question, we created training data EJ_auto by including both EN_auto and JA_auto and constructed yet another structural-feature-based model with EJ_auto. As shown in the lower half of Table 5, we found that the model trained on both languages performed better than the model trained on only one.

These results confirm that chorus sections can be detected by a model trained on data in another language, that patterns of repeating lyric lines are language-independent and that mixing different language data allows the model to learn the general structure of chorus sections and thereby

perform better. This could have an impact on low-resource languages because large-scale training data can be created by mixing other available language resources.

5. RELATED WORK

Previous work in the MIR community has addressed musical structure analysis and chorus-section detection based on repeated patterns in musical audio signals [23–41]. Studies in the chorus-section detection for audio signals typically used SSMs to capture repeated structures, and we share this motivation. Our approach differs from those audio-based approaches in that it exploits multiple lyrics-based SSMs and linguistic features within chorus sections.

On the other hand, recent work in the NLP community has tackled lyrics segmentation and summarization tasks by exploiting SSMs. Fell et al. and Watanabe et al. proposed a neural network model and logistic regression model for segmenting paragraphs (sections) without labeling them by using SSMs as features [18, 19]. Those tasks, however, are essentially different from detecting all chorus sections that are the most representative sections in lyrics text. Addressing a task similar to chorus-section detection, Fell et al. [53] proposed a method of summarizing lyrics by combining general document summarization methods with audio thumbnailing methods. They focus on extracting individual informative lines as a summary from lyrics text, not redundant repeated lines. On the other hand, the focus of our paper is to detect chorus sections whose successive lines are often repeated in lyrics text.

6. CONCLUSION

This paper has addressed the novel task of detecting chorus sections in English and Japanese lyrics. We proposed a neural-network-based sequence labeling model that learns structural (i.e., phrase-repetition) and linguistic features to detect lyric lines of chorus sections. We also generated over 100,000 training data with chorus-section annotations. No previous work has ever conducted chorus-section detection for text-only lyrics with this much data.

The contributions of this study are summarized as follows: (1) We designed a variety of features to capture structural and linguistic properties of chorus sections. (2) We proposed a sequence labeling model that can detect chorus sections in lyrics. (3) We showed how to generate a large training dataset of lyrics with chorus-section annotations. (4) We demonstrated that our Bi-LSTM-based method outperforms alternative baseline methods. (5) We thoroughly investigated this detection task and the nature of chorus sections of lyrics from different perspectives such as the importance of features, the amount of training data, and language dependency.

We plan to extend our method to detect other sections, such as verse and bridge sections. Future work will also develop MIR applications using our method, such as those discussed in Section 1.

CHORD JAZZIFICATION:
LEARNING JAZZ INTERPRETATIONS OF CHORD SYMBOLS

ABSTRACT

Chord symbols, typically notating the root note and the chord quality, are extensively used yet oversimplified representation of tonal harmony and chord progressions in popular music. In spite of its convenience, the chord symbol notation only provides basic information about the chordal configuration, and leaves much room for interpretation. With such limitations, an algorithm generating merely chord symbols is usually insufficient for a wide range of music genres such as jazz. To solve this problem, we propose *chord jazzification*, a process to generate realistic chord configurations in jazz style. With deep learning approaches, we decompose chord jazzification into *coloring* and *voicing*. Coloring concerns the choice of color tones, while voicing concerns the configurations of chords. We also create a new dataset featuring interpretations of chord symbols in pop-jazz compositions. By conducting experiments on the new dataset, we show that 1) the two-stage process outperforms an end-to-end generation approach in modeling chord configurations, and 2) attention-based models are better at capturing the structure of chord sequences in comparison with recurrent neural networks.

1. INTRODUCTION

Harmony and chords are the central topic in the study of tonal music. To facilitate the study, researchers in the fields of music information retrieval (MIR) and computational musicology have developed various techniques, such as automatic chord recognition [1–5], chord similarity and tonal distance [6–9], harmonic analysis [10–13], and chord generation [14–16].

Most of these aforementioned techniques process the chord data using *chord symbol* representation, i.e., a symbolic notation system indicating the root note, quality, and other additional information of the chord. For example, the chord symbol `C:7` stands for the C dominant seventh chord in root position, whose theoretical configuration is

Figure 1: Three configurations of the C dominant seventh chord. In music theory, the C dominant seventh chord in root position is configured as (a). (b) and (c) are two alterations of the chord.

depicted in Figure 1a. This symbol, however, does not explicitly point out the actual configuration, e.g., every specific note performed by a musician. Hence, the notation system is limited in describing the nuances in real-world performance. Learning to interpret the chord symbols is challenging in two aspects. First, expert musicians often *color* a chord by adding notes to, or omitting notes from the chord according to the musical context, although the chord symbol itself does not specify such alterations. Second, chords composed of the same set of pitch classes can be *voiced* differently by spacing and doubling the chord tones. Take the *comping* technique in jazz music as an instance.[1] Instead of sticking to the typical configuration of a chord, a jazz pianist may play the C dominant seventh chord with the configuration shown in Figure 1b, in which the 5th of the root, `G4`, is omitted, and the 9th of the root, `D5`, is added; while another jazz pianist may arrange these notes in a totally different way as demonstrated in Figure 1c, where `Bb` is doubled and `D` is spaced a register lower. In fact, the way how musicians interpret chord symbols in a given context involves not only their thorough understanding of various musical styles, but also their personal tastes. Therefore, to generate the realization of chord symbols through MIR approaches is a challenging yet valuable task, despite this topic is rarely discussed possibly because of the lack of data.

In this paper, we propose *chord jazzification*, a process to realize chord symbols with jazz harmony through deep learning approaches. Based on the two aforementioned aspects of interpreting the chord symbols, the chord jazz-

---

[1] Comping means accompanying or complementing a soloist by playing the chords to fill the harmonic and rhythmical vacancies in the music.

Chord Symbol	Db:M	$\frac{\text{Db:M}}{\text{F}}$	Gb:M7	$\frac{\text{D:M}}{\text{E}}$	$\frac{\text{Bb:m7}}{\text{Eb}}$	Eb:m7	Ab:7	G:dim	F:m7

Structure: Metrical Position	0	2	0	3	0	1	2	3	0

Figure 2: Annotations of the proposed dataset. *Chord Symbol* specifies the root and the quality of each chord (a bass note is explicitly notated with a slash when it is not the root note), e.g., `Db:M/F` stands for a Db major triad with the bass note `F`. *Time* indicates the *onset* and the *duration* (measured in beats) of each chord. *Voicing* represents the configuration of each chord with a set of scientific pitch notations. *Coloring* indicates the chord degrees which appear in the voicing but are not specified by the chord symbol, and vice versa, e.g., `(o1,9)` indicates that the root is omitted and the 9th is added. Note that `7` is explicitly qualified by {`M`, `m`, `d`} (major, minor, diminished) to disambiguate its interval. *Roman Numeral Analysis* denotes the scale degree on which a chord is built, as well as the quality and the inversion information, e.g., `V7` stands for a dominant seventh chord in root position. *Structure* includes the annotations of *phrase*, *measure* and *metrical position*. To specify the phrase a chord belongs to, each chord is labeled with a letter plus a number in a way similar to musical form analysis. Metrical position shows the position of a chord with respect to the metric grid (starting with 0).

ification task is formulated as two subtasks, namely the *chord coloring* and the *chord voicing*. The chord coloring task decides which pitch classes are to be played for elaborating a chord symbol, while the chord voicing task deals with the spacing and the doubling of the pitch classes to be played. Although the jazzification of chord progressions is not limited to coloring and voicing, we focus on the two aspects for the primary study. To facilitate the research on chord jazzification, we also compile a new dataset consisting of chord symbols and corresponding chord configurations in pop-jazz compositions. In comparison with other jazz-related datasets, such as the Charlie Parker's Omnibook data [17], the Jazz Audio-Aligned Harmony (JAAH) dataset [18], the JazzCorpus [19], and the Weimar Jazz Database [20], our dataset includes more detailed information of chords, especially the chordal configuration. With the newly compiled dataset, we conduct several experiments to verify the two-stage framework for chord jazzification. Experiment results indicate that it is effective to decompose chord jazzification into coloring and voicing, rather than to adopt an end-to-end approach.

The current work is different from the accompaniment or harmonization tasks [21,22], in terms of that such works require melodies as prior knowledge and regard chords as appendages to melodies. Besides, our work concerns both the voicings of a chord sequence and the interpretation of each single chord, thus is distinct from the voice leading generation task [23,24]. The jazzification of a chord progression is part of the music composition process to expand

a tonal structure, i.e., the *prolongation* described in Heinrich Schenker's music theory [25]. Chord jazzification can advance other MIR-related tasks such as style analysis and chord generation [26–29]. We hope that our work can draw more attention to the musical knowledge regarding the implicit relations between the notated chord symbols and the actual harmony being performed.

In summary, our contribution is threefold. First, we address the issue of interpreting chord symbols by chord jazzification. Second, we compile a new dataset for the generation of jazzy harmony and for the study of chord embellishments. Finally, a deep learning framework is proposed to generate jazz-style chord progressions. In the following, we will first present the new dataset (Section 2), and then formulate the framework of chord jazzification (Section 3); based on the framework, several experiments are introduced thereon (Section 4).

2. THE CHORD JAZZIFICATION DATASET

The corpus is composed of 50 musical pieces selected from published Japanese pop-jazz piano solos, in which chord symbols are explicitly specified.[2] To obtain the corresponding voicing of each chord symbol, we manually perform harmonic reduction for each piece. Concretely, notes within the region of a chord symbol are selected to build the configuration of the chord symbol. With the chord

---

[2] The dataset is available at `https://github.com/Tsung-Ping/Chord-Jazzification`.

Figure 3: Chord qualities and chord colorings in the proposed dataset (the long tail of the coloring distribution is left out). Chord degrees of compound intervals are merged with simple ones in the coloring figure for simplicity.

symbols and the transcribed voicings, coloring and harmonic information are annotated. Specifically, there are six types of annotations in the dataset: *Chord Symbol*, *Time*, *Voicing*, *Coloring*, *Roman Numeral Analysis* [10, 30], and *Structure*. Figure 2 gives an example.

A brief introduction of the chord qualities and colorings used in the corpus is illustrated in Figure 3. Not surprisingly, the three seventh chords, major seventh (M7), minor seventh (m7), and dominant seventh (7), account for more than half of the chords, as jazz harmony is notable for the use of seventh chords. On the other hand, characteristic colorings of pop-jazz music can also be found in many chords, such as adding a major second or a compound major second (2) and omitting the perfect fifth (o5).

In summary, 796 musical phrases amounting to 6700 chord labels are included in the dataset. These annotations provide information concerning the relationship between the symbolic notation and the actual configuration of chords in human compositions. It therefore has the potential to be applied to many MIR-related research topics, such as corpus-based study of tonal harmony in music practice, generation of colorful chord progressions, and computer-aided composition, to name but a few. It has to be acknowledged that the dataset has some limitations in describing an actual interpretation of chord symbols, in the sense that the transcription of chords eliminates the harmonic and rhythmical variances within the region of each chord symbol. Nevertheless, the dataset can be a starting point for performers and composers to learn to elaborate and develop a tonal structure through the chord jazzification process, which is relatively easier compared to learning the elaboration directly from a complete musical piece.

3. CHORD JAZZIFICATION

The goal of chord jazzification is to endow plain chords (e.g., a sequence of triads) with jazz harmony. We tackle the chord jazzification task through two successive steps, that is, coloring and voicing. The coloring part functions as an intermediate state which specifies chords in terms of pitch classes, and the voicing part assigns pitch heights to the specified pitch classes.

3.1 Coloring

In this paper, 48 triads in root position ({major, minor, augmented, diminished} by 12 semitones) are considered for coloring. We define the *chord coloring* task as predicting the bass note and the pitch classes to render each triad in a given sequence.

Formally, the input of the coloring task is a triad sequence $\{\mathbf{x}_i\}_{i=1}^T$ and a duration sequence $\{\mathrm{d}_i\}_{i=1}^T$, where i denotes time steps, T is the length of the sequence, $\mathbf{x}_i \in \mathbb{R}^{12}$ is a chroma representation of the ith triad, and d_i is the duration of $\mathbf{x}_i$. The coloring task predicts the bass sequence $\{\mathbf{b}_i^c\}_{i=1}^T$ and the pitch class sequence $\{\mathbf{p}_i^c\}_{i=1}^T$ for the input sequence, where c stands for coloring, $\mathbf{b}_i^c \in \mathbb{R}^{12}$ is a softmax-activated chroma vector indicating the 12 pitch classes' probabilities to be the bass of colored $\mathbf{x}_i$, and $\mathbf{p}_i^c \in \mathbb{R}^{12}$ is a sigmoid-activated chroma vector indicating the 12 pitch classes' probabilities to be the constituent notes (except the bass) of colored $\mathbf{x}_i$. For example, $\mathbf{b}_i^c = [0.8, 0, 0, 0, 0.2, 0, 0, 0, 0, 0, 0, 0]$ indicates the pitch classes C and E respectively have a probability of 80% and 20% to be the bass note, and $\mathbf{p}_i^c = [0, 0.9, 0, 0, 0.9, 0, 0, 0, 0, 0, 0.9, 0]$ suggests that there is a 90% chance that Db, E, and Bb are activated to render $\mathbf{x}_i$.

We employ a basic sequential learning architecture for the coloring task. As shown in Figure 4a, the architecture is composed of three layers: 1) an input embedding layer, 2) a sequential modeling layer, and 3) an output layer. Specifically, the three layers are formulated as follows:

$$
\begin{aligned}
\mathbf{e}_i^c &= \mathbf{W}^{e^c}(\mathrm{d}_i \mathbf{x}_i), \quad \text{(Input Embedding)} \\
\mathbf{h}_i^c &= f^c(\mathbf{e}_i^c \mid \mathbf{e}_{1:T}^c), \quad \text{(Sequential Modeling)} \\
\mathbf{p}_i^c &= \mathrm{sigmoid}(\mathbf{W}^{p^c}\mathbf{h}_i^c), \quad \text{(Output)} \\
\mathbf{b}_i^c &= \mathrm{softmax}(\mathbf{W}^{b^c}\mathbf{h}_i^c),
\end{aligned}
\tag{1}
$$

where $\mathbf{W}^{e^c} \in \mathbb{R}^{d\times 12}$, $\mathbf{W}^{p^c} \in \mathbb{R}^{12\times d}$, and $\mathbf{W}^{b^c} \in \mathbb{R}^{12\times d}$ are learnable parameters, $f^c : \mathbb{R}^d \to \mathbb{R}^d$ denotes a trainable neural network, and d is a hyperparameter indicating the dimensions of the embedding space. Two candidate networks are employed for the sequential modeling layer:

- Bi-directional Recurrent Neural Network with Long Short-Term Memory (BLSTM):

$$
\begin{aligned}
\mathbf{h}_i^c &= \overrightarrow{\mathbf{h}}_i^c \oplus \overleftarrow{\mathbf{h}}_i^c, \\
\overrightarrow{\mathbf{h}}_i^c &= \mathrm{LSTM}(\mathbf{e}_i^c \mid \mathbf{e}_{1:i-1}^c), \\
\overleftarrow{\mathbf{h}}_i^c &= \mathrm{LSTM}(\mathbf{e}_i^c \mid \mathbf{e}_{i+1:T}^c),
\end{aligned}
\tag{2}
$$

where $\oplus$ denotes vector concatenation.

Figure 4: (a) The coloring model. (b) The voicing model. (c) The two-stage chord jazzification model.

- Multihead Self-attention Network (MHSA):

$$\mathbf{h}_i^{c(l)} = \mathbf{W}^{outer}\sigma(\mathbf{W}^{inner}\mathbf{u}_i + \mathbf{b}_1) + \mathbf{b}_2,$$

$$\mathbf{u}_i = \mathbf{W}^u(\mathbf{u}'_{i1} \oplus \cdots \oplus \mathbf{u}'_{iJ}) + \mathbf{h}_i^{c(l-1)},$$

$$\mathbf{u}'_{ij} = \mathbf{V}_j \text{ softmax}\left(\frac{\mathbf{K}_j^\top \mathbf{q}_{ij}}{\sqrt{d}}\right),$$

$$\mathbf{q}_{ij} = \mathbf{W}_j^Q \mathbf{h}_i^{c(l-1)}, \qquad (3)$$

$$\mathbf{K}_j = \mathbf{W}_j^K[\mathbf{h}_1^{c(l-1)}, \cdots, \mathbf{h}_T^{c(l-1)}],$$

$$\mathbf{V}_j = \mathbf{W}_j^V[\mathbf{h}_1^{c(l-1)}, \cdots, \mathbf{h}_T^{c(l-1)}],$$

where l denotes the iteration step, and the initial value $\mathbf{h}_i^{c(0)} = \mathbf{e}_i^c$; σ represents the ReLU activation function; J is the number of heads; $\mathbf{W}_j^{outer} \in \mathbb{R}^{d \times 4d}$, $\mathbf{W}_j^{inner} \in \mathbb{R}^{4d \times d}$, $\mathbf{W}^u \in \mathbb{R}^{d \times d}$, and $\mathbf{W}_j^Q, \mathbf{W}_j^K, \mathbf{W}_j^V \in \mathbb{R}^{\frac{d}{J} \times d}$ are learnable parameters. This network is equivalent to the encoder of the Transformer [31], while we leave out layer normalization and position encoding terms for simplicity. In this paper, we set $d = 512$, $l = 2$, and $J = 8$.

The binary cross entropy (BCE) and the categorical cross entropy (CCE) are used to calculate the losses. Let $\mathbf{p}_i^{c*}$ and $\mathbf{b}_i^{c*}$ denote the ground truths of $\mathbf{p}_i^c$ and $\mathbf{b}_i^c$; the total loss of the coloring model $\mathcal{L}^c$ is defined as:

$$\mathcal{L}^c = \sum_{i=1}^T \left[\text{BCE}(\mathbf{p}_i^{c*}, \mathbf{p}_i^c) + \text{CCE}(\mathbf{b}_i^{c*}, \mathbf{b}_i^c)\right]. \qquad (4)$$

3.2 Voicing

We define *chord voicing* as a task which predicts the voicings of a chord sequence. Formally, given a chord sequence of T time steps in terms of their basses $\{\mathbf{b}_i^v\}_{i=1}^T$, constituent pitch classes $\{\mathbf{p}_i^v\}_{i=1}^T$, and durations $\{d_i\}_{i=1}^T$, the task predicts the voicings $\{\mathbf{v}_i\}_{i=1}^T$ for the chord sequence, where v stands for voicing, $\mathbf{b}_i^v \in \mathbb{R}^{12}$ is a one-hot chroma vector indicating the bass of the ith chord,

$\mathbf{p}_i^v \in \mathbb{R}^{12}$ is a multi-hot chroma vector representing the pitch classes of the ith chord except the bass note, and $\mathbf{v}_i \in \mathbb{R}^{88}$ is a voicing vector indicating the 88 tones' probabilities to be played on the piano.

Similar to the coloring task, we employ a 3-layer architecture for the voicing task, as shown in Figure 4b. The three layers are formulated as follows:

$$\mathbf{e}_i^v = \mathbf{W}^{e^v}(d_i(\mathbf{p}_i^v \oplus \mathbf{b}_i^v)), \quad \text{(Input Embedding)}$$

$$\mathbf{h}_i^v = f^v(\mathbf{e}_i^v \mid \mathbf{e}_{1:T}^v), \quad \text{(Sequential Modeling)} \qquad (5)$$

$$\mathbf{v}_i = \text{sigmoid}(\mathbf{W}^v \mathbf{h}_i^v), \quad \text{(Output)}$$

where $\mathbf{W}^{e^v} \in \mathbb{R}^{d \times 24}$ and $\mathbf{W}^v \in \mathbb{R}^{88 \times d}$ are learnable parameters, and $f^v : \mathbb{R}^d \to \mathbb{R}^d$ is a neural network. Likewise, the BLSTM and the MHSA networks are two options for the sequential modeling layer.

Let $\mathbf{v}_i^* \in \mathbb{R}^{88}$ denote the target voicing of the ith chord; we define the loss as:

$$\mathcal{L}^v = \sum_{i=1}^T \text{BCE}(\mathbf{v}_i^*, \mathbf{v}_i). \qquad (6)$$

As the voicing task is to arrange the constituent notes of chords on an 88-key piano based on the given basses and the sets of pitch classes, the outcome of $\mathbf{v}_i^*$ can be known to a certain degree. More precisely, a note in $\mathbf{v}_i^*$ can be activated only if its pitch class is activated in $\mathbf{b}_i^v$ or $\mathbf{p}_i^v$. With this consideration, we design corresponding masks to modify the loss computation. Let $\mathbf{b}_i^{v'} \in \mathbb{R}^{88}$ and $\mathbf{p}_i^{v'} \in \mathbb{R}^{88}$ be the extensions of $\mathbf{b}_i^v$ and $\mathbf{p}_i^v$ to all octaves of the piano. Then, the loss constrained by the masks becomes:

$$\mathcal{L}^{v'} = \sum_{i=1}^T \text{BCE}(\mathbf{v}_i^*, \mathbf{m}_i \odot \mathbf{v}_i),$$

$$\mathbf{m}_i = \mathbf{b}_i^{v'} \vee \mathbf{p}_i^{v'}, \quad \text{(Mask)} \qquad (7)$$

where $\odot$ stands for the Hadamard product, and $\vee$ denotes the logical OR operator.

363

3.3 Two-stage Chord Jazzification

We stack the chord voicing model on the top of the chord coloring model by setting $\mathbf{b}_i = \mathbf{b}_i^v = \text{onehot}(\arg\max \mathbf{b}_i^c)$ and $\mathbf{p}_i = \mathbf{p}_i^v = \text{round}(\mathbf{p}_i^c)$, as illustrated in Figure 4c. In other words, the outputs of the coloring model are first converted into binary vectors, and then taken as inputs by the voicing model. Such an integrated model jazzifies chord progressions in two stages: first, for a given sequence of triads $\{\mathbf{x}_i\}_{i=1}^T$ and the corresponding durations $\{\mathbf{d}_i\}_{i=1}^T$, the coloring model generates a colored sequence represented by $\{\mathbf{b}_i\}_{i=1}^T$ and $\{\mathbf{p}_i\}_{i=1}^T$; based on the colored sequence, the voicing model subsequently generates a voiced chord progression $\{\mathbf{v}\}_{i=1}^T$.

4. EXPERIMENTS

4.1 Chord Jazzification with Supervised Learning

With the formulations of chord jazzification as multi-class classification (for $\mathbf{b}_i^c$) and multi-label classification (for $\mathbf{p}_i^c$ and $\mathbf{v}_i$) problems, we train the coloring and voicing models using the new dataset, and perform 4-fold cross validation. For the coloring task, the input triad sequences and the input duration sequences are respectively derived from the *Chord Symbol* and the *Time* annotations of the dataset, while the ground truths of the bass sequences and the pitch class sequences are obtained from the *Voicing* labels. As for the voicing task, the duration sequences and the ground truth labels of the coloring task are taken as the inputs, while the *Voicing* labels are used as the ground truths of the output sequences. We augment the training set through transposing the data from 4 semitones down to 5 semitones up (within the valid range of the piano), leading to 10 times the training data. As a result, there are 5970 and 199 sequences for training and testing respectively.

Evaluation results are shown in Table 1. For both the coloring and voicing tasks, the employment of either the BLSTM or the MHSA as the sequential modeling layers yields comparable performance to the other, while the MHSA appears to surpass the BLSTM in cases of multi-label classification, i.e., the predictions of pitch classes and voicing. When the input embedding layers in the two sub-tasks are removed, all the performances decrease by from 3.19% to 4.69%. This indicates that the transformation to dense vectors benefits the learning process when the input data is sparsely represented. Moreover, the introduction of the input-related masks to the loss calculation in Eqn (7) also improves the modeling of voicing; precisely, the F1 score increases 2.66% if the masks are utilized. It is worth noting that the amount of training data is quite limited, and therefore the performance seems to be satisfactory in the current experimental setting.

4.2 End-to-end Chord Jazzification

To motivate the decomposition of chord jazzification into 2 stages, we train a chord jazzification model in an end-to-end manner for comparison. Technically, we replace the output module of the coloring model with that of the voicing model; and we employ a 2-layer BLSTM, rather than

Model	Coloring		Voicing
	Bass	Pitch Classes	
BLSTM	**81.87**	76.52	63.64
MHSA	80.78	**77.02**	**64.86**
BLSTM w/o E	77.18	73.33	60.12
BLSTM w/o M	-	-	60.98
End-to-End	-	-	37.87

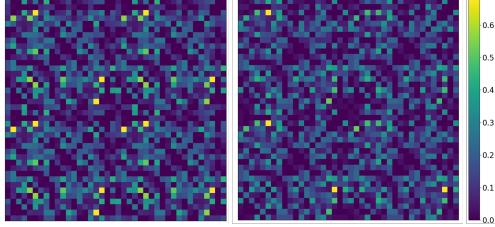
Table 1: Results of the coloring and the voicing tasks. The lower part shows the ablation tests without the embedding layer (w/o E) and without masks (w/o M), as well as the result using end-to-end training. All the values indicate the average F1 scores (%) over 4 validations.

a 1-layer BLSTM as defined in Eqn (2), for the sequential modeling layer in order to make the number of parameters comparable to the two-stage chord jazzification model. The evaluation result is shown in Table 1.

In this end-to-end architecture, the performance drops substantially to nearly half of the value. This result conversely validates the two-stage approach. Given the fact that the prediction of polyphony is often challenging, it turns out to be beneficial to generate an intermediate stage, that is, the chroma representations with respect to coloring, before the overall jazzification of chords.

4.3 Consistency of Chord Jazzification

Chord progressions often have a repetitive structure, therefore it is important for a model to preserve this property and generate chord sequences of self-consistency. To measure the consistency of a model's generations, we compute the self-similarity matrices (SSMs) of each generated voicing sequence and corresponding label sequence, and then calculate the difference between each generation-label SSM pair. Let $\overline{\mathbf{V}} = [\overline{\mathbf{v}}_1, \cdots, \overline{\mathbf{v}}_T]$ denote the normalized voicing sequence generated by a model, and $\overline{\mathbf{V}}^* = [\overline{\mathbf{v}}_1^*, \cdots, \overline{\mathbf{v}}_T^*]$ denote the normalized label sequence, where $\overline{\mathbf{v}}_i = \frac{\text{round}(\mathbf{v}_i)}{\|\text{round}(\mathbf{v}_i)\|}$ is a binarized and normalized voicing, and $\overline{\mathbf{v}}_i^* = \frac{\mathbf{v}_i^*}{\|\mathbf{v}_i^*\|}$ is a normalized target voicing; we define the consistency score (CS) of a generated sequence as follows:

$$\begin{aligned}
\text{CS} &= 1 - \text{reduce\_mean}(\Delta\text{SSM}), \\
\Delta\text{SSM} &= |\text{SSM}_{pred} - \text{SSM}_{label}|, \\
\text{SSM}_{pred} &= \overline{\mathbf{V}}^\top \overline{\mathbf{V}}, \\
\text{SSM}_{label} &= \overline{\mathbf{V}}^{*\top} \overline{\mathbf{V}}^*.
\end{aligned} \quad (8)$$


The more similar the structures of the two sequences are, the higher the CS score is.

Table 2 shows the average consistency score over 4 cross-validation folds. To provide a benchmark for the consistency measure, we also show the CS score computed from label sequences and randomly-generated sequences (denoted as *RANDOM*). Both the two models get higher scores than the random condition, indicating that they learn some structural information. Besides, the MHSA outperforms the BLSTM due to an essential difference between them: the BLSTM processes each time step of a

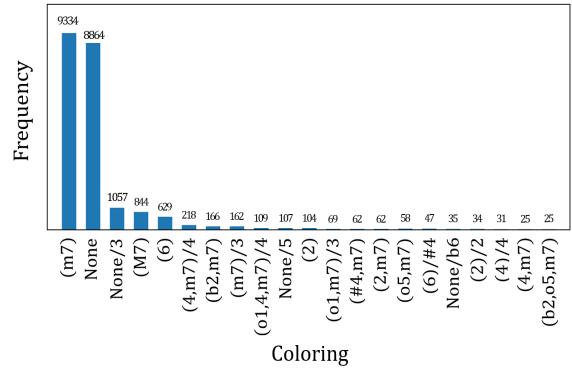
Model	BLSTM	MHSA	RANDOM
CS Score (%)	86.91	**87.68**	72.80


Table 2: Consistency measure of chord jazzification.

Figure 5: The difference of self-similarity matrices. Left: ΔSSM of the BLSTM. Right: ΔSSM of the MHSA. The origin of the matrices is at the lower left corner.

sequence recurrently, while the MHSA accesses the entire sequence simultaneously. As a result, the MHSA can capture more structural features than the BLSTM does, leading to more consistent generations. Two examples of the ΔSSM are demonstrated in Figure 5. Evidently, there are fewer bright regions in the ΔSSM of the MHSA, indicating that the generation by the MHSA is structurally closer to the ground truth than that by the BLSTM.

4.4 Generating Jazz Harmony

We train the two-stage chord jazzification model using the proposed dataset, and generate jazzified chord progressions with input triad sequences derived from the JAAH dataset. [3] In total, 2210 sequences with 23199 chords were generated. To examine the effect of jazzification, we quantitatively analyze the difference between each input triad and its jazzified counterpart. Particularly, we are interested in changes with respect to chord coloring: 1) what notes are added to or omitted from a triad? 2) Is a note other than the root being chosen as the bass note?

The result is represented in Figure 6. Around 40% of the input triads are embellished with a minor seventh (`m7`). And the addition of a major seventh (`M7`) also accounts for around 3.6%, ranked in the top fourth. These frequent colorings with a major or minor seventh reflect the characteristics of jazz music in which most triads that appear in lead sheets or fake books can have sevenths added to them. Moreover, extended chords and inverted chords can also be found. For instance, the coloring (`b2,m7`) for a major triad will lead to a dominant seventh flat ninth chord; and the coloring `None/3` indicates the first inversion of triads. It is worth mentioning that some generated slash chords are not inverted chords. An example is shown in the bottom of Figure 6. With the coloring (`2,M7`)`/2`, the last triad `Db:M` becomes `Db:M7/Eb`, which can be interpreted as an Eb dominant thirteenth chord—the dominant chord of the relative major mode (assuming `F` is the tonic). In other words, this coloring not only breaks the repetitive structure

---

Figure 6: Top: the coloring distribution of the generated chords (part of the distribution is omitted). Bottom: a generated example. A number after the slash symbol indicates the degree of the bass note relative to the root note.

of the input triad sequence, but also implies a new tonality. In addition to coloring, it can be observed that the linear progressions of voices are quite smooth, showing that the model also learns the knowledge of voice leading.

5. CONCLUSION

To learn the interpretation of chord symbols from musical data, we proposed chord jazzification, a process of generating realistic jazz-style chord progressions through two musical techniques: chord coloring and chord voicing. Chord coloring decides a bass and a set of pitch classes for elaborating a triad, while chord voicing arranges the bass and the set of pitch classes on the piano. We correspondingly built a dataset which includes coloring and voicing annotations, and hence can be used as the training data of the chord jazzification task. By formulating the chord coloring and chord voicing tasks as classification problems, we experimentally showed that the two-stage framework is capable of generating plausible chord configurations from a sequence of chord symbols.

Chord jazzification has the potential to be applied to two different yet related practices in music: performing and composing. For music performing, it is practical and desirable to interpret the chord symbols on lead sheets through jazzification. For music composing, the generated sequence by the chord jazzification model can be regarded as an intermediate product with which a musician can further create a human-machine collaborative musical work. In future research, we are planning to include more rhythmical and structural information, such as metrical position, to better represent the harmonic features, and apply more advanced deep learning techniques to improve the chord jazzification task.

ABSTRACT

The dominant approach for music representation learning involves the deep unsupervised model family *variational autoencoder* (VAE). However, most, if not all, viable attempts on this problem have largely been limited to monophonic music. Normally composed of richer modality and more complex musical structures, the polyphonic counterpart has yet to be addressed in the context of music representation learning. In this work, we propose the PianoTree VAE, a novel tree-structure extension upon VAE aiming to fit the polyphonic music learning. The experiments prove the validity of the PianoTree VAE via (i)-semantically meaningful latent code for polyphonic segments; (ii)-more satisfiable reconstruction aside of decent geometry learned in the latent space; (iii)-this model's benefits to the variety of the downstream music generation.[1]

1. INTRODUCTION

Unsupervised machine learning has led to a marriage of symbolic learning and vectorized representation learning [1–3]. In the computer music community, the MusicVAE [4] enables the interpolation in the learned latent space to render some smooth music transition. The EC^2-VAE [5] manages to disentangle certain interpretable factors in music and also provides a manipulable generation pathway based on these factors. Pati *et al*. [6] further utilizes the recurrent networks to learned music representations for longer-term coherence.

Unfortunately, most of the success has been limited to monophonic music. The generalization of the learning frameworks to polyphonic music is not trivial, due to its much higher dimensionality and more complicated musical syntax. The commonly-adopted MIDI-like event sequence modeling or the piano-roll formats fed to either recurrent or convolutional networks have fell short in learn-

---

Figure 1: An illustration of the proposed polyphonic syntax.

ing good representation, which usually leads to unsatisfied generation results [7–9]. In this paper, we hope to pioneer the development of this challenging task. To begin with, we conjecture a proper set of **inductive bias** for the desired framework: (i)-a sparse encoding of music as the model input; (ii)-a neural architecture that incorporates the hierarchical structure of polyphonic music (i.e., musical syntax).

Guided by the aforementioned design principles, we propose PianoTree VAE, a hierarchical representation learning model under the VAE framework. We adopt a tree structured musical syntax that reflects the hierarchy of musical concepts, which is shown in Figure 1. In a top-down order: we define a `score` (indicated by the yellow rectangle) as a series of `simu_note` events (indicated by the green rectangles), a `simu_note` as multiple `note` events sharing the same onset (indicated by blue rectangles), and each `note` has several attributes such as *pitch* and *duration*. In this paper, we focus on a simple yet common form of polyphonic music—piano score, in which each note has only pitch and duration attributes. For future work, this syntax can be generalized to multiple instruments and expressive performance by adding extra attributes such as voice, expressive timing, dynamics, etc.

The whole neural architecture of PianoTree VAE can be seen as a tree. Each node represents the embedding of either a `score`, `simu_note`, or `note`, where a higher level representation has larger receptive fields. The edges are bidirectional where a recurrent module is applied to either encode the children into the parent or decode the parent to generate its children.

Through extensive evaluations, we show that PianoTree VAE yields semantically more meaningful latent representations and further downstream generation quality gains, on top of the current state-of-the-art solutions.

2. RELATED WORK

The complex hierarchical nature of music data has been studied for nearly a century (e.g. GTTM [10], Schenklerian Analysis [11], and their follow-up works [12–15]). However, the emerging deep representation-learning models still lack the compatible solutions to deal with the complex musical structure. In this section, we first review different types of polyphonic music generation in Section 2.1. After that, we discuss some popular deep music generative models indexed by their compatible data structure from Section 2.2 to Section 2.4.

2.1 Different Types of Polyphony

In the context of deep music generation, *polyphony* can refer to three types of music: 1) multiple monophonic parts (e.g., a four-part chorus), 2) a single part of a polyphonic instrument (e.g., a piano sonata), and 3) multiple parts of polyphonic instruments (e.g., a symphony).

The first type of polyphonic music can be created by simply extending the number of voices in monophonic music generation with some inter-voice constraints. Some representative systems belonging to this category include DeepBach [16], XiaoIce [17], and Coconet [18]. Music Transformer [19] and the proposed PianoTree VAE both focus on the generation of the second type of polyphony, which is a much more difficult task. Polyphonic pieces under the second definition no longer have a fixed number of "voices" and consist of more complex textures. The third type of polyphony can be regarded as an extension of the second type, and we leave it for future work.

2.2 Piano-roll and Compatible Models

Piano-roll and its variations [7, 20–22] view polyphonic music as 3-D (one-hot) tensors, in which the first two dimensions denote time and pitch and the third dimension indicates whether the token is an onset, sustain or rest. A common way for deep learning models to encode/decode a piano-roll is to use recurrent layers along the time-axis while the pitch-axis relations are modeled in various ways [20, 21, 23]. Another method is to regard a piano-roll as an image with three channels (onset, sustain and rest) and apply convolutional layers [7, 22].

Through the proposal of PianoTree VAE, we argue that a major way to improve the current deep learning models is to utilize the built-in priors (intrinsic structure) in the musical data. In our work, we primarily use the sparsity and the hierarchical priors.

2.3 MIDI-like Event Sequence and Compatible Models

MIDI-like event sequence is first used in deep music generation in performanceRNN [24] and Multi-track Music-VAE [9], and then broadly applied in transformer-based generation [19, 25, 26]. This direction of work leverages the sparsity of polyphonic data to efficiently flatten polyphonic music into an array of events. The vocabulary size of events usually tripples the vocabulary size of MIDI pitches, including "note-on" and "note-off" events for 128 MIDI pitches, "time shifts", and so on.

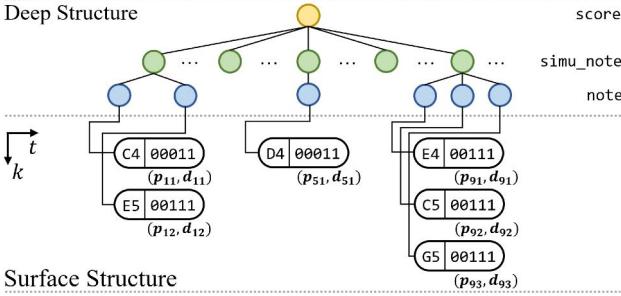
However, the format of MIDI-like events lacks the proper flexibility. A few operations are made difficult due to its very nature. For instance, during addition or deletion of notes, often numerous "time shift" tokens must be merged or split with the "note-on" or "note-off" tokens being changed all-together. This has caused the model being trained inefficient for the potential generation tasks. In addition, this format has a risk of generating illegal sequences, say a "note on" message without a paired "note off" message.

Similarly, we see the note-based approaches [27, 28], in which polyphonic music is represented as a sequence of note tuples, as an alternative to the MIDI-like methods. The representation has resolved the illegal generation problem but still not revealed much of the intrinsic music structure. We argue that our work improves on the note-based approaches by utilizing deeper musical structures implied by the data. (See Section 3.1 for details.)

2.4 GNN as a Novel Structure

Recently, we see a trend in using graph neural networks (GNN) [29] to represent polyphonic score [30], in which each vertex represents a note and the edges represent different musical relations. Although the GNN-based model offers sparse representation learning capacity, it is limited by the specification of the graph structure design and it is nontrivial to generalize it for score generations.

3. METHOD

3.1 Data Structure


We first define a data structure to represent a polyphonic music segment, which contains two components: 1) *surface structure*, a data format to represent the music observation, and 2) *deep structure*, a tree structure (containing `score`, `simu_note` and `note` nodes) showing the syntactic construct of the music segment.

Each music segment lasts T time steps with $\frac{1}{4}$ beat as the shortest unit. We further use K_t, where $1 \leq t \leq T$ to denote the number of notes having the same onset t. The current model uses $T = 32$, i.e., each music segment is 8-beat long.

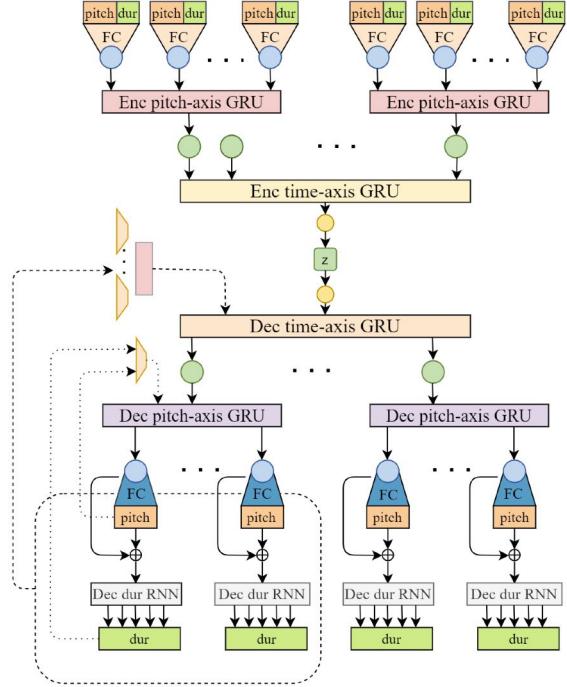
3.1.1 Surface Structure

The surface structure is a nested array of *pitch-duration* tuples, denoted by $\{(p_{t,k}, d_{t,k}) | 1 \leq t \leq T, 1 \leq k \leq K_t\}$. Here, $(p_{t,k}, d_{t,k})$ is the kth lowest note starting at time step t. The pitch attribute $p_{t,k}$ is a 128-D one-hot vector corresponding to 128 MIDI pitches. The duration attribute $d_{t,k}$ encodes the duration ranging from 1 to T using a $\log_2 T$-bit binary vector. For example, when $T = 32$ ($\log_2 T = 5$), '00000' represents a 16th note, '00001' is an 8th note, '00010' is a dotted 8th note, and so on so forth. The base-2 design is inspired by the similar binary relation among different note values in western musical notation.

The bottom part of Figure 2 illustrates the surface structure of the music example in Figure 1. We see that the data structure is a sparse encoding of music, and it eliminates illegal tokens since every possible nested array has a correspondent music.

Figure 2: An illustration of PianoTree data structure to encode the music example in Figure 1.

3.1.2 Deep Structure

We further build a syntax tree to reveal the hierarchical relation of the observation. First, for $1 \leq t \leq T, 1 \leq k \leq K_t$, we define $\texttt{note}_{t,k}$ as the summary (i.e., embedding) of $(p_{t,k}, d_{t,k})$, which are the bottom layers of the tree. Then, for $1 \leq t \leq T$, we define $\texttt{simu\_note}_t$ as the summary of $\texttt{note}_{t,1 \leq k \leq K_t}$, which are the middle layers of the tree. Finally, we define the $\texttt{score}$ as the summary of $\texttt{simu\_note}_{1 \leq t \leq T}$, which is the root of the tree. The upper part of Figure 2 illustrates the deep structure built upon its surface structure.


The syntax tree, so-called the deep structure has both musical and linguistic consideration. In terms of music, $\texttt{note}$, $\texttt{simu\_note}$ and $\texttt{score}$ roughly reflect the musical concept of a note, chord and grouping. In terms of linguistics, the tree is analogous to a constituency tree, with surface structure being the terminal nodes and deep structure being the non-terminals. Recent studies in natural language processing have revealed that incorporating natural language syntax results in better semantics modeling [31, 32].

3.2 Model Structure

We use the surface structure of polyphonic music as the model input. The VAE architecture is built upon the deep structure.

We denote the music segment in the proposed surface structure as x and the latent code as z, which conforms to a standard Gaussian prior denoted by $p(z)$. The encoder models the approximated posterior $q_\phi(z|x)$ in a bottom-up order of the deep structure. First, $\texttt{note}$ embeddings are computed through a linear transform of pitch-duration tuples. Second, the $\texttt{note}$ embeddings (sorted by pitch) are then embedded into $\texttt{simu\_note}$ using a bi-directional GRU [33] by concatenating the last hidden states on both ends. With the same method, the $\texttt{simu\_note}$ embeddings (sorted by onsets) are summarized into $\texttt{score}$ by another bi-directional GRU. We assume an isotropic Gaussian posterior, whose mean and log standard deviation are computed by a linear mapping of $\texttt{score}$. Algorithm 1 shows the details.

The decoder models $p_\theta(x|z)$ in a top-down order of the deep structure, almost mirroring the encoding process. We use a uni-directional time-axis GRU to decode $\texttt{simu\_note}$, another uni-directional (pitch-axis) GRU to decode $\texttt{note}$, a fully connected layer to decode pitch at-

Figure 3: An overview of the model architecture. The recurrent layers are represented by rectangles and the fully-connected (FC) layers are represented by trapezoids. The $\texttt{note}$, $\texttt{simu\_note}$ and $\texttt{score}$ events are represented by circles.

tributes, and finally another GRU to decode duration attribute starting from the most significant bit. Algorithm 2 shows the details.

We use the ELBO (evidence lower bound) [34] as our training objective. Formally,

$$\mathcal{L}(\phi, \theta; x) = -\mathbb{E}_{z \sim q_\phi} \log p_\theta(x|z) + \beta \mathrm{KL}\Big(q_\phi || p(z)\Big), \quad (1)$$

where β is a balancing parameter used in β-VAE [35].

We denote the embedding size of $\texttt{note}$, $\texttt{simu\_note}$ and $\texttt{score}$ as e_n, e_sn and e_sc; the dimension of latent space as d_z; and the hidden dimensions or pitch-axis, time-axis and dur GRUs as h_p, h_t and h_d respectively. In this work, we report our result on the following model size: $e_\text{n} = 128$, $e_\text{sn} = h_\text{p,dec} = 2 \times h_\text{p,enc} = 512$, $e_\text{sc} = h_\text{t,dec} = 2 \times h_\text{t,enc} = 1024$, $h_\text{d,dec} = 64$ and $d_z = 512$.

Algorithm 1: The **PianoTree Encoder**. n, sn, sc are short for $\texttt{note}$, $\texttt{simu\_note}$, $\texttt{score}$.

return $\{(p_{t,k}, d_{t,k}), 1 \leq t \leq T, 1 \leq k \leq K_t\}$;

4. EXPERIMENTS

In this section, we compare PianoTree VAE with several baseline models. We present the dataset in Section 4.1, baseline models in Section 4.2,and the training details in Section 4.3. We present the objective evaluation on reconstruction accuracy in Section 4.4. In Section 4.5, we inspect and visualize the latent space of note and simu_note. After that, we present the subjective evaluation on latent space traversal in Section 4.6. Finally, we apply the learned representation to downstream music generation task in Section 4.7.

4.1 Dataset

We collect around 5K classical and popular piano pieces from Musicalion [2] and the POP909 dataset [36]. We only keep the pieces with $\frac{2}{4}$ and $\frac{4}{4}$ meters and cut them into 8-beat music segments (i.e., each data sample in our experiment contains 32 time steps under sixteenth note resolution). In all, we have 19.8K samples. We randomly split the dataset (at song-level) into training set (90%) and test set (10%). All training samples are further augmented by transposing to all 12 keys.

4.2 Baseline Model Architectures

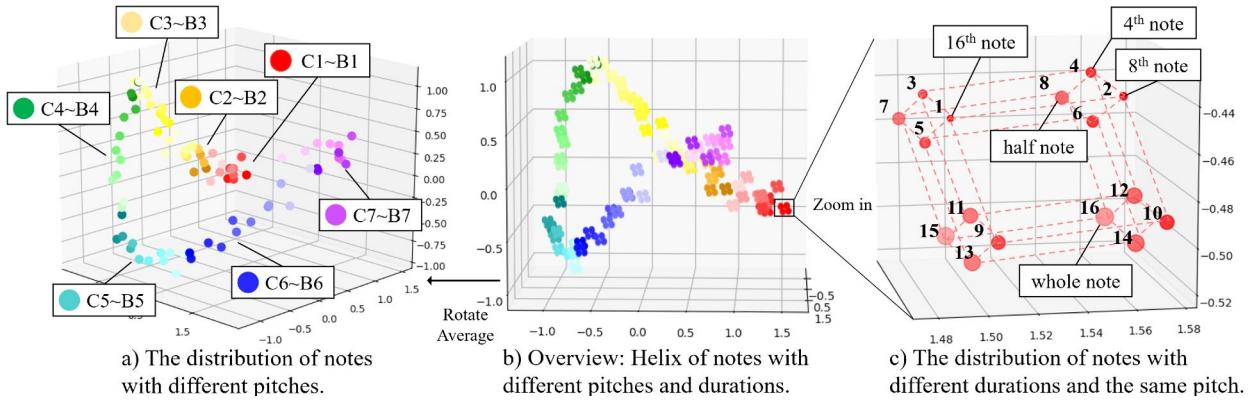
We train four types of baseline models in total using piano-roll (Section 2.2) and MIDI-like events (Section 2.3) data structures. As a piano-roll can be regarded as either a sequence or a 2-dimensional image, we couple it with

---

[2] Musicalion: https://www.musicalion.com.

three neural encoder-decoder architectures: a recurrent VAE (**pr-rnn**), a convolutional VAE (**pr-cnn**), and a fully-connected VAE (**pr-fc**). For the MIDI-like events, we couple it with a recurrent VAE model (**midi-seq**). All models share the same latent space dimension ($d_z = 512$). Specifically,

- The piano-roll recurrent VAE (**pr-rnn**) model is similar to a 2-bar MusicVAE proposed in [4]. The hidden dimensions of the GRU encoder and decoder are both 1024.
- The piano-roll convolutional VAE (**pr-cnn**) architecture adopts a convolutional–deconvolutional architecture. The encoder contains 8 convolutional layers with kernel size 3×3. Strided convolution is performed at the 3rd, 5th, 7th and 8th layer with stride size $(2 \times 1), (2 \times 3), (2 \times 2)$ and (2×2) respectively. The decoder adopts the deconvolution operations in a reversed order.
- The piano-roll fully-connected VAE (**pr-fc**) architecture uses a time-distributed 256-dimensional embedding layer, followed by 3 fully-connected layers with the hidden dimensions [1024, 768] for the encoder. The decoder adopts the counter-operations in a reversed order.
- The MIDI-like event recurrent VAE (**midi-seq**) adopts the recurrent model structure similar to **pr-rnn**. Here, the event vocabulary contains 128 "note-on", 128 "note-off" and 32 "time shift" tokens. The embedding size of a single MIDI event is 128. The hidden dimensions of the encoder GRU and decoder GRU are 512 and 1024 respectively.

4.3 Training


For all models, we set batch size = 128 and use Adam optimizer [37] with a learning rate starting from 1e-3 with exponential decay to 1e-5. For PianoTree VAE, we use teacher forcing [38] for decoder time-axis and pitch-axis GRU and for other recurrent-based baselines, we use teacher forcing in the decoders. The teacher forcing rates start from 0.8 and decay to 0.0. PianoTree VAE converges within 6 epochs, and the baseline models converge in approximately 40 to 60 epochs.

Models	PianoTree	midi-seq	pr-rnn	pr-cnn	pr-fc
Onset Precision	**0.9558**	0.8929	0.9533	0.9386	0.9211
Onset Recall	**0.9532**	0.6883	0.9270	0.8818	0.8827
Onset F1	**0.9545**	0.7774	0.9399	0.9093	0.9015
Duration Precision	**0.9908**	0.3826	0.9777	0.9757	0.9688
Duration Recall	0.9830	**0.9899**	0.9891	0.9796	0.9743
Duration F1	**0.9869**	0.5519	0.9834	0.9777	0.9715

Table 1: Objective evaluation results on reconstruction criteria. PianoTree is our proposed method. Other columns correspond to the baseline models described in Section 4.2.

4.4 Objective Evaluation of Reconstruction

The objective evaluation is performed by comparing different models in terms of their reconstruction accuracy of pitch onsets and note duration [39, 40], which are commonly used measurements in music information retrieval tasks. For note duration accuracy, we only consider the

a) The distribution of notes with different pitches.

b) Overview: Helix of notes with different pitches and durations.

c) The distribution of notes with different durations and the same pitch.

Figure 4: A visualization of `note` embeddings after dimensionality reduction using PCA.

notes whose onset and pitch reconstruction is correct. Table 1 summarizes the results where we see that the PianoTree VAE (the 1st column) is better than others in terms of F1 score for both criteria.

4.5 Latent Space Visualization

Figure 4 shows the *latent note space* by plotting different `note` embeddings after dimensionality reduction by PCA (with the three largest principal components being reserved). Each colored dot is a `note` embedding and a total of 1344 samples are displayed; note pitch ranges from C-1 to C-8 and note duration from a sixteenth note to a whole note.

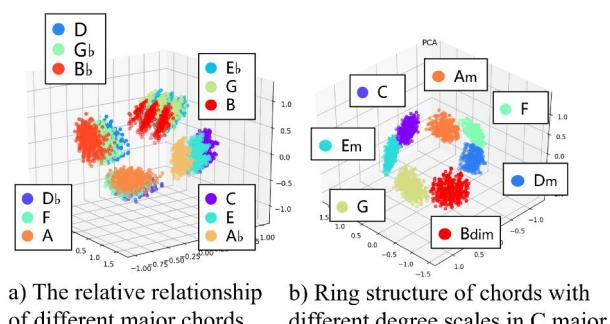
We see that the `note` embeddings have the desired geometric properties. Figure 4 (a) & (b) show that at a macro level, notes with different pitches are well sorted and form a "helix" in the 3-D space. Figure 4 (c) further shows that at a micro level, 16 different note durations (with the same pitch) form a "fractal parallelogram" due to the binary encoding of duration attributes. One of the advantages of the encoding method is the translation invariance property. For example, the duration difference between the upper left cluster and the lower left cluster is 8 semiquavers, so is the difference between the upper right and lower right cluster. The same property also applies to the four smaller-scale parallelograms.

a) The relative relationship of different major chords.

b) Ring structure of chords with different degree scales in C major.

Figure 5: A visualization of `simu_note` embeddings after dimensionality reduction using PCA.

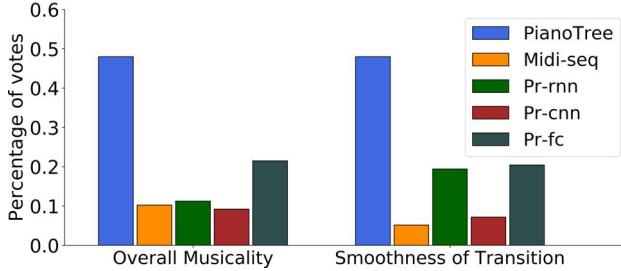
Figure 5 is a visualization of the latent chord space by plotting different `simu_note` embeddings under PCA di-

mensionality reduction. Each colored cluster corresponds to a chord label realized in 343 different ways (we consider all possible pitch combinations within three octaves, with a minimum of 3 notes and a maximum of 9 notes). The duration for all chords is one beat.


The geometric relationships among different chords are consistent and human interpretable. In specific, Figure 5 (a) shows the distribution of 12 different major chords, which are clustered in four different groups. By unfolding the circle in a counterclockwise direction, we can observe the existence of *the circle of the fifth*. Figure 5 (b) is the visualization of seven C major triad chords: forming a ring in the order of 1-3-5-7-2-4-6 degree in the counterclockwise direction.

4.6 Subjective Evaluation of Latent Space Interpolation

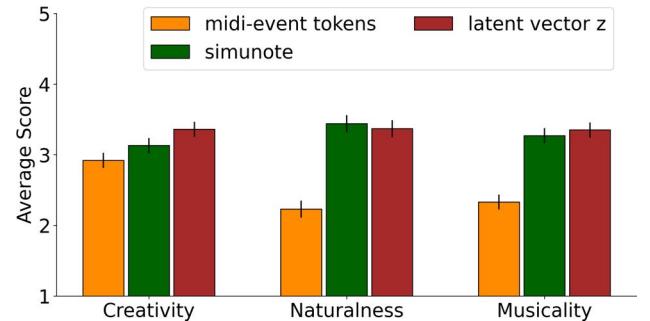
Latent space traversal [4, 5, 41] is a popular technique to demonstrate model generalization and the smoothness of the learned latent manifold. When interpolating from one music piece to another in the latent space, new pieces can be generated by mapping the representations back to the signals. If a VAE is well trained, the generated piece will sound natural and form a smooth transition.

To this end, we invite people to subjectively rate the models through a double-blind online survey. During the survey, the subjects first listen to a pair of music, and then listen to 5 versions of interpolation, each generated by a model listed in Table 1. Each version is a randomly selected pair of music segments, and the interpolation is achieved using SLERP [42]. Since the experiment requires careful listening and a long survey could decrease the quality of answers, each subject is asked to rate only 3 pairs of music, i.e., $3 \times 5 = 15$ interpolations in a random order. After listening to the 5 interpolations of each pair, subjects are asked to select two best versions: one in terms of the *overall musicality*, and the other in terms of the *smoothness of transition*.


A total of n = 33 subjects (12 females and 21 males) with different music backgrounds have completed the survey. The aggregated result (as in Figure 6) shows that the interpolations generated by our model are better than the ones generated by baselines, in terms of both overall musi-

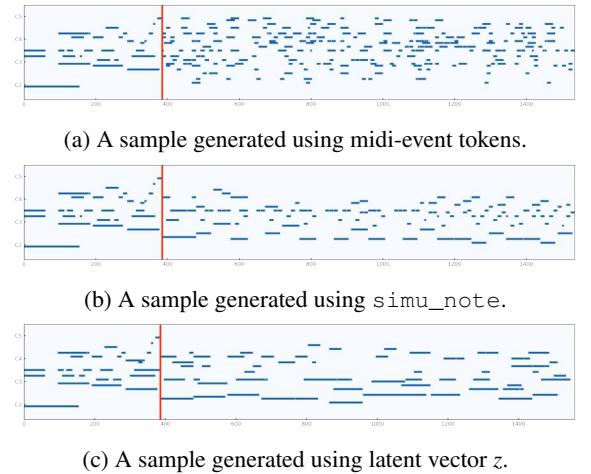
cality and smoothness of transition. Here, different colors represent different models (with the blue bars being our model and other colors being the baselines), and the height of the bars represent the percentage of votes (on the best candidate).

Figure 6: Subjective evaluation results of latent space interpolation.

4.7 Downstream Music Generation


In this section, we further explore whether the polyphonic representation helps with *long-term music generation* when coupled with standard downstream sequence prediction models. (Similar tasks have been applied to *monophonic music* in [43] and [6].)

The generation task is designed in the following way: given 4 measures of piano composition, we predict the next 4 measures using a Transformer decoder (as in [44]). We compare three different music representations: MIDI-like event sequence (Section 2.1), pretrained (decoder) `simu_note` embeddings, and latent vector z for every 2-measure music segment (without overlap). Here z is the mean of the approximated posterior from the encoder. For all three representations, we use the same Transformer decoder architecture (outputs of dimension = 128, number of layers = 6 and number of heads = 8) with the same training procedure. Only the loss functions are correspondingly adjusted based on different representations: cross entropy loss is applied to midi-event tokens and MSE loss is applied to both `simu_note` and latent vector z. We use the same datasets mentioned in Section 4.1 and cut the original piano pieces into 8-measure subsequent clips for generation purposes. We still keep 90% for training and 10% for testing.

We then invited people to subjectively rate different music generations through a double-blind online survey (similar to the one in Section 4.6). Subjects are asked to listen to and rate 6 music clips, each of which contains 3 versions of 8-measure generation using different note representations. Subjects are told that the first 4 measures are given and the rest are generated by the machine. For each music clip, subjects rate it based on *creativity*, *naturalness* and *musicality*.


A total of n = 48 subjects (20 females and 28 males) with different music backgrounds have participated in the survey. Figure 7 summarizes the survey results, where the heights of bars represent means of the ratings and the error bars represent the confidence intervals computed via within-subject ANOVA [45]. The result shows that `simu_note` and latent vector z perform significantly better

than the midi-event tokens in terms of all three criteria (p < 0.005).

Figure 7: Subjective evaluation results of downstream music generation.

Besides the aforementioned generation task, we also iteratively feed the generated 4-measure music clips into the model to get longer music compositions. Figure 8 shows a comparison of 16-measure generation results using all three representations. The first 4 bars are selected from the test set, and the subsequent 12 bars are generated by the models. Generally speaking, using `simu_note` and latent vector z as data representations yields more coherent music compositions. Furthermore, we noticed that long generations using the `simu_note` representation tend to repeat previous steps in terms of both chords and rhythms, while those generations using the latent vector z usually contain more variations.

5. CONCLUSION AND FUTURE WORK

In conclusion, we proposed PianoTree VAE, a novel representation-learning model tailored for polyphonic music. The key design of the model is to incorporate both the music data structure and model architecture with the sparsity and hierarchical priors. Experiments show that with such inductive biases, PianoTree VAE achieves better reconstruction, interpolation, downstream generation, and strong model interpretability. In the future, we plan to extend PianoTree VAE for more general musical structures, such as motif development and multi-part polyphony.

ABSTRACT

Many sounds that humans encounter are hierarchical in nature; a piano note is one of many played during a performance, which is one of many instruments in a band, which might be playing in a bar with other noises occurring. Inspired by this, we re-frame the musical source separation problem as hierarchical, combining similar instruments together at certain levels and separating them at other levels. This allows us to deconstruct the same mixture in multiple ways, depending on the appropriate level of the hierarchy for a given application. In this paper, we present various methods for hierarchical musical instrument separation, with some methods focusing on separating specific instruments (like guitars) and other methods that determine what to separate based on a user-supplied audio example. We additionally show that separating all hierarchy levels is possible even when training data is limited at fine-grained levels of the hierarchy.

1. INTRODUCTION

The field of source separation has seen notable performance improvements with the introduction of deep learning techniques, most notably in the areas of speech enhancement [1–4], speech separation [5–8], and music separation [9–12]. These techniques succeed in cases where the notion of a source is well defined; in the case of speech enhancement or separation, the target is always defined as the speech of a single speaker. However, real-world scenarios can have more complicated definitions of a source. Consider the case where a band is playing on the radio while two people are having a conversation: how does one segment this audio scene? Is the radio one source and the talkers each a source? Or are each of the instruments in the band on the radio a source as well? Clearly, there are many correct answers to this question, but one way to understand this auditory scene is to apply a hierarchical structure to its parts. In this work, we re-frame the source separation problem as hierarchical, focusing on the example of music source separation, where we use musical instruments as elements in a complex hierarchical auditory scene.

When considering music separation, determining what

Figure 1. Annotated t-SNE [13] projection of the learned anchors from a hierarchical query-by-example separation model on a test set.

constitutes a target source is not well defined. Even in a well-studied problem like singing voice separation [9–11], in which the singer is isolated from non-vocal background music, the definition of what is "singing voice" is somewhat muddled. Many popular songs often contain a lead vocal part, possibly several additional background vocal parts, and sometimes additional vocal effect tracks. This is a simple case; when we consider instrument categories with a larger variety of possible timbres, like synthesizers or guitars, deciding what particular instrument part to isolate can become even harder to nail down. One may want to go even further and separate each instrument into unique notes or chord instances.

Framing a musical scene as hierarchical has precedent in fields that study human audition. Evidence shows that human auditory perception has many hierarchical characteristics [14–17]. As Bregman notes in *Auditory Scene Analysis* [18]: "It makes sense [...] to think of the auditory perceptual organization of [a musical] duet as having a hierarchical structure [...]. This argument implies that there are levels of perceptual belongingness intermediate between 'the same thing' and 'unrelated things'". While perceptual auditory hierarchies can involve timing, timbre, rhythm, and much more, in this paper we focus on the task of building hierarchical source separation systems via an instrument hierarchy.

In the field of musicology, musical instruments have long been thought of as hierarchical. Almost all human cultures throughout history have created musical instrument classification systems [19], many of which are inherently hierarchical. One prominent example is the

Hornbostel-Sachs system [20], which classifies musical instruments by their sound production mechanisms in a hierarchical manner similar to the Dewey Decimal System [21]. Another system widely used in Western music classifies instruments by their musical range, with terms named after singing voice classifications: *soprano*, *alto*, etc. We use a hierarchy inspired by both of these approaches for hierarchical source separation.

There is also an element of a musical instrument hierarchy when making recordings in the recording studio. Each track is assumed to be an isolated recording of a single instrument, or part of one instrument. At the mixing board, a sound engineer can mix together multiple tracks into a "submix", which acts as a single unit in the recording session, having effects and other signal routing configurations be specific to the submix rather than the individual tracks therein [22]. The submixes are then manipulated alongside other tracks, which may contain only a single instrument. For example, a standard practice is to record every separate piece of a drum kit with a single microphone and then combine those into a drum submix. This configuration is hierarchical; the engineer can choose to manipulate all of the drum sounds (the drum submix) or manipulate individual drum tracks within it.

In this paper, we re-frame the problem of musical source separation as hierarchical. We propose two main strategies for hierarchical source separation, one solely based on the well-studied source-specific mask inference approach to source separation [3], and another based on more recently proposed query-by-example source separation systems [23, 24]. In both cases, we learn to simultaneously separate submixes of instruments corresponding to multiple levels of an instrument label hierarchy. By learning to separate sources at multiple levels of granularity, we observe performance benefits even in cases where training data is limited for the most fine-grained source types.

2. RELATED WORK

Music source separation has recently seen a great deal of success. Most of this success is owed to the availability of the MUSDB18 [25] dataset. This dataset has avoided the "source definition ambiguity" by grouping all audio within a track into four target sources: vocals, bass, drums, and other. The "other" source contains a variety of different instruments, like guitars, pianos, strings, and synthesizers. While MUSDB18 has undoubtedly helped to advance the field of music source separation, its source groupings remain overly coarse for many real-world remixing applications. In this work, we propose systems to separate sources historically grouped as the "other" source.

Our proposed work is related to source separation algorithms that attempt to estimate multiple musical sources with one network. Some works accomplish this by outputting a set of masks for each target source, improving performance via specialized training techniques [26, 27] or by giving the networks additional tasks to solve, like music transcription [28]. Other works accomplish this by conditioning a network to output different sources depending on

the desired source [23, 29, 30]. None of these approaches have any requirements that the sources they separate have any inherent structure in relation to other sources, especially not in a hierarchical manner as we propose here.

This work also draws inspiration from query-by-example (QBE) networks. Within the speech separation literature, the task of using a query to separate a specific speaker from a mixture with many speakers is called speaker extraction, and this task has garnered much attention recently [31–33]. Specifically, this work builds off of work [34] that extends deep attractor networks [35] for the QBE case. Deep attractor networks have been successfully used for music separation [23, 36], where QBE music separation was considered as an auxiliary benefit of the learned embedding space. Although systems specifically tailored to QBE separation of musical instruments have also been proposed [24], none of these systems assume or enforce any hierarchical structure on an auditory scene.

3. AUDITORY HIERARCHIES

In this work, we are interested in hierarchies of sound producing objects, where top levels of the hierarchy correspond to broad groups (e.g., midrange stringed instruments) and lower levels are more specific (e.g., acoustic guitar). With regard to source separation, we can define an auditory hierarchy such that sources at higher levels in the hierarchy are composed of mixtures of sources at lower levels of the hierarchy. Each source node can potentially be further separated into child sources and combined with its siblings to create parent sources. Considering a hierarchy with L levels, we denote by $\mathcal{S}_{l,c}$ the c-th source type node at hierarchy level l, for $l = 1, \ldots, L$, where we assume that the set of leaf source types $\mathcal{S}_{1,c}$ cannot be decomposed into further source types, and $\mathcal{S}_{L,1}$ is the sole source type at the top of the hierarchy and includes all source types. Further denoting by $\mathcal{C}_{l,c}$ the set of indices of the child sources at level $l - 1$ of $\mathcal{S}_{l,c}$, the hierarchy can be defined as

$$\mathcal{S}_{l,c} = \bigcup_{c' \in \mathcal{C}_{l,c}} \mathcal{S}_{l-1,c'}, \forall l = 2, \ldots, L. \qquad (1)$$

We define a *path* down the hierarchy as a sequence of source types from a beginning source type node $\mathcal{S}_a$ to a destination source type node $\mathcal{S}_b$ at a lower level.

When using this hierarchy to decompose a mixture x, we denote by $\mathbf{S}_{l,c}$ the corresponding source component in x whose source type is $\mathcal{S}_{l,c}$, where the submix of all signals of the same type are considered as a single component. By definition, $\mathbf{S}_{L,1} = x$. Each c-th source component $\mathbf{S}_{l,c}$ at a level l can be decomposed into source components $\mathbf{S}_{l-1,c'}$, such that $\mathbf{S}_{l-1,c'}$ is the signal corresponding to all sources belonging to the child source type $\mathcal{S}_{l-1,c'}$:

$$\mathbf{S}_{l,c} = \sum_{c' \in \mathcal{C}_{l,c}} \mathbf{S}_{l-1,c'}, \text{ s.t. } \mathbf{S}_{l-1,c'} \in \mathcal{S}_{l-1,c'}, \qquad (2)$$

for $l = 2, \ldots, L$. For simplicity, we use the sum operator to denote mixing, although the mixing process is often more complex than a simple summation of signals.

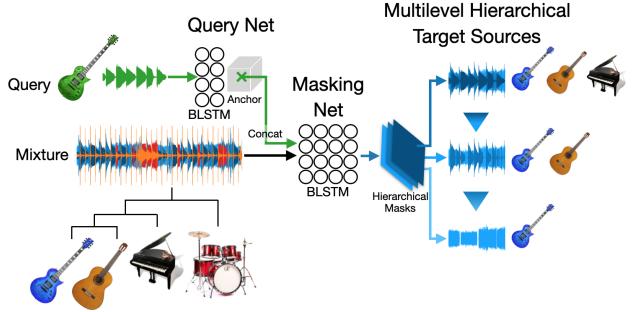
In this paper, we specifically examine auditory hierarchies composed of mixtures of musical instruments, but

we note that this hierarchical formulation can be applied to mixtures with any type of source content.

4. HIERARCHICAL SOURCE SEPARATION

In general, source separation is formulated as trying to estimate C complex spectrograms, $\boldsymbol{S}_c \in \mathbb{C}^{F \times T}$ for $c = 1, \ldots, C$, that represent a set of desired sources within the spectrogram $X \in \mathbb{C}^{F \times T}$ of an audio mixture. In this general formulation, there is no requirement that source $\boldsymbol{S}_c$ have any relationship to source $\boldsymbol{S}_d$, for $c \neq d$.

Given an audio mixture X, a hierarchical separation algorithm under a given hierarchy may attempt to extract a submix of all sources belonging to some source type $\mathcal{S}_{l,c}$ at a level l. For instance, separating out all guitars (acoustic and electric) from a mixture that includes electric guitar, acoustic guitar, piano, and drums (as depicted in Fig. 2).

4.1 Hierarchical Source-Specific Separation


Conventional source-specific separation (SSS) networks based on mask inference typically attempt to estimate a real-valued mask $\hat{M}_c \in \mathbb{R}^{F \times T}$ for a single target source c by minimizing some distortion measure between the source estimate obtained from the mask and a reference $\boldsymbol{S}_c$. A commonly used example of such an objective function, which we use in this work, is the truncated phase sensitive approximation (tPSA) objective [3]:

$$\mathcal{L}_{\text{tPSA}} = \left\| \hat{M}_c \odot |X| - \text{T}_0^{|X|} \left(|\boldsymbol{S}_c| \odot \cos(\angle \boldsymbol{S}_c - \angle X) \right) \right\|_1, \tag{3}$$

where $\odot$ denotes element-wise product, $|Y|$ and $\angle Y$ denote the magnitude and phase of a spectrogram Y, and $\text{T}_0^{|X|}(x) = \min(\max(x,0),|X|)$ is a truncation function ensuring the target can be reached with a sigmoid activation function. The estimated mask $\hat{M}_c$ is element-wise multiplied with the original mixture spectrogram X to obtain an estimate for the target source $\boldsymbol{S}_c$.

As a first naive strategy for building hierarchical SSS networks, we can train single networks which output a single node $\mathcal{S}_{n,c}$ at a given level of the hierarchy. Each such single-level network can be trained to minimize the tPSA objective above, where the target source is $\boldsymbol{S}_{n,c}$, the component corresponding to the targeted source type in the hierarchy within the mixture X. Each of these networks outputs one mask $\hat{M}_{n,c}$ for its targeted source type, and they are trained independently of each other.

In order to make further use of the hierarchical structure of the data, we propose a multi-level strategy in which we train a network to output multiple levels of the hierarchy at once. A potential advantage of this strategy is that the network may be able to leverage learned knowledge about a mask $\hat{M}_{n,c}$ to reinforce and improve its estimate for another mask $\hat{M}_{n',c'}$ in the hierarchy. A trivial implementation of this strategy would be to output a mask for each leaf node in the hierarchy, and recompose the leaf sources as we travel through the hierarchy, training the network by combining loss functions for all nodes

Figure 2. One of the proposed methods for hierarchical source separation. We assume that a mixture contains a hierarchy of musical instruments (bottom left), and use an audio query (the green electric guitar, top left) to separate instruments at multiple levels of the hierarchy, with the closest target at the lowest level (blue electric guitar).

in the hierarchy. However, any sufficiently realistic hierarchy likely contains dozens of leaf nodes, leading to memory and computation issues as well as difficulties balancing the contributions of all the losses. To avoid these issues, we consider instead a single network that outputs N masks for N levels along a single path down the hierarchy, e.g., [strings/keys] → [guitars] → [clean guitars] ("Clean" indicates acoustic and electric guitars with no overdrive or distortion applied).

4.2 Hierarchical Query-by-Example

The approaches described above cannot capture many instruments in an instrument hierarchy: using one network per level only allows the network to learn one node in the hierarchy at a time, and using a multilevel network only learns one path down the instrument hierarchy. If we want to capture relationships between different instruments in a hierarchy, we need a method for separating multiple instruments at different levels with a single network.

A successful recent strategy involves query-by-example (QBE) networks that ingest a mixture and an example of the desired source to separate from the mixture [24]. By extending this to a hierarchical case, we can model an entire instrument hierarchy for source separation. Note that, instead of conditioning on a query, we could alternatively condition the separation on the leaf node label, leading to a hierarchical extension of conditional source separation methods [23, 29, 30]. We here focus on QBE, as an audio query can be considered as a generalization of a class label, and QBE may further provide the ability to interpolate to unseen source types during inference.

Our proposed realization of hierarchical QBE relies on two networks, a query net and a masking net. The query net calculates a query anchor $A_q \in \mathbb{R}^k$ for some input query $Q \in \mathbb{R}^{F \times T_q}$ as a weighted sum of k-dimensional query embeddings $V_{q,i}$ produced by the network at each time-frequency bin $i = (f,t)$ of the query spectrogram space:

$$A_q = \frac{\sum_i P_{q,i} V_{q,i}}{\sum_i P_{q,i}}, \tag{4}$$

where $P_q \in \mathbb{R}^{FT_q}$ is a query presence vector for query Q, defined such that $P_{q,i} = 1$ if the magnitude at bin $i = (f,t)$ is above a threshold (set to -60 dB from the maximum in our experiments), and 0 otherwise. The query anchor A_q is concatenated with the frequency vector of the mixture X_t at each frame t, and used as input to the masking network, which produces, for each hierarchy layer n of interest, a mask $\hat{M}_{n,c}$ for a target source $S_{n,c}$ which is in the same node $\mathcal{S}_{n,c}$ of the hierarchy as the query Q. This architecture is depicted in Fig. 2.

This QBE system is trained to minimize the tPSA objective in Eq. 3 based on a target source $S_{n,c}$, where the target source used to train the network is here determined both by the query and a given level in the hierarchy. Other QBE systems [24] apply a loss directly on the query embedding space; while we leave this direction to future work, we note that we are already able to learn some form of hierarchical structure without introducing a specific loss on the embedding space, as exemplified in Fig. 1.

Using an acoustic guitar query as example, the training procedure for a hierarchical QBE system is as follows: an acoustic guitar query is used to train a network that attempts to extract the corresponding sources at the leaf node level, in which case the target will consist of the submix of all clean guitars in the mixture. Note that we leave the problem of separating instruments of the same fine-grained type (e.g., multiple clean guitars) using techniques such as permutation-invariant training [5, 6] for future work. The same acoustic guitar query may also be used to train a network that attempts to extract the corresponding sources one level up, in which case the target will consist of the submix of all guitars in the mixture, regardless of whether they are clean guitars or not. When there is no target in the mixture corresponding to the query at the given level of the hierarchy, the target is set to silence.

As with hierarchical SSS networks, we can make a single-level QBE network for each separate level in the hierarchy and only separate instruments at that level, as described in the above example, or we can make a single hierarchical multi-level QBE network that returns multiple (or even all) levels of the hierarchy. For the latter strategy, we can consider enforcing a hierarchical constraint on the masks, as described below.

4.3 Constraints on Hierarchical Masks

Assuming the components of a mixture exist in some hierarchy, we can leverage knowledge about its structure to impart constraints on the network. For instance, we can use the relationship defined in Eq. 2 to require the set of masks produced by a multi-level hierarchical network to follow the same structure as the hierarchy, namely that masks at higher levels be composed of masks at lower levels.

However, this would require us to output masks for every node in the hierarchy, which is infeasible for any sufficiently realistic hierarchy. Instead, we consider imposing a hierarchical constraint that does not depend on knowledge of the whole hierarchy. This hierarchical constraint requires that masks at higher levels in the hierarchy must

Level	Submixes to be separated
3	Keyboards, guitars, and orchestral strings
2	All guitars (both clean and effected)
1	Only clean guitars (both electric and acoustic)

Table 1. Contents of hierarchical levels used for training and testing the hierarchical single-instrument source-specific separation (SSS) networks[1]. Hierarchical SSS can only learn one path down the hierarchy at a time.

apportion at least the same amount of energy as masks at lower levels. More precisely, the mask at level l is set as

$$\hat{M}_l = \max(\hat{M}'_l, \hat{M}_{l-1}), \qquad (5)$$

where $\max$ is applied element-wise to every TF bin, and $\hat{M}'_l$ is the mask estimate output by the network for level l.

5. EXPERIMENTAL DESIGN

We design a set of experiments to determine the validity of our hierarchical source separation methods outlined above. We want to understand how well the proposed methods work in a hierarchical scenario. We look specifically at the case of a musical instrument hierarchy.

5.1 Dataset and Evaluation

To test the proposed methods in this paper, we required a large dataset with isolated sources of many instruments that could be combined in a hierarchical way. Specifically, we required a dataset with a wide variety of granular source labels, i.e., not only "guitars", but "acoustic guitars", "electric guitars", "effected guitars", and so on for every instrument in the dataset. Because of this, we chose Slakh2100 [37], which contains 2,100 musical mixtures along with isolated sources. This dataset has 145 hours of mixture data split into 34 instrument categories.

Before selecting excerpts from the dataset, we created a musical instrument hierarchy from Slakh's included instrument categories [1]. For these experiments, we define a hierarchy with three levels (excluding the trivial level consisting of the mixtures of all sources). The top level contains four categories: mid-range strings and keys (guitars, keyboards, and orchestral strings), bass instruments (acoustic and electric basses), winds (flutes, reeds, and brass), and percussion (drum sets and chromatic percussion). The middle level has seven categories (e.g., from mid-range strings: orchestral strings, guitars, keyboards, and electric keyboards), and the lowest level has eighteen categories (e.g., from guitars: clean guitars, and effected guitars). We note that this is just one of many possible hierarchies and almost all of the instruments described here would be classified as "other" in MUSDB18 [25].

To select examples from the dataset, we create multiple instantaneous submixes for each track, corresponding to the different levels of the hierarchy. As an example illustrated in Table 1, at the highest level, all pianos, guitars, and strings are considered one source, while at the next

---

[1] The full hierarchy can be seen at: `https://git.io/JJ4gx`

level all guitars are considered one source, and at the lowest level only clean guitars are considered one source. For each mixture in the dataset, we compute the saliency of each hierarchical submix in 10 second chunks, with a hop size of 2.5 seconds. If the source in the submix has energy above -30 dB in that chunk, it is considered salient. For the experiments involving multiple levels, we ensure that for a given node, its parent (or grandparent) has energy from child nodes other than itself. In other words, we want to make sure that a parent is not exactly the same as the child, meaning that some of the child node's siblings or cousins are also salient.

For our experiments, we use the *Slakh2100-split2* stratification and downsample the audio to 16 kHz. We do the mixing on the fly and select chunks randomly from the pool of salient examples for the specific experiment. For training, the networks see 20,000 examples per epoch ($\approx$55.5 h), and we use 3,000 examples ($\approx$8.3 h) for the validation and test sets. To ensure we have enough examples and a rich enough hierarchy to train, for the hierarchical SSS experiments we choose to separate sources down a path of the hierarchy as shown in Table 1, although the proposed methods can be extended to other paths down this or other hierarchies. For the QBE networks, we separate every instrument type in the hierarchy. Query chunks are selected from the pool of salient chunks such that they are always leaf nodes along the same path as the target regardless of the target level, but originate from different tracks.

For all experiments, we use the scale-invariant source-to-distortion ratio (SI-SDR) [38] to determine the output quality of our models. For reference, we also report the SI-SDR when doing no processing on the mixes.

5.2 Experiments and Model Configurations

In this paper, we evaluate four types of hierarchical source separation models. We vary models along two dimensions: whether they are single-instrument (i.e., source-specific separation, or SSS) or multi-instrument (i.e., query-by-example, or QBE), and whether they output a single level, or multiple levels. We describe each configuration below:

- **Single-instrument, Single-level:** A trio of instrument-specific SSS models each corresponding to one level of the hierarchy along one hierarchical path.

- **Single-instrument, Multi-level:** One SSS model that outputs a hierarchical set of masks, separating at all levels of a single hierarchical path simultaneously.

- **Multi-instrument, Single-level:** A trio of multi-instrument QBE models outputting one mask at one level of the hierarchy as determined by an input query.

- **Multi-instrument, Multi-level:** One QBE model that outputs a hierarchical set of masks for every level of the hierarchy along a path determined by an input query.

For the single-instrument models, we separate along one path of the hierarchy as referenced in Table 1. The multi-instrument, multi-level model is trained to separate a source based on a query, and thus can learn the full hierarchy (i.e., all instruments) instead of just one path as in the single-instrument, multi-level case.

Model Type	HC	Level 3	Level 2	Level 1
SSS (Guitar)		3.5	4.0	4.0
SSS (Guitar)	✓	3.2	3.6	3.8
QBE		3.2	2.4	0.2
QBE	✓	3.3	2.1	1.6

Table 2. Improvement in SI-SDR (dB) for hierarchical SSS (Guitar) and QBE models. Each model is trained either with the hierarchical constraint (HC) described in Section 4.3 or with no constraints on the masks produced for sources at different levels of granularity.

For the multi-level models, we test the effect of the hierarchical constraint proposed in Section 4.3. We can also test how well they learn with limited data about the leaf source. To do this, we train the three-level SSS and QBE models under the assumption that the leaf ground truth is unavailable either 50% or 90% of the time, in which cases only the upper levels are directly involved in the objective function. For comparison, we also evaluate models where *all* nodes are missing either 50% or 90% of the time during training. These experiments can tell us how well the multi-level network can leverage higher (i.e., coarser) levels of the hierarchy at the leaf node. Such an ability would be particularly advantageous as it is typically more difficult to collect data with fine-grained ground truth sources compared to data with a mixture and only a few source components gathered in broad categories, and could potentially help breaking open the "other" category of MUSDB18 with limited annotations.

All single-level and multi-level networks we test have the same architecture. The SSS models are composed of 4 bidirectional long short-term memory (BLSTM) layers with 600 hidden units in each direction and dropout of 0.3, followed by a fully connected layer with sigmoid activation function that outputs a mask. As described in Section 4.2, the QBE models are composed of two sub-networks, a query net and a masking net. The query net is composed of 2 BLSTM layers with 600 nodes in each direction and dropout of 0.3, followed by a fully-connected layer with linear activation that maps each time-frequency bin to an embedding space with 20 dimensions. The masking net is the same as the SSS models, with a larger input feature vector to accommodate the concatenated query anchor.

All models were trained with the Adam optimizer at a learning rate of 1e-4 for 100 epochs and a batch size of 25. The learning rate was halved if the loss on the validation set did not decrease for 5 straight epochs. The gradient was clipped to the 10th percentile of historical gradient norms if the norm of the minibatch was above that value [39].

6. RESULTS

In Table 2, we examine the effect of the hierarchical constraint (HC) on multi-level hierarchical networks. We observe that, for the source-specific separation network (which in this case only separates guitars), the HC slightly diminishes performance at all levels, indicating that SSS models are able to learn the specific hierarchical relation-

Model Type	# lvls	All Levels			Level 3			Level 2			Level 1		
		Mix	SI-SDR	Δ	Mix	SI-SDR	Δ	Mix	SI-SDR	Δ	Mix	SI-SDR	Δ
SSS (Guitar)	1	−3.9	−2.1	1.8	0.9	4.1	3.2	−5.9	−3.2	2.7	−6.6	−7.3	−0.7
SSS (Guitar)	3	−3.9	0.0	3.9	0.9	4.3	3.4	−5.9	−1.9	4.0	−6.6	−2.6	4.0
QBE	1	−4.9	−3.9	1.0	−1.3	2.0	3.3	−5.3	−3.9	1.4	−8.0	−9.8	−1.9
QBE	3	−4.9	−2.5	2.3	−1.3	2.0	3.3	−5.3	−3.2	2.1	−8.0	−6.4	1.6

Table 3. SSS and QBE model results in terms of SI-SDR (dB), where Δ denotes improvement over the noisy mix. SSS networks are only trained to separate sources in the hierarchy containing clean guitars (See Table 1), whereas QBE networks separate any source in the hierarchy. Here we compare single-level networks (denoted by a "1") to multi-level networks (denoted "3"). There is only one multi-level network for all three levels, but three single-level networks (one for each level).

	Data Reduction		Levels			
	%	type	All	Level 3	Level 2	Level 1
SSS (Guitar)	0	-	3.8	3.5	4.0	4.0
	50	all	3.3	3.1	3.4	3.4
	50	leaf	3.5	3.3	3.6	3.6
	90	all	0.1	1.5	−0.7	−0.5
	90	leaf	3.6	3.4	3.7	3.7
	Mix		−3.9	0.9	−5.9	−6.6
QBE	0	-	2.3	3.3	2.1	1.6
	50	all	−1.5	−2.1	−1.4	−1.1
	50	leaf	2.2	3.4	2.1	1.1
	90	all	−1.8	−2.1	−1.8	−1.5
	90	leaf	1.9	3.1	1.7	0.8
	Mix		−4.9	−1.3	−5.3	−8.0

Table 4. SI-SDR improvement (dB) over the unprocessed mix ("Mix") for hierarchical SSS and QBE models (separated by the thick broken line). Each model is trained while removing either just the leaf ("leaf") or the whole example ("all") for a specified percentage of the data. Reducing just leaf nodes up to 90% shows only a 0.3 dB drop for SSS and 0.8 dB drop for QBE compared to using all of the leaves.

ship for a single source (in this case, guitar) at different levels without additional help. For the query-by-example network (which separates all types of instruments), the HC marginally hinders performance at Level 2, but helps considerably for the leaf node (Level 1). We hypothesize that QBE networks benefit more because they are unable to learn the specific mask "shapes" of any individual source, and thus need the additional help offered by the HC. Therefore, in all subsequent experiments we include the HC for QBE networks, but omit it for the SSS networks.

In Table 3, we expand on the results from Table 2 and compare the results from single-level and multi-level hierarchical models for both SSS and QBE separation models. In both cases, the multi-level hierarchical networks improve over the single-level models, with the largest gains occurring at lower hierarchy levels. This implies that the networks can leverage their shared knowledge of the hierarchy to aid themselves at the lower levels, where individual instruments are more difficult to discern in the mix.

From the Level 1 results in Table 3, we see that sepa-

rating sources at this fine level of detail (e.g., clean electric guitars vs. distorted electric guitars) is extremely difficult, especially with a MIDI-synthesized data set such as Slakh2100, where several different instrument types may sound similar. In fact, when trying to train a single network to only separate these fine-grained sources, we are unsuccessful as noted by the negative SI-SDR improvements in the # lvls=1 (single level) rows for Level 1 sources. Training networks on multiple levels simultaneously mitigates this to some extent, although we have informally noticed the multi-level network sometimes outputting nearly identical separated sources between Level 1 and Level 2. We also note that the highest output SI-SDR values are obtained when separating Level 3 sources in Table 3, and we mention that Level 3 sources can be considered similar to the "other" source class in MUSDB18 [25]. Therefore, separating sources at the more fine-grained Levels (1 and 2) is more difficult than what is typically attempted in musical source separation.

In Table 4, we can observe the effect of removing leaf sources (Level 1 sources, see Table 1 for guitar example) from the training set. Compared to reducing *all* of the data by 50% or 90%, the performance of reducing only the leaves degrades very minimally. In cases where we have rich data at higher levels but sparse data at lower levels, hierarchical multi-level networks can do a respectable job at separating lower levels. We see the same story for both SSS and QBE networks: even a small amount of leaf data can help ward off a large drop in performance.

7. CONCLUSIONS

In this paper, we re-framed the source separation problem as hierarchical, and demonstrated the benefit of learning to simultaneously separate sources at different levels of granularity. In the present work, we considered network architectures that output masks for source separation at all relevant levels together. We showed that in doing so, we are still able to separate out the most granular source types when training data is severely limited. A major drawback of this work is the need for a large quantity of labeled and curated data, a limitation that we hope future work can address. Other future directions include architectures that output relevant levels sequentially, such as cascaded models [40], or directions inspired by hierarchical audio classification models [41, 42].

ABSTRACT

Musical preferences have been considered a mirror of the self. In this age of Big Data, online music streaming services allow us to capture ecologically valid music listening behavior and provide a rich source of information to identify several user-specific aspects. Studies have shown musical engagement to be an indirect representation of internal states including internalized symptomatology and depression. The current study aims at unearthing patterns and trends in the individuals at risk for depression as it manifests in naturally occurring music listening behavior. Mental well-being scores, musical engagement measures, and listening histories of Last.fm users (N=541) were acquired. Social tags associated with each listener's most popular tracks were analyzed to unearth the mood/emotions and genres associated with the users. Results revealed that social tags prevalent in the users at risk for depression were predominantly related to emotions depicting *Sadness* associated with genre tags representing *neo-psychedelic-, avant garde-, dream-pop*. This study will open up avenues for an MIR-based approach to characterizing and predicting risk for depression which can be helpful in early detection and additionally provide bases for designing music recommendations accordingly.

1. INTRODUCTION

According to reports from the World Health Organization, an estimated 322 million people worldwide were affected from depression, the leading cause of disability [1]. Recent times have witnessed a surge in studies on using social multimedia content, such as those from Facebook, Twitter, Instagram, to detect mental disorders including depression [2–6]. Music plays a vital role in mental well-being by impacting moods, emotions and other affective states [7]. Musical preferences and habits have been associated with the individual's need to satisfy and reinforce their psychological needs [8, 9]. Empirical evidence exists linking musical engagement strategies to measures of ill-health including internalized symptomatology and depression [10, 11]. Also, increased emotional dependency on music during periods of depression has been reported [12]. Specifically, the Healthy-Unhealthy Music Scale (HUMS), a 13-item questionnaire was developed for assessing musical engagement strategies that identified maladaptive ways of using music. Such strategies are characterized by using music to avoid other people, resort to ruminative thinking and ending up feeling worse after music engagement. Such unhealthy musical engagement was found to correlate with higher psychological distress and was indicative of depressive tendencies [13]. Furthermore, the high predictive power observed from the machine learning models in predicting risk for depression from HUMS further bolsters its efficacy as an indirect tool for assessing mental states [14]. Research suggests that such musical engagement does not always lead to alleviating depressive symptoms [15]. This indeed calls for developing intervention strategies that allow for altering music listening behavior to suit the individual's state, traits, and general musical preferences which may lead to a positive outcome. Thus, it is of vital importance not only to identify individuals with depressive tendencies but also to unearth music listening habits of such individuals that will provide bases for designing music recommendations accordingly.

Past research studying the link between music listening habits and depression has been done using self-reported data and controlled listening experiments wherein participants may have wished to conform to social expectations, or their responses might be influenced by how they want other people to perceive them thereby resulting in demand characteristics [16]. This has also been identified as a limitation by Nave et al. [8], who have proposed collecting data in more ecologically valid settings, such as user listening histories from music streaming platforms which are a better reflection of the users' true preferences and behaviours. To date no studies have looked at the link between active music listening and depression using the music listening histories of users which motivates us for this study.

In this age of big data, online music streaming platforms such as Last.fm, Spotify, and Apple Music provide access to millions of songs of varying genres and this has allowed

Figure 1: Methodology

for assessing users' features from their digital traces on music streaming platforms. To the best of our knowledge, Last.fm is the only platform that makes it possible to extract the listening history of users and other metadata describing their listening behavior using its own public API. Last.fm has been used extensively by researchers for various purposes such as music emotion classification, user behavior analysis, and social tag categorization [17, 18]. Last.fm has an abundance of social tags that provide a wide range of information about the musical tracks including audio low- and high-level feature description, emotions and experiences evoked, genre, etc. These tags have been found to predict short-term user music preferences [19] and in successfully predicting next played songs in the design of a recommendation system [20]. Our aim is to identify the tags and their respective occurrences in the listening behavior of individuals at risk for depression, which makes Last.fm an apt choice for this study. The data was collected using an online survey comprising of Last.fm music listening histories, in addition to music engagement strategies (HUMS), and mental well-being scores of the participants. Specifically, each track in the data was semantically represented by the tags assigned to it. We leverage these representations of tags as social descriptors of music to uncover emotional experiences and concepts that are associated with users with risk for depression.

1.1 Research Objectives and Hypotheses

In this study we investigated whether people's music listening history, in terms of social tags, could be used to predict a risk for depression. Our research questions were:

- What are the social tags associated with music chosen by At-Risk users?

- What emotions do these tags signify in the context of musically evoked emotions?

- What genres are mostly associated with At-Risk users?

- How well can we classify users as At-Risk given user-specific social tags?

We expected the social tags linked with At-Risk listeners to contain emotions with low arousal and low valence, being typical of depressive mood. Owing to the lack of research

associating music genres and risk for depression [15], this part of the study was exploratory.

2. METHODOLOGY

The methodological approach and procedure of our study is illustrated in Figure 1. The steps of data collection, processing, and analysis are described below.

2.1 Data Collection

An online survey was designed wherein participants were asked to fill their Last.fm usernames and demographics followed by standard scales for assessing their mental well-being, musical engagement strategies and personality. Participants were solicited on the Last.fm groups of social media platforms like Reddit and Facebook. The inclusion criterion required being an active listener on Last.fm for at least a year prior to filling the survey. The survey form required the users' consent to access their Last.fm music history.

2.1.1 Participants

A total of 541 individuals (Mean Age = 25.4, SD = 7.3) were recorded to be eligible and willing to participate in the study consisting of 444 males, 82 females and 15 others. Most of them belonged to the United States and the United Kingdom accounting for about 30% and 10% of the participants respectively. Every other country contributed to less than 5% of the total participants.

2.1.2 Measure of Well-Being, Musical Engagement, and Personality

The Kessler's Psychological Distress Scale (K10) questionnaire [21] was used to assess mental well-being. It is a measure of psychological distress, particularly assessing anxiety and depression symptoms. Individuals scoring 29 and above on K-10 are likely to be at severe risk for depression and hence, constitute the "At-Risk" group. Those scoring below 20 are labeled as the "No-Risk" group [22] as they are likely to be well. There were 193 participants in the No-Risk group and 142 in the At-Risk group. The HUMS survey was administered to assess musical engagement strategies which resulted in two scores per participant, *Healthy* and *Unhealthy*. Personality information was obtained using the Mini-IPIP questionnaire [23]

which results in scores for the Big Five traits of Personality namely *Openness*, *Conscientiousness*, *Extraversion*, *Agreeableness* and *Neuroticism*. HUMS and personality data were collected in order to identify if specific personality traits engage more in *Unhealthy* music listening and as additional measures to assess internal validity.

2.1.3 Music Listening History

Each participant's music listening history was extracted using a publicly available API. The data included tracks, artists, and social tags associated with the tracks. For each participant, the top n (n=500,200,100) tracks based on play-counts were extracted centered around the time t (t = $\pm$ 3 months,2 months) they filled in the questionnaire. The reason for varying n and t was to find converging evidence in music listening behavior in order to make our results more robust. For each track, the top 50 social tags based on tag weight (number of times the tag has been assigned to the track) were chosen for subsequent analysis.

2.2 Social Tags Processing

2.2.1 Tag Filtering

Music-related social tags are known to be descriptors of genre, perceived emotion, artist and album amongst others. It is therefore important to filter them to organize them according to some structure and interpretable dimensions for the task at hand. The purpose of this preprocessing step was to retrieve tags that could be mapped onto a semantic space representing music-evoked emotions. To this end, we used four filtering stages: first, include lower-casing, removal of punctuation and stop-words, spell-checking and checking for the existence of tag words in the English corpus; second, retain tags that are most frequently assigned adverbs or adjectives via POS (Part Of Speech) tagging since POS tags representing nouns and pronouns do not have emotion relevance in this context; third, remove tags containing 2 or more words to avoid valence shifters [24] and sentence-like descriptions from our Last.fm corpus; fourth, manually filter them by discarding tags without any mood/emotion associations.

2.2.2 Tag Emotion Induction

To project the tags onto an emotion space, we used dimensional models that represent the emotions. Multiple research studies have shown the usefulness of both two-dimensional and three-dimensional models to represent emotions [25–27]. We therefore used both these models for further analysis in order to check for trends and the effect of the third dimension when dealing with emotions.

The first model is one of the most popular dimensional models, the Russell's Circumplex Model of Affect [28], where an emotion is a point in a two-dimensional continuous space representing *Valence* and *Arousal* (VA). *Valence* reflects pleasantness and *Arousal* describes the energy content of the emotion. The second model is an extension of the Russell's model with an added *Dominance*

dimension (VAD), which represents control of the emotional state. The VAD model has been a popular framework used to construct emotion lexicons in the field of Natural Language Processing. The projection in the VAD space is based on semantic similarity and has been largely used to obtain affective ratings for large corpora of English words [29] [30]. Another common emotion model is the VAT model wherein the third dimension represents *Tension* (VAT) and has been used in retrieving mood information from Last.fm tags [17]. However, Saari et. al.'s [17] approach was based on tag co-occurrence rather than semantic similarity. Moreover, a subsequent study by the same authors reported a positive correlation (r=0.85) between *tension* and *dominance* [31]. Also, multiple studies have supported the use of the VAD space for analysing emotions in the context of music [32, 33]. We therefore have chosen the VAD framework for the purpose of our study. Since VA dimensions alone were found to sufficiently capture musical emotions [26], we also repeat our analysis based on the VA model to observe the effect of the omitted *Dominance* dimension.

The tags were projected onto the VAD space using a word-emotion induction model introduced by Buechel and Hahn [29]. We used the FastText embeddings of the tags as input to a 3-layer multi-layer perceptron that produced VAD values ranging from 1 to 9 on either of the dimensions. FastText has shown better accuracy for word-emotion induction [29] when compared to other commonly used models like Word2vec and GloVe. Moreover, FastText embeddings incorporate sub-word character n-grams that enable the handling of out-of-vocabulary words. This results in a large advantage over the other models [34]. In addition, FastText works well with rarely occurring words because their character n-grams are still shared with other words. This made it a suitable choice since some of the user-assigned tags may be infrequent or absent in the training corpus of the embedding model. We used the same approach to project the tags onto the VA space by changing the number of nodes in the output layer from 3 to 2.

Both the models were trained using the EN+ dataset which contains *valence*, *arousal* and *dominance* ratings (on a 9-point scale) for a majority of well-known English words [35]. This module resulted in an n-dimensional vector (n=3 for VAD, n=2 for VA) for each tag. The remainder of the pipeline describes the 3-dimensional VAD vector processing. The same procedure is repeated for the VA scores.

2.2.3 Tag Emotion Mapping

The social tags were grouped into broader emotion categories. These categories consisted of 9 first-order factors of Geneva Emotional Music Scale (GEMS) [36]. These were *Wonder, Transcendence, Nostalgia, Tenderness, Peacefulness, Power, Joyful activation, Tension and sadness.* Table 1 in the supplementary material displays the factor loadings for these first-order factors of GEMS. GEMS contains 40 emotion terms that were consistently chosen to describe musically evoked emotive states across

a wide range of music genres. These were subsequently grouped to provide a taxonomy for music-evoked emotions. This scale has outperformed other discrete and dimensional emotion models in accounting for music-evoked emotions [37]. In order to project these 9 emotion categories onto the VAD space, we first obtained the VAD values for the 40 emotion terms. Next, the VAD values were weighted and summed according to the weights provided in the original GEMS study to finally obtain VAD values for each of the emotion categories. Figures 1 & 2 in supplementary material display the projections of these emotion categories onto the VAD and VA spaces. Each of the tags are then assigned the emotion category based on the proximity in the VAD space as evaluated by the euclidean distance.

2.3 User-Specific Emotion Prevalence Score

After every user's tags had been mapped onto the 9 emotion categories, we calculated an *Emotion Prevalence Score* $S_{u,c}$ for every user. This represents the presence of tags belonging to that particular emotion category in the user's listening history.

$$S_{u,c} = \frac{\sum_{j \epsilon V_{\text{tr}}} (N_{j,c} \times tr_{\text{u,j}})}{\sum_{i \epsilon T_{\text{u}}} tr_{\text{u,i}}} \quad (1)$$

where

$$N_{j,c} = \sum_{k \epsilon Tags_{\text{c}}} \frac{tw_{\text{j,k}}}{\sum_{l \epsilon V_{\text{tg}}} tw_{\text{j,l}}} \quad (2)$$

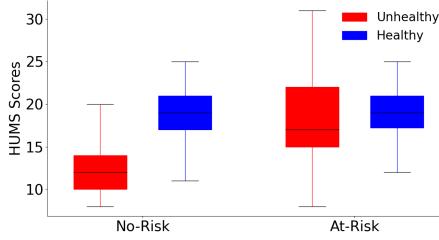
c : emotion category
$N_{j,c}$: the association of track j with c
T_u : all tracks for user u
V_{tg} : all tags obtained after tag filtering
V_{tr} : all tracks having at least one tag from V_{tg}
$tr_{u,i}$: playcount of track i for user u
$tw_{j,k}$: tag weight of tag k for track j
$Tags_c$: all tags in V_{tg} which belong to c

Since the objective of this work was to identify which of the 9 categories are most characteristic of At-Risk individuals when compared to No-Risk individuals, we performed group-level statistical tests of difference as described in the following section.

2.4 Emotion-based Analysis : Group Differences and Bootstrapping

For each emotion category, we performed a two-tailed Mann-Whitney U (MWU) Test on the *Emotion Prevalence Scores* between the No-Risk and At-Risk groups. For a category, the group having higher mean rank from MWU Test indicates a stronger association of the category with that group. For the emotion categories that exhibited significant differences ($p < .05$), we further performed bootstrapping to account for Type I error and ensure that the observed differences are not due to chance. Bootstrapping (random sampling) with replacement was performed with 10,000 iterations. Each iteration randomly assigned participants to the At-Risk or No-Risk group. The U-statistic

for each iteration was calculated. As a result, we obtain a bootstrap distribution for the U-statistic from which we estimate the significance of the observed statistic.

2.5 Genre-Prevalence Analysis


To further analyse the types of music associated with the tags of emotion categories, we explored genre-related social tags. In order to select the genre-related tags from our data, we collected the results of the multi-stage model proposed by Ferrer et al. [38] which assigned tags of Last.fm to different semantic layers namely genre, artist, affect, instrument, etc. In order to understand the underlying genre tag structure and obtain broader genre categories, we employed the approach described by Ferrer et al. [39] to cluster genre tags (details in Equation 1 in the Supplementary material). In this, music tags were hierarchically organized revealing taxonomy of music tags by means of latent semantic analysis. The clusters thus obtained were labelled based on the genre-tags constituting the core points of the cluster [40].

For the emotion categories that exhibited significant group differences, the genre tags co-occurring with its tags were used to calculate a user-specific *Genre Prevalence Score* for each genre-tag cluster. The formula used was similar to *Emotion Prevalence Scores* with the change in definition of the following terms: c represents the genre cluster, T_u is the set of all tracks for user u which have a tag belonging to the particular emotion category and V_{tg} is the set of all genre tags. Finally, we performed a biserial correlation between *Genre Prevalence Scores* for each genre-tag cluster and the users' risk for depression (represented as a dichotomous variable with 0 = No-Risk; 1 = At-Risk).

3. RESULTS

3.1 Internal Consistency and Criterion Validity

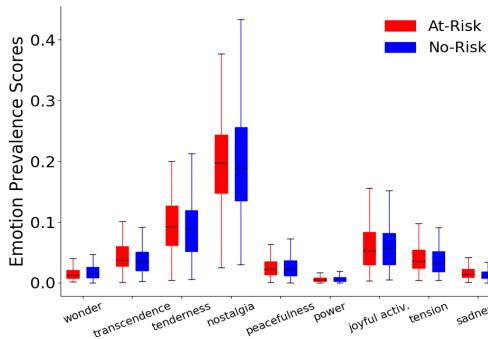
The Cronbach's alphas for *Unhealthy* scores obtained from HUMS and K10 scores were found to be relatively high at 0.80 and 0.91 respectively. A significant correlation (r=0.55, df=539, p<0.001) between *Unhealthy* Score and K10 was found which is in concordance with past research studies in the field [13]. Also, in line with previous research [41, 42], a significant positive correlation was observed between K10 score and Neuroticism (r=0.68, p<0.0001) adding to the internal consistency of the data and confirming construct validity. As can be seen in Figure 2, the At-Risk group displayed higher mean and median *Unhealthy* score compared to No-Risk while *Healthy* scores were comparable. Partial correlations between *Unhealthy*, *Healthy*, and K10 are presented in Table 1. K10 scores exhibit significant positive correlation only with *Unhealthy* for both the groups. The moderate correlation between *Healthy* and *Unhealthy* scores for the No-Risk population indicates that both of these subscales capture a shared element, most likely active music listening.


Figure 2: Boxplot of HUMS scores for No-Risk and At-Risk Groups.

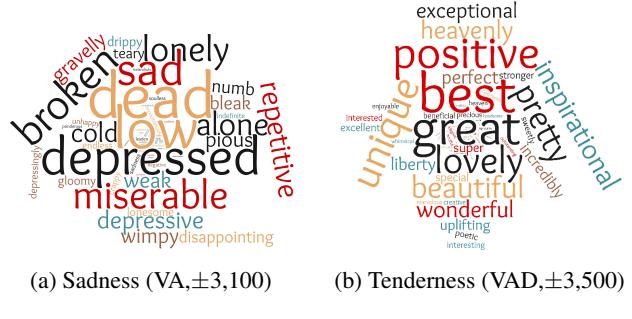
	No-Risk		At-Risk	
Scales	Healthy	Unhealthy	Healthy	Unhealthy
Healthy	1.0	0.36**	1.0	-0.14
Unhealthy	0.36**	1.0	-0.14	1.0
K10	0.07	0.26**	-0.11	0.22*

Table 1: Partial Correlation Values between HUMS & K10. (*p<0.01 & **p<0.001)

3.2 Emotion-based Results


The data ($t=\pm3$,$n=500$) consisted of 3,80,261 social tags. The tag filtering process resulted in a final set of 1254 unique tags (Mean=109, SD = 24 tags per user) which were then mapped onto the VA and VAD emotion spaces. Figure 3 in supplementary material displays the tags closest to each of the Emotion Categories based on VA and VAD models.

Figure 3: Boxplot of Emotion Prevalence Scores for No-Risk and At-Risk based on VA.

Figure 3 illustrates the *Emotion Prevalence Scores* for both groups for VA mapping (Supplementary Figure 4 displays the same for VAD, showing a similar distribution). The overall pattern appears similar between both the groups with minor observable differences for the emotion categories *wonder, transcendence, tenderness, tension, and sadness*. Table 2 displays the emotion categories that exhibited significant differences between the groups (MWU U-statistic and bootstrap p-values in Table 2 of Supplementary material). The At-Risk group consistently exhibits higher Prevalence Scores in *Sadness* while the No-Risk group vacillates between *Wonder* and *Transcendence*. The most significant difference was observed in *Sadness* (VA model,$t=\pm3$,$n=100$) with a significantly greater *Emotion Prevalence Score* for the At-Risk group (Median

= 0.0117) than the No-Risk group (Median = 0.0091), U=11414.5, p=0.009. Significant difference was also observed for *Tenderness* with greater *Emotion Prevalence Score* for the At-Risk group (Median = 0.1271) than the No-Risk group (Median = 0.1189), U=11905.0, p=0.04. On the other hand, the *Emotion Prevalence Score* in *Wonder* (VA model,$t=\pm2$,$n=100$) was significantly greater for the No-Risk group (Median = 0.0131) than the At-Risk group (Median = 0.0086), U=16270.0, p=0.003. The word-clouds of tags comprising *Sadness* and *Tenderness* are displayed in Figure 4a and Figure 4b. A score per tag is computed for each group (Equation 2 in Supplementary material). A rank was assigned to the tag based on the absolute difference of the tag scores between No-Risk & At-Risk groups. The size of the tag in the word-cloud is directly proportional to its rank in the category. Supplementary figures 5 and 6 depict word-clouds for *Transcendence* and *Wonder*.

(a) Sadness (VA,±3,100)   (b) Tenderness (VAD,±3,500)

Figure 4: Wordclouds for emotion categories associated with At-Risk group.

We also assessed the predictive power of social tags for risk of depression by classifying participants into At-Risk or No-Risk groups using their tag information (feature details in Equation 4 in Supplementary material). The SVM model with 'rbf' kernel (C=2301, gamma=101) gave the best results with a 5-fold cross-validation accuracy of 66.4%.

3.3 Genre-Prevalence Results

Out of the 5062 tags assigned to the genre layer in [38], 94% (4766) of the tags were present in our data. The clustering of the genre tags resulted in 17 clusters and is displayed in Table 3 of Supplementary material. Figure 7 in Supplementary material displays mean genre prevalence scores between both groups for these 17 clusters. Overall, genre-cluster representing *indie-,alternative-pop/rock* represented by Cluster 4 is predominant in both groups. Genre prevalence scores were then evaluated specific to the tracks associated with the emotion categories that exhibited most significant group differences, that is, *Wonder* and *Sadness* (VA model, $t=\pm3$, $n=100$). For *Sadness*-specific tracks, the highest correlation (r=0.2, p<0.01) was observed between the Genre-Prevalence scores in the cluster representing *neo psychedelic-, avant garde-, dream-pop* and K-10 scores. Also, genre clusters representing *electronic rock* (r=0.17, p<0.01), *indie-, alternative-pop/rock* (r=0.12, p<0.05), and

Group	Top Tracks	VAD		VA	
		$t=\pm3$	$t=\pm2$	$t=\pm3$	$t=\pm2$
At-Risk	$n=100$	Sadness*		Sadness**	
	$n=200$	Sadness*	Sadness*, Tenderness*	Sadness*	Sadness*, Transcendence*
	$n=500$	Sadness*, Tenderness*	Tenderness*	Sadness*	Sadness*, Transcendence*
No-Risk	$n=100$		Transcendence*		Wonder**
	$n=200$	Transcendence*	Transcendence*	Wonder*	Wonder**
	$n=500$	Transcendence*	Transcendence*	Wonder*	Wonder**

Table 2: Emotion Categories with Significant Differences between At-Risk and No-Risk groups.*p<0.05; **p<0.01

world music (r=-0.11, p<0.05) demonstrated significant correlations for *Tenderness*. For *Wonder* (VA model, $t=\pm2$, n=100), the K-10 scores exhibited significant negative correlation with *Genre Prevalence Scores* of clusters representing *black metal* (r=-0.11, p<0.05) and *neo-progressive rock* (r=-0.13, p<0.05).

4. DISCUSSION

This study is the first of its kind to examine the association between risk for depression and social tags related to music listening habits as they occur naturally as opposed to self-reported or lab-based studies. A clear difference in the music listening profiles was observed between the At-Risk group and the No-Risk group, particularly in terms of the emotional content of the tags. *Sadness* was significantly more prevalent in the At-Risk group and the word-cloud of sadness was highly illustrative of other low-arousal, low-valence emotions such as *dead, low, depressed, miserable, broken*, and *lonely*. The stronger association of the At-Risk group with sadness is in concordance with the past research studies in the field [43] and confirms our hypothesis. The At-Risk group is attracted to music that reflects and resonates with their internal state. Whether this provides emotional consolation as an adaptive resource or whether it only worsens repetitive negative feelings and fuels rumination, remains an open question. Nonetheless, statistically, such listening style can be seen as a highly predictive factor of psychological distress.

In addition, *Tenderness*, which represents low-arousal and high-valence, was also more prevalent in the At-Risk group, especially for shorter-term (± 2 months) music listening habits. *Tenderness* appears to be more significant in the shorter time period in addition to *Sadness*, possibly indicating that At-Risk people tend to oscillate between positive and negative states within a general state of low arousal. These findings appear to be very much in line with the results found by Houben et al. [44] who found high levels of emotional inertia and emotional variability to be linked with depression and ill-being. The consistent results related to *Sadness* in our study reflect the overall inert states in which the At-Risk tend to be. On the other hand, the *Tenderness* results reflect their tendency to jump to positive affective states while retaining low arousal, thereby demonstrating emotional variability. Furthermore, the omission of the *Dominance* dimension causes most of the tags to shift from *Tenderness* to *Transcendence* and *Transcendence* to *Wonder*, which explains

the results in a reversal of the group association as evidenced in the results. Nevertheless, *Sadness* appears to be the predominant state as it is largely consistent for ±3 months as well as for ±2 months of music listening histories.

The At-Risk group also exhibited a tendency to gravitate towards music with genre tags such as *neo-psychedelic-, avant garde-, dream-pop* co-occurring with *Sadness*. Such genres are characterized by ethereal-sounding mixtures that often result in a wall of sound comprising electronic textures with obscured vocals. Similarly, the genres co-occurring with *Tenderness* (VAD model) or *Transcendence* (VA model) comprise similar mixtures with heavy synthesizer-based sounds (such as mellotron) which result in sounds that seem otherworldly. Such out-of-this world soundscapes have been also associated with transcendent druggy and mystical imagery and immersive experiences [45]. These results strengthen the claim that depression may foster musical immersion as an escape from a reality that is perceived to be adverse. This is somewhat in line with prior research that has linked depression with the use of music for avoidant coping [46]. On the other hand, music listening history of the No-Risk group was characterized by an inclination to listen to music tagged by positive valence and higher arousal as characterized by *Wonder* with a predilection for *Heavy metal* and *Progressive Rock* genres.

The use of only single word tags in the third stage of tag filtering is one limitation of this study which is due to lack of compatibility of the word emotion induction model with multi-word tags. Our results could potentially be extended to find significant differences in emotional concepts after considering multi-word social tags. We achieve a decent classification accuracy of 66.4% which is significantly above the chance level which indicate that social tags indeed may be indicative of At-Risk behavior. This may further be improved by considering additional descriptors of music such as acoustic features and lyrical content of the tracks. Another future direction is to incorporate the temporal evolution of these emotion categories in the listening histories to characterize depression, since past research suggests depression to be a result of gradual development of daily emotional experiences [47]. This study is intended to be one of many to come that will be helpful in early detection of depression and other potential mental disorders in individuals using their digital music footprints.

PROGRAMMING INEQUALITY: GENDER REPRESENTATION ON CANADIAN COUNTRY RADIO (2005-2019)

Jada Watson

School of Music, University of Ottawa

`jada.watson@uOttawa.ca`

ABSTRACT

In May 2015, a consultant for country radio revealed a decades' long practice of limiting space for songs by female artists. He encouraged program directors to avoid playing songs by women back-to-back and advocated for programming their songs at 13-15% of station playlists. His words sparked debate within the industry and drew attention to growing inequalities on radio and within the genre. The majority of these discussions have centered on US country radio, with limited attention to the growing imbalance on the format in Canada. While country format radio in both countries subscribe to a practice of gender-based programming, Canadian program directors are governed by the federal *Broadcasting Act,* which regulates dissemination of Canadian content. Using metadata extracted from one of the main radio monitoring services – Mediabase, this paper examines gender-related trends on Canadian country format radio between 2005 and 2019. Through data-driven analysis of Mediabase's weekly reports, this paper shows declining representation of songs by women on Canadian country radio and addresses the impact of Canadian content regulations on this process.

1. INTRODUCTION

Gender has long been a central dynamic of programming in the country music industry. In the early days of the genre, male artists were associated with "public work" and commercial success, while women were tucked away in domestic, administrative and musically supporting roles [1-2]. Despite their significant contributions to the genre on the stage and behind the scenes, female artists have historically been limited on radio playlists, tours, television programs, and label rosters [3-5]. Since the 1960s, radio programmers have employed a form of gender-based scheduling as a means to structure and balance playlists; claiming they had fewer songs by women, programmers "spread out" their songs to avoid repetition [6]. This practice formalized in the late 1990s through the work of a radio consultant who developed a system for programming songs by women at 13-15% of playlists [7]. In May 2015, after nearly two decades of promoting his formula, the consultant spoke openly about his method, arguing that the format's majority female fanbase prefers male voices and advocated employing his formula to make ratings [7].

In the 5 years following this interview, research has addressed the growing imbalance on terrestrial radio. Data-driven studies have challenged the industry's growing "anti-female" myth and evaluated the decline in representation on industry charts [8-11]. Using airplay reports to investigate programming practices, recent studies revealed a 66% decline in the number of songs by women within the Top 150 on Mediabase's Yearend reports [12] and an increase in the ratio of spins for songs by men and women from 2 to 1 in 2000 to 10 to 1 by 2018. They also evaluated the distribution of spins for songs by women and found that women were underrepresented across all dayparts in the 24-hour cycle [13]. Taken together, these studies reveal the long-term impact of the gender-based programming on US country format radio.

While gender representation on US country format has been widely discussed, growing inequalities on terrestrial radio in Canada has not received the same attention. A September 2019 report took preliminary steps toward evaluating representation on Canadian country format radio [14], finding similar disparity as in the US but did not fully address the impact on Canadian artists. Given the federal laws regulating Canadian Content, it is important to consider representation through a geo-cultural lens. The present study seeks to extend this framework to consider compliance with federal content regulations and its impact on programming female artists on Canadian country radio.

Adopting methods for Big Data research in the humanities and social sciences [15-18], and influenced by prosopography [19-21], this paper presents an approach for using music industry data to study what airplay and biographic metadata can tell us about socio-cultural and institutional frameworks that govern popular cultures. To do so, I extracted weekly reports of aggregated radio airplay metadata from the Mediabase radio monitoring service's database and built a prosopography of all artists whose songs were played on Canadian country radio between 2005 and 2019. Using RapidMiner, these datasets were then joined to enable data-driven analysis of the community of artists whose songs are programmed on Canadian country radio. This study aims to answer several inter-related questions about representation. First, does the number of songs by male artists exceed those by women on Canadian country radio as it does in the US? Second, how often are songs by women programmed and at what time of day? Finally, how does this programming impact contention on weekly charts? Through each of these questions, the geo-origins of artists are considered in order to facilitate a deeper understanding of how Canadian Content regulations might help or hinder representational issues.

2. CONTEXT – CANADIAN RADIO

Broadcast radio in Canada began in the early 1920s (like the USA), with licenses for purchase from the national Department of Marine and Fisheries by groups that operated limited daytime programming [22-23]. As Canadian radio developed through the first half of the century, programming did not reflect the country's cultural heritage. By the late 1960s, as a renewed sense of nationalism emerged surrounding the country's centenary celebrations, there was a growing concern of Americanization of Canadian culture in general, and on broadcast radio specifically. Terrestrial radio was dominated by musical imports: by 1968 only 4% to 7% of the songs broadcasted were Canadian, with the remaining songs programmed primarily by musicians from the USA [22]. With little support from radio, Canadian artists struggled to break through the national market – which limited their reach outside of the country [22-23].

Debate came to a head in 1971 with the passage of the *Broadcasting Act*, which outlined Canadian content regulations that would be overseen by the newly formed Canadian Radio-Television Commission (CRTC) [24-25]. These regulations sought to carve out space for Canadian music on AM and (later) FM radio, governing the minimum percentage of songs aired and their time of day – to ensure that Canadian songs are not ghettoized in the overnights. As of 1998, stations are required to play 35% Canadian content [26-27].

In addition to a content quota, the *Broadcasting Act* also outlines criteria for evaluating a song's "Canadianness". Known by its acronym **MAPL**, the system includes the following criteria:

1. **M**usic is composed entirely by a Canadian;
2. **A**rtist performing the music or lyrics is Canadian;
3. **P**erformance is (i) recorded wholly in Canada or (ii) performed and broadcast wholly in Canada; and
4. **L**yrics are written entirely by a Canadian [28].

A musical work must fulfill two of these conditions to qualify as Canadian and count toward a station's quota.

3. DATASET

The dataset for this study was curated from the weekly airplay reports generated by Mediabase, a music industry service that monitors airplay in the US and Canada. The dataset contains 319,369 records capturing the weekly activity of the 6,675 unique songs played on Canadian country format radio between 2005 and 2019. The reports include descriptive metadata about the songs played on Canadian country radio (artist, featured artist, title, label and release year) as well as information about their weekly activity (report date, weekly ranking and status, as well as distribution of spins overall and across all 5 dayparts). The 780 weekly reports were downloaded directly from Mediabase's database, cleaned and merged, and then structured to discover gender- and race-related trends that characterize programming on country format radio. As such, they were augmented with a metadata capturing the biographic details of the artists and ensembles, including genre, ensemble type, gender, race/ethnicity and country of origins.

Country radio programmers use just two labels to code artists in their scheduling software: "male" and "female," and apply the latter designation to male-female ensembles

– even if the group has a male lead [29]. Moving outside of the industry's strict binary coding system, this study follows the practice employed in previous studies, using three codes to define artists their biological and sociological status: M for men, W for Women, and M-F for male-female ensembles [11-16]. While this coding system still works with gender binaries, the aggregated radio reports do not include transgender and gender non-binary artists. Thus, while more nuanced categories could be used, the absence of LGBTQ artists in the dataset is suggestive of larger socio-culture issues within programming that are in dire need of attention. This study thus acknowledges their absence and advocates for more inclusive programming.

4. RESULTS

The stations reporting to country format radio play contemporary country music (sometimes referred to as "country-pop"), not what one might call "classics" (i.e. songs by older generations often credited with developing the sound and culture of the genre). The reports include both current singles vying for chart contention and songs in "recurrent" status, which are comprised of songs that have exited the chart but still played regularly on radio that have become part of a station's back catalogue of standards. Generally, these songs include only those that were released within the preceding five years. Sections 4.1 to 4.3 evaluate representation across all songs played on radio, and Section 4.4 focuses just on the charting activity of current singles.

4.1 Gender representation

Over the course of this 15-year study period, songs by 1,309 artists were played on Canadian country format radio, 59.6% were men, 34.0% were women, 6.4% were male-female ensembles. While this amounts to a 60/40 split for male-only acts and acts that include women (as per radio coding), just 27.9% of all artists are played regularly on country format radio and with enough daily support to make the weekly charts. As such, even fewer female artists are heard regularly on radio. The overwhelming majority of these artists – 94.9% – are white, while 1.4% are Black, 0.8% are Indigenous, 1.1% are multi-racial, and 0.7% identify as having Filipino, Columbian, Hispanic, Latin, and Portuguese heritage. The ethnicity of 1.2% of the artists was unverifiable. This preliminary level of evaluating the identity of the artists reveals gender imbalance, to be sure, but also an overwhelming racial inequality that privileges white artists and excludes Black, Indigenous, Musicians of Colour (hereafter as BIMOC).

Table 1 parses data for the 6,675 songs played on country radio by gender and geo-origins, summarizing the number and percentage of unique songs by Canadians and non-Canadians played on Canadian country format radio between 2005 and 2019. Songs by Canadian artists consistently occupy 46% of the weekly programming. The remaining 54% of the songs are by non-Canadian artists (mostly from the USA). The majority of the songs were by non-Canadian men (37.9%) with those by Canadian men (29.4%) coming in second. Songs by Canadian and non-Canadian women and male-female ensembles occupy approximately the same percentage (16.3%) of songs.

This picture changes when evaluating representation of all songs on the weekly reports, which reveals how many times these songs are included on weekly playlists across the country. As Table 2 summarizes, 75.5% of the songs were by men, 19.3% were by women, and 5.1% were by male-female ensembles. Here, too, non-Canadian men dominate the Canadian country format soundscape, with both Canadian and non-Canadian women occupying just under 10% of weekly radio playlists. These results show that there are not just fewer songs by women (Table 1), but that they are less frequently included on station playlists (Table 2) than those by their male colleagues. The gap thus increases from 59.2% unique songs by men and women to 74.4% when evaluating the rate at which those songs appear on weekly playlists.

	Canadians	Non-Canadians
Men	1,965 (29.4%)	2,528 (37.9%)
Women	942 (14.1%)	892 (13.4%)
Male-female ens.	162 (2.4%)	186 (2.8%)
Total songs	3,069 (45.9%)	3,606 (54.1%)

Table 1. Gender representation of unique songs played on Canadian country format radio

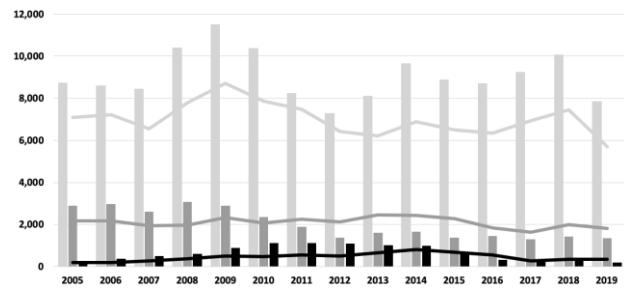
	Canadians	Non-Canadians
Men	105,166 (32.9%)	136,052 (42.6%)
Women	31,486 (9.9%)	30,230 (9.5%)
Male-female ens.	6,747 (2.1%)	9,688 (3.0%)
Total Songs	143,399 (44.9%)	175,970 (55.1%)


Table 2. Gender representation of all songs played on Canadian country format radio

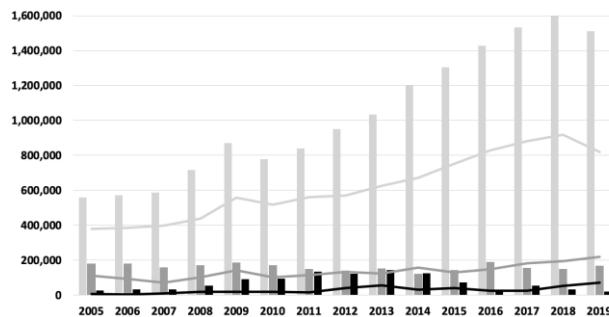
As with the number of unique artists, 96.4% of the unique titles are by white artists. This figure does not change when evaluating the full representation of all songs on the weekly reports. In both perspectives, songs by Black artists make up just 1.3% of the songs played on Canadian country radio, with 1.0% by Indigenous artists, 0.4% by multi-racial artists and all other ethnicities performing the final 0.9%. Few titles by artists who are BIMOC are included on Canadian country radio station playlists.

Figure 1 graphs distribution of songs on the weekly reports by artists' gender and geographic origins. Songs by Canadian artists are displayed in the line graph with those by non-Canadians in the columns, with light grey representing men, dark grey for women, and black for male-female ensembles. This graph shows that all male artists were programmed at a higher rate every year in this study period. Although the number of songs by men fluctuates, they consistently average 75.6% of the songs played and increase to 82% by 2017, as the percentage of songs by women decline. Canadian male artists consistently occupy 33% of the weekly reports, with songs by non-Canadian men receiving averaging 43% of the weekly playlists.

At the start of this period, women were responsible for an average of 22.7% of the songs played. But between 2009 and 2012, there was a 33% decline in the number of songs by men and women on the weekly airplay reports. Despite the fact that the change appears to have impacted men more in this period, both suffered a 33% loss in songs

on the reports. The gap between men and women remains relatively stable through this period of decline, but steadily widens to a high of 69.2 percentage points by 2017. As the number of songs by women declined between 2009 and 2012, male-female ensembles increased from 5.3% to 9.1%, and then declined back to 2.9% by 2019. This shows more clearly the impact of coding male-female ensembles as "females" in programming, as the ensembles simply replace solo female and all-female ensembles in playlists.

Figure 1. Distribution of songs by Canadians (lines) and non-Canadians (columns)

While male artists maintain their strong placement on Canadian country format playlists, songs by female artists declined from 23.8% in 2005 down to 14.9% by 2017 – a period low for women on Canadian country radio. However, as revealed in Figure 1, this decline had a greater impact on non-Canadian women. Songs by non-Canadian women dropped 13.6% of the weekly reports to a 7.3% average for the last seven years of the study period. Canadian women, though certainly underrepresented, are not impacted to the same degree as non-Canadians, as their songs consistently make up 10% of the weekly reports.


4.2 Distribution of spins

The results above show that an average of 19.3% of the songs played on Canadian country radio are by women, but that picture begins to change when evaluating how often songs are played at the level of accumulated "spins". Not only does this provide a sense of the space available for songs by women on radio, but it also aids in understanding how often the average listener actually *hears* women's voices on radio.

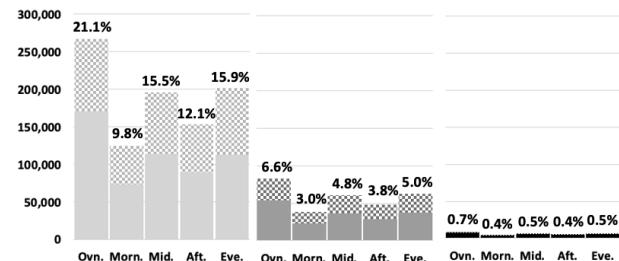
Figure 2 maps the distribution of all songs played on radio according to the total spins accumulated weekly, using the same geo-cultural and gender distribution as Figure 1. This figure paints a strikingly different picture of Canadian country radio culture. The number of spins for songs on country radio increased 55% overall between 2005 and 2019, with the majority of spins are granted to songs by non-Canadian men (averaging 50% of the spins), with those by Canadian men coming in second (averaging 30%). Combined, male artists average 80% of the spins over the course of this period. This leaves the remaining 20% for female artists and male-female ensembles. Songs by Canadian women average 7% of the spins on weekly playlists, while airplay for non-Canadian women declines steadily from 14% in 2005 down to 6% by 2019.

Here, too, as with the number of titles included on playlists, songs by artists who are BIMOC are drastically

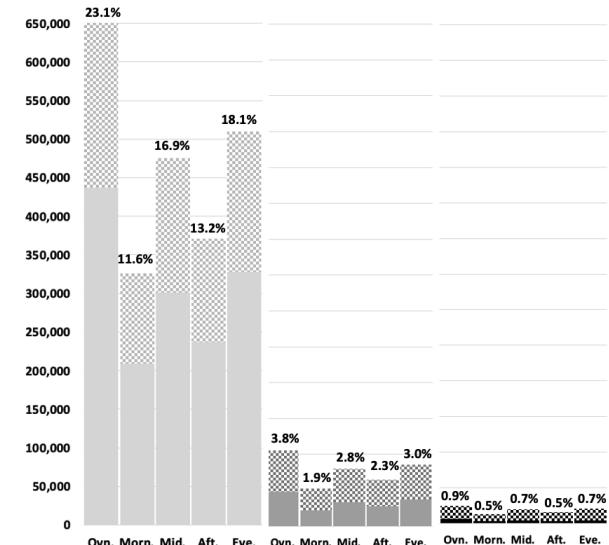
underrepresented. White artists received a majority of the annual airplay, with more than 90% annually. While this level of racial inequity is disheartening, the data shows that the percentage of spins for Black and Multi-racial artists increased from 0.2% to 8.3% by 2019. These spins are divided between 15 country artists, 10 of which are men who receive 7.8% of the spins. The 4 women of colour played on radio received a combined 0.5% of the annual spins.

Figure 2. Distribution of spins for songs by Canadians (lines) and non-Canadians (columns)

The picture that emerges in Figure 2 is one of growing inequality and cultural imbalance. While the number of spins for songs by women *increases* between 2005 and 2019, their representation within the full ecosystem *decreases,* dropping 10 percentage points over the course of this period. The decline in overall representation of women can be explained by an increase in the number of country format stations from 21 stations reporting to Mediabase in 2005 to 36 by 2019. As such, songs aren't being played more, they are spread out across more stations.

4.3 Time of Day


It is also important to understand the time of day that these songs are heard by the majority of radio listeners. The 24-hour period at radio is divided into 5 dayparts:

- Overnights (12:00 a.m. to 6:00 a.m.),
- Morning (6:00 a.m. to 10:00 a.m.),
- Midday (10:00 a.m. to 3:00 p.m.),
- Afternoon (3:00 p.m. to 7:00 p.m.), and
- Evening (7:00 p.m. to 12:00 p.m.) [30].


The evening and overnight dayparts register the smallest listening audiences (8% and 4% of the listening audience [31]), but this is when the majority of songs are played with 22% of the spins in the evening and 28% in the overnights. The morning, midday and afternoons periods have the highest percentages of tuned-in listeners (21%, 26% and 21%, respectively [31]); and yet, these three dayparts have the lowest percentage of songs played. Just 13% of the daytime spins occur in the morning, with 20% in the midday and 16% in the afternoon.

Figures 3a and b map the distribution of spins for men, women and male-female ensembles in 2005 and 2019 according to the time of day that songs are played and by country of origins, drilling further into the distribution of spins reported in Figure 2. The columns are presented in temporal order from the overnights (left) to the evening (right) for each category, with shading to represent geo-origins of the artists (non-Canadians in a solid shade, with

Canadians in a patterned shade). While the amount of spins for songs by women has increased (as in Figure 2), there is an overall decline in representation because of the significant increase for songs by men. In 2005, songs by men received 74.4% of the daytime spins, with 23.1% for songs by women and 2.5% for male-female ensembles. By 2019 (Figure 3b), male artists were receiving 83.3% of the total daytime spins. Despite an increase in spins for songs by women over this period, by 2019 songs by women occupy a smaller percentage of the daytime spins.

Figure 3a. Distribution of spins by daypart in 2005

Figure 3b. Distribution of spins by daypart in 2019

What is more disconcerting is the distribution across all five dayparts: songs by women register nearly the same percentage overall as men do in a single daypart for both periods. What this distribution shows is that songs by women are barely heard in daytime hours (6:00 a.m. to 7:00 p.m.), periods with the most listeners. Graphing distribution in this manner also shows clearly how the increase in spins for Canadian women factors on a 24-hour cycle. While they occupy the same space percentage of spins over this period, the number of spins distributed to Canadian women increases, while spins for non-Canadian women decreases.

Taking into account the increase in the number of stations reporting to Mediabase between 2005 and 2019, the number of songs per day can then be mapped to each daypart. As summarized in Tables 2a and 2b, songs by women are not being heard more on Canadian country format radio, they are spread across *more stations*. Thus, this type

of programming marginalizes female artists and ghettoizes their songs to a time of day when the majority of the listening audience is sleeping.

	Canadians			Non-Canadians		
	M	W	MF	M	W	MF

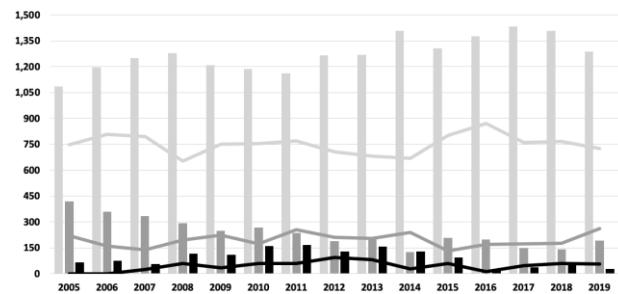
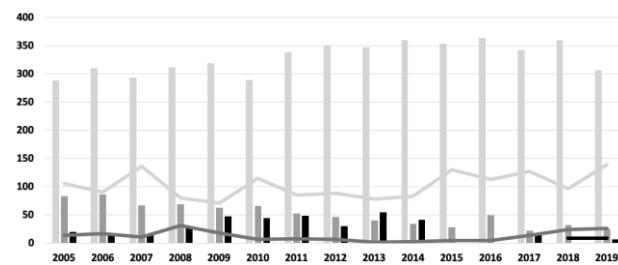
Table 2b. Number of songs played by non-Canadian and Canadian artists in 2019

4.4 Women on the Charts

How often a song is played on radio significantly impacts its chart contention. Songs that enter and climb the weekly airplay charts receive the most weekly spins across Canada's reporting stations and are most often heard by audiences. Just 32.7% of the unique songs played on country radio appeared on weekly airplay charts, 75% by men, 19% by women and 6% by male-female ensembles. While the charts are certainly not a measure of "quality", they are an industry standard of measuring a song's success and are integral to an artist's development: success on the airplay chart is linked to opportunities within the industry, including tours, festivals and eligibility for industry awards.


Between 2005 and 2019, the average amount of spins needed for a song to break into the 50-position chart increased 50% from 100 to 150 weekly spins. As this base number increased, the number of charting songs by women decreased. Figure 4 maps the distribution of these songs on the 50-position weekly airplay chart, showing the dominance of non-Canadian men (46.7%), followed by Canadian men (28%). Representation of female artists declines from 25.2% to 12.2% in 2018 before increasing to 17.7% (with 10.2% for Canadians and 7.5% for non-Canadians).

Given the racial inequity noted at the level of the full weekly reports, it is not surprising that the 50-position chart is dominated by white artists. Though significantly underrepresented, there have been increasingly more songs by artists who are BIMOC – from 1.0% in 2005 to 9.2% by 2019. These songs, however, are performed by just 14 unique artists, 10 of which are men and who are responsible for 80% of the 83 charting songs by BIMOC.


Representation worsens when drilling into the top positions on the weekly airplay charts. The bar for entering the

Top 10 positions on the weekly chart increased 59%, from 390 to 950 weekly spins by 2019. This, coupled with declining number of songs by women, resulted in a gradual disappearance of their songs from the top positions. As visible in Figure 5, the same general geo-cultural pattern is maintained: non-Canadian men dominate the chart and Canadian men come in second. Unlike above, however, Canadian women are significantly underrepresented in the Top 10, with an average of just 2.4% of the songs against 9.8% by non-Canadian women. By 2019, songs by both groups make up 5% of the annual Top 10.

Representation in the top positions of the chart is particularly dire when evaluating racial equity: just 3.5% of the Top 10 songs are by artists who are BIMOC. Despite the noted absence overall, there percentage of Top 10 songs by artists who are BIMOC increases from 0% in 2005 to 8.6% by 2019. Just two women of colour – Ojibwe artist Crystal Shawanda and Columbian-Canadian Kira Isabella – were responsible for five Top 10 songs between 2008 and 2014, none of which reached the top of the chart. Women of colour are thus absent from the top 10 positions of the chart, significantly limiting their exposure and shutting them out of opportunities within the industry.

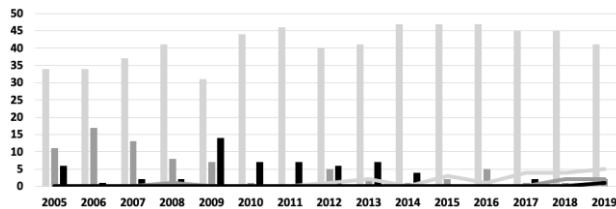
Figure 4. Distribution of songs in the Top 50 chart by Canadians (lines) and Non-Canadians (columns)


Figure 5. Distribution of Top 10 songs in the chart by Canadians (lines) and non-Canadians (columns)

The picture is most bleak at the top of the chart. Reaching the #1 position on an airplay chart requires a significant amount of weekly spins. As with other benchmark positions, the number of spins required for a song to reach #1 more than doubled between 2005 and 2019, increasing from 550 to 1,370 weekly spins.

Figure 6 reveals that the majority of the #1 songs in 2005 were by men (66%), increasing to a high of 96% in 2015 before declining to 90% by 2019 – and almost exclusively for non-Canadian artists. There is a period high of 36% for songs by women in the #1 spot in 2006, but this is followed by a steady decline to no songs in 2011 and an

average of 3% in the final years. Canadian artists are nearly absent from the top of the chart in the first 7 years of the period. With the exception of one #1 song for Terri Clark in 2008, Canadians were completely shut out of the top position of the chart until 2012, when Canadian male artists begin to achieve #1 songs – averaging three a year. Given the trends discussed thus far, Canadian women (and male-female ensembles) are the most underrepresented group, with just five #1 songs over 15 years. As the space available for women on station playlists declines, that accolade becomes increasingly unattainable for female artists.

Figure 6. Distribution of #1 songs on the weekly chart by Canadians (lines) and non-Canadians (columns)

5. DISCUSSION

The findings of this study illustrate that gender and racial inequality plagues Canadian country format radio. Not only do white, male artists have more songs on Canadian country radio overall and annually, but their songs are also played more often throughout the 24-hour cycle. The findings here echo the inequality identified in studies of US country format radio [12-13]. In Canada, as in the US, the gap between songs by men and women increases from 67.9% in 2005 to 76.5% by 2019 – a disparity that holds true (and indeed worsens) at the level of weekly airplay, time of day programming, and on the weekly charts. Racial inequity, though not surprising for this genre, is particularly problematic: while there has been an increase in representation of artists who are BIMOC over this period, their voices are nearly absent from radio. Only 14 artists who are BIMOC had enough airplay to have charting songs, just 4 of whom are women. Thus, over the course of this 15-year period, not only have songs by women started to disappear from the Canadian country charts and from the #1 position on the weekly reports, but women of colour are excluded from participation.

The Canadian content regulations offer another layer to this discussion. While this study revealed that 44% of the songs played on radio are performed by Canadians, those songs receive just 38.2% of the annual spins, with 30.3% songs by men, and just 6.6% by women and 1.3% by male-female ensembles. Thus, even though stations are fulfilling their content requirements, they average just above the quota and privilege non-Canadian artists. Indeed, non-Canadian men dominate at all levels of programming: they have the most songs, the most spins, the highest percentage of daytime programming and the most charting songs. Canadian men are second to non-Canadian men at all levels, with the exception of #1 songs – where non-Canadian women rank second overall in the number of chart-topping songs. While Canadian women are underrepresented, to be sure, the trend at all levels of analysis (with the exception

of the #1 position) is one of decline for non-Canadian women against an increase in songs, spins and daytime activity for Canadian women. This is not simply a result of the dwindling number of songs by women in the broader country music market but is suggestive of a trend in which program directors are creating more opportunities for the Canadian female artists – even if marginal.

Drilling into these weekly reports in this manner reveals the dominance and success of non-Canadians. Canadian artists receive enough spins to fulfill federal regulations on programming but are not favored enough within daily programming to have greater successes within the top positions of the weekly charts. Their near absence from the top of the chart– especially in the case of Canadian women – reveals a limit on success for the country's most prominent country artists on Canadian radio. While this of course makes business sense when considering that Nashville, Tennessee has been the centre of the industry since the genre formed, this is a missed cultural opportunity to further develop the industry north of the 49th parallel.

6. CONCLUSION AND FUTURE WORK

Music industry data offers a unique opportunity to evaluate the changing dynamics of a genre's culture and gain a better understanding of the composition of its cultural ecosystem. What emerges in the results of this study is a feedback loop that has slowly eliminated opportunities (in the form of daily airplay) for female artists, and gradually erases them from the industry's ecosystem. Women of colour are most impacted by this practice and excluded from participation. Program directors use this same airplay data to make programming decisions for their stations and then use the absence of songs by women on weekly reports and popularity charts to justify and maintain a gender-based programming practice. This is what data scientists refer to as "digital redlining" [32-33], a system by which data indirectly or directly uses criteria like gender, sexuality, and ethnicity to make assessments and recommendations.

Beyond the impact that these practices have on the livelihood of female artists, gender-based programming is also culturally damaging. Current practices, which focus heavily on repetition of songs by white, male voices, creates increased familiarity with those male artists and results over time in a more homogenized sound [34]. In this context, female voices – especially of artists who are BIMOC, have become increasingly *unfamiliar* to country radio audiences. This type of programming completely alters the public's perception of who is contributing to country music culture and contributes to a growing crisis of inequality.

Radio airplay is only one part of the story regarding gender inequality. The lack of radio airplay for songs by women deters labels and publishers from investing in female artists, and songwriters are discouraged from writing songs for them [35]. As such, next steps in this project will evaluate representation across label and publishing rosters to better understand how they operate within this system. In this regard, gender-identity and sexuality must be incorporated into future studies to investigate how these practices have been structured to establish and maintain the white, male, heteronormative discourse that pervades country music's narrative and culture.

DANCE BEAT TRACKING FROM VISUAL INFORMATION ALONE

Fabrizio Pedersoli   **Masataka Goto**

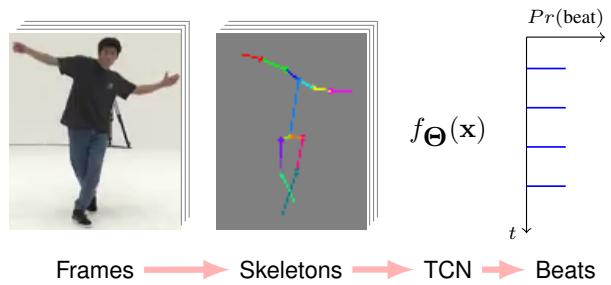
National Institute of Advanced Industrial Science and Technology (AIST), Japan

{fabrizio.pedersoli, m.goto}@aist.go.jp

ABSTRACT

We propose and explore the novel task of *dance beat tracking*, which can be regarded as a fundamental topic in the *Dance Information Retrieval* (DIR) research field. Dance beat tracking aims at detecting musical beats from a dance video by using its visual information without using its audio information (i.e., dance music). The visual analysis of dances is important to achieve general machine understanding of dances, not limited to dance music. As a sub-area of Music Information Retrieval (MIR) research, DIR also shares similar goals with MIR and needs to extract various high-level semantics from dance videos. While audio-based beat tracking has been thoroughly studied in MIR, there has not been visual-based beat tracking for dance videos.

We approach dance beat tracking as a time series classification problem and conduct several experiments using a Temporal Convolutional Neural Network (TCN) using the AIST Dance Video Database. We evaluate the proposed solution considering different data splits based on either "dancer" or "music". Moreover, we propose a periodicity-based loss that considerably improves the overall beat tracking performance according to several evaluation metrics.

1. INTRODUCTION


One of core tasks of *Dance Information Retrieval (DIR)* [1] is to extract high-level semantics from dance videos, which could be similar to what Music Information Retrieval (MIR) tasks attempt to detect from music. For instance, some common tasks among the two research fields are: beat tracking, structure analysis, genre recognition, and automatic tagging. Although DIR shares similar objectives with MIR, DIR tasks are typically solved by analyzing video frames of dance motions (visual information). Of course, those tasks could also be solved by analyzing audio signals of dance music (audio information) when such

---

[1] Dance Information Retrieval is almost the same as *Dance Information Processing* [1] as Music Information Retrieval often means Music Information Processing/Research, but in this paper we use the term Dance Information Retrieval to focus on tasks analyzing dance information, which could be either audio or video.

Figure 1. Our approach for dance beat tracking.

signals are given or by analyzing both visual and audio information (multimodal information). As research on dance motions has not yet received much attention in the MIR community [1], the goal of this paper is to initiate *dance beat tracking* as a novel DIR task. Dance beat tracking is named to differentiate it from a standard task of music beat tracking and is defined as the task of detecting musical beats by using only visual analysis of video frames. Figure 1 shows an overview of our approach for dance beat tracking.

Since dance motions are usually related to the accompanying dance music, several dance characteristics can be inferred by joint analysis of motion and music. In fact, various researchers have already worked on multimodal aspects of dance music and motions [2–5]. In the MIR community, dance music such as traditional dances [6–9], electronic dance music [10–14], and ballroom dance music [15–17] has been a popular target of research. The literature on analysis of dance motions by using only video frames, however, is rather limited [1, 18, 19]. To the best of our knowledge, no work has focused on dance beat tracking using visual information of dance videos and evaluated its performance.

As music beat tracking is one of the most fundamental MIR tasks, dance beat tracking is also one of the most fundamental DIR tasks. *Beat* is the basic unit of time and can be used as a basis for further processing. For example, beat-synchronous analysis is effective and frequently used in the MIR community: music audio signals and dance videos could be divided into temporal sections associated with beats, which are then used to obtain beat-synchronous or beat-wise representations for various higher-level tasks [20–24]. Some direct applications of dance beat tracking systems would include automatic synchronization of dancing with music. Although dance videos usually have video frames synchronized with mu-

sic audio signals, there are irregular video files such as those in which the timing of video frames is out-of-sync with audio signals, and those in which a dancer is dancing without music or at different tempi. Dance beat tracking is useful for synchronizing and temporally-aligning (time-stretching) such video frames, or even identifying such out-of-sync videos.

Whether it is possible to automatically track beats of a dance video using only video frames is an open question [25]. To answer this question, we developed a dance beat tracking system that extracts skeletal body keypoints of a dancer from each video frame and uses Temporal Convolutional Neural Network (TCN) architectures to classify each frame as either a "beat" frame or a "non-beat" frame. In our experiments with a shared large-scale dance database, the AIST Dance Video Database [1], we found that it is possible to achieve dance beat tracking with the best F-measure performance of 61.20% and there is still large room for improvement. We also found that TCN architectures are more effective than architectures based on bidirectional Long Short-Term Memory (LSTM) Recurrent Neural Networks (RNNs), and that the use of an additional loss term based on periodicity, which we propose in this paper, considerably improves beat tracking performances.

2. RELATED WORK

2.1 Audio-based music beat tracking

Initial work on music beat tracking for audio signals was based on spectral features, such as onset strength. By relying on these features, previous studies proposed multiple beat tracking agents [26, 27]. Further research on beat tracking was based on a dynamic programming framework [28–30]. Moreover, solutions based on the Kalman filter for detecting the beat locations were studied as well [31, 32]. Another popular way of approaching beat tracking was through the bar pointer model, originally proposed by Whiteley et al. [33], and improved by others [34, 35].

More recently, beat tracking research has largely adopted deep learning models to predict the beat positions, mainly by means of RNNs. The core idea of these deep learning solutions is to feed spectrogram frames, or features extracted from them, into an LSTM RNN. The network outputs the beat activation function, which is post-processed, usually by HMM decoding, to obtain the final beat locations. Previous work which adopted this processing setup is described in the papers of Durand et al. [36], Krebs et al. [37], Böck and Schedl [34], Böck et al. [38], and Cheng et al. [39].

RNN architectures have recently started to be replaced by more computationally efficient deep learning models such as Temporal Convolutional Networks (TCNs) [40, 41]. TCNs have also been used for beat tracking, as in the papers of Davies and Böck [42] and Böck et al. [43].

2.2 Visual or multimodal dance analysis related to beats

Guedes et al. [44] developed Max/MSP objects to control the tempo and rhythm of a music performance by using dance movements instead of a conducting baton. Although those objects extracted musically relevant rhythmic information from the video frames, they did not detect any dancer and their purpose was different from dance beat tracking. Ho et al. [45] developed a multimodal system that evaluated a street dance performance by estimating how well dance motions from a Kinect device correlated with musical beats. The system detected motion velocity drops as candidate motion beats, which did not necessarily have regular intervals, and then evaluated the synchronization between their candidates and musical beats.

Automatic dance motion generation for artificial characters, such as robot dancers and computer-graphics animation dancers, often needs beat-related audio-visual dance analysis. Ohkita et al. [46] presented a multimodal audio-visual beat tracking algorithm that enabled a robot to dance in synchronization with music and a human dancer. Audio-visual features were also used in the work of Shiratori et al. [47]. In their work, the authors proposed a method that synthesized a robot dance performance imitating the performance of a human dancer listening to the same music.

In addition, Davis et al. [18] presented a method that extracts visual rhythm from motions in video and aligns it with its musical counterpart. Visual rhythm was also at the base of a Xie et al. [48] article. In their work, the authors extracted several features from video frames, and proposed the use of an attention network to align them to the correspondent audio onsets through sequence labeling layers.

Although the above references do not directly deal with the task of dance beat tracking, they show its potential applications.

2.3 Orchestra conductor analysis

In the work of Huang et al. [49] body movements of the conductor were analyzed with the goal of inferring musical expressiveness. The authors proposed a multi-task learning model based on a bidirectional RNN to jointly identify dynamic, articulation, and phrasing cues of music from conducting movements.

A similar study on orchestral director movement was described in Schmidt et al. [50]. Musical beats were detected in correspondence of a director's hand's velocity peaks, where the movements were recorded by using a wrist e-watch. The paper of Schramm et al. [51] also focused on a director's hand gestures acquired by Kinect with the purpose of detecting duple, triple, and quadruple patterns by using a probabilistic Dynamic Time Warping framework.

Although motion analysis of dancers and conductors could have some technical similarities, conductor motions tend to give more explicit cues for musical beats. On the other hand, since dancer motions do not necessarily corre-

late with musical beats, dance beat tracking is harder than conductor analysis in general.

3. PROPOSED SYSTEM

Inspired by the success attained in audio-based music beat tracking, we address dance beat tracking as a sequence classification problem. According to this framework, a classifier takes as input a sequence of observations $x_{1:T} = \{x_1, \dots, x_T\}$, and produces an output of the same length $y_{1:T} = \{y_1, \dots, y_T\}$ where each observation is classified into "beat" ($y = 1$) or "non-beat" ($y = 0$), by taking into account past observations. In our application each observation consists of a video frame.

Two main technical challenges of dance beat tracking are modeling long time sequences and extracting meaningful descriptors from video frames. The former challenge has been successfully tackled in recent years initially by using RNNs and then by using TCNs [41]. TCNs, as explained in Section 3.1, are deep learning architectures based on stacks of causal dilated convolutions [40] which serve the same purpose as an RNNs while offering several advantages over them. TCNs are more computationally efficient since convolutions can be easily parallelized. In addition, TCNs do not suffer from exploding/vanishing of gradients, which is a major drawback when dealing with long time sequences such as the one used in this application. The latter challenge can be dealt with by using standard computer vision convolutional networks to extract meaningful features from the video frames.

We thus chose to use a TCN as a sequence classifier. From each video frame (60 fps) we extract the (x, y) position of dancer body keypoints by using the OpenPose framework [52]. Thus, we represent a video as a sequence of keypoints (Section 4.2). Although extracting the body keypoints requires preprocessing of the dance video, we found this description to be at the same time powerful for effectively modeling dance movements. We do not directly use video frame pixels since it is difficult to prepare a training dataset with sufficient variations of dancer clothes, colors, and backgrounds, and using video frame pixels limits generalization of the model.

3.1 Temporal convolutional networks

TCNs process the input x_n by taking into account only the past information, and produces an output y_n of the same length as the input. To achieve this goal, 1D causal[2] convolutional layers with the "same" padding[3] are used. In order to model long time sequences, the network must have a large receptive field. We therefore use a stack of *dilated* convolutional layers so that we can increase the receptive field while maintaining the same (small) kernel size of each layer. Each layer of the stack has the same number of features. The dilation factor increases in an exponential way

at each convolution stack. More precisely, at a particular network level i, the dilation factor d is 2^i.

Stacking more dilated convolutional layers to model longer time sequences results in a deeper network, which is harder to train. It has been shown that for very deep networks, training on residual connections ensures a better gradient flow which allows more effective training [53].

In our work we use a TCN in the configuration proposed by Bai et al. [41]. The authors proposed a deep learning architecture which is composed of several TCN residual blocks. Each TCN residual block is composed of two dilated causal convolutional layers (of same dilation factor) and Rectified Linear Units activation (ReLU [54]). In order to accelerate the training of the model, a weight normalization layer [55] is placed after each dilated causal convolutional layer. In addition, a spatial dropout layer [56] is utilized after activations so that overfitting is mitigated. Finally, an optional 1×1 convolution is used on the identity path to match the feature map size of the input to the output when these two differ.

3.2 Network training

We train our model by using the Adam optimizer [57] with default PyTorch parameters, a learning rate of 0.5×10^{-3}, and batch size of 32. Training is stopped when the loss on a validation dataset does not improve for subsequent 30 epochs. The best model is then selected according to the best performance achieved on the validation dataset. For data augmentation, Gaussian noise $\mathcal{N}(0, 1)$ is added to the keypoint delta values before feeding them to the network.

3.2.1 Loss function

The basic loss criterion used to train the network is the cross-entropy, L_{ce}. Giving an input sequence of M observations, for each observation $m = 0, 1, \dots, M - 1$, the model outputs a softmax distribution $\hat{\mathbf{y}}_m$ over two classes: "beat" and "non-beat". Since probabilities of "beat" and "non-beat" in the ground truth are largely unbalanced, we weight the cross-entropy loss with a weight vector $\mathbf{w}$ of empirically chosen values: 1 and 0.1 respectively for "beat" and "non-beat". Thus, given a particular sample pair n of true sequence $\mathbf{y}^{(n)}$ and predicted sequence $\hat{\mathbf{y}}^{(n)}$, the weighted cross-entropy loss is defined as follows:

$$L_{ce}^{(n)} = -\mathbf{w} \sum_{m=0}^{M-1} \mathbf{y}_m^{(n)} \log\left(\hat{\mathbf{y}}_m^{(n)}\right). \qquad (1)$$

We also propose an additional loss term that takes account of *periodicity*, L_p. It is reasonable to assume that a dance is characterized by repeating patterns which are correlated to the music beats. By using the periodicity loss we inform the model that predictions made in correspondence of multiples of the music tempo T should be considered similar. In a training dataset the music tempo is known a priori and constant throughout the audio clips. Note that this additional loss term is used only during training. The periodicity loss is simply the summation of the absolute difference of predictions made at multiples of the music

---

[2] The result of the convolution at time $t = T$ is obtained using inputs at and before $t \leq T$.

[3] For a kernel $h_1, \dots, h_M$ the "same" convolution padding length is $M - 1$.

BPM	Street Dance Genre									
	BR	PO	LO	WA	MH	LH	HO	KR	JS	JB
T_0	21	23	23	23	24	25	23	23	21	22
T_1	23	23	23	23	24	23	23	23	23	24
T_2	23	24	23	24	24	23	24	23	23	22

T_5	24	24	24	24	23	23	22	24	23	24

Table 1. Video counts of the AIST Dance Video Database subset used in our work.

tempo kT:

$$L_p^{(n)} = \left\| \sum_{\substack{k=0 \\ k'=k+1 \\ k''=k'+1}}^{N_b-3} \hat{y}_{kT:k'T}^{(n)} - \hat{y}_{k'T:k''T}^{(n)} \right\|_1, \qquad (2)$$

where N_b is the number of beats contained in the ground truth sequence. The output sequence is zero-padded to a multiple of ground truth tempo.

We get the total loss by adding together the weighted cross-entropy and a scaled version of the periodicity loss. The scale parameter α is empirically chosen by grid-search. Finally, we take the average among the training batch of N samples:

$$L = \frac{1}{N} \sum_{n=0}^{N-1} L_{ce}^{(n)} + \alpha L_p^{(n)}. \qquad (3)$$

4. DATASET AND DATA PROCESSING

The AIST Dance Video Database [1] is a large-scale collection of dance videos. This database includes 10 street dance genres: "Break" (BR), "Pop" (PO), "Lock" (LO), "Waack" (WA), "Middle Hip-Hop" (MH), "LA-style Hip-Hop"(LH), "House" (HO), "Krump" (KR), "Street Jazz" (JS), and "Ballet Jazz" (JB). For each dance genre, 6 musical pieces of different tempi are used. In particular, the music tempi are: $T_0 = 80$, $T_1 = 90$, $T_2 = 100$, $T_3 = 110$, $T_4 = 120$, and $T_5 = 130$ beats per minute (bpm) for all the genres, except the "House" genre whose tempi are : $T_0 = 110$, $T_1 = 115$, $T_2 = 120$, $T_3 = 125$, $T_4 = 130$, and $T_5 = 135$ bpm.

In this work we consider dance videos where a single dancer is performing ("Basic Dance" and "Advanced Dance" in the database), and we use the frontal camera as the source of information [4]. The total number of dance videos considered in our experimental evaluation is 1396. The resolution of the videos is 1920×1080 pixels. Table 1 shows a detailed breakdown of our dataset.

4.1 Data splits

We split the data according to "music" and "dancer". For each of the split configurations, we randomly split

[4] The frontal view of the dancer is the most reliable for detecting the body keypoints because body part occlusions are minimized by this visual perspective

the data samples in training, validation, and test datasets with percentages of 70%, 20%, and 10%, respectively. In order to make balanced splits, we adopt the following strategy. In the case of the "music" data split, for each of the 60 music clips, we select the correspondent videos, and randomly split them according to the aforementioned train/validation/test percentages. We then concatenate the individual micro splits to obtain the final "music" train/validation/test splits. The same process is executed according to the individual dancer for compiling the "dancer" data splits.

4.2 Data preprocessing

All the dance videos are preprocessed by extracting the body keypoints by using the OpenPose framework [52]. We use the `BODY_25` pose model which represents the human body by 25 skeletal keypoints. However, in our application a subset of the `BODY_25` keypoints was problematic to detect with high reliability, and therefore it was discarded from the body pose. These problematic keypoints correspond to "eyes", "ears", "nose", "heels", and "big/small toe". After removing these keypoints we end up with a total of 13 keypoints: "neck", "shoulders", "elbows", "wrists", "mid hip", "hips", "knees", and "ankles". However, missed detections of body keypoints can still happen. The missed detections are recovered by spline interpolation.

The body keypoints are defined by their pixel position (x, y) within a video frame on the basis of the OpenPose output. However, this representation has the drawback of not being invariant to the dancer's position and of being dependent on the dancer's body size. To overcome these issues, we convert the absolute $(x_n, y_n)^{(i)}$ position of the i-th keypoint at time n into its displacement (delta values) in time:

$$(\Delta x_n, \Delta y_n)^{(i)} = (x_n - x_{n-1}, \ y_n - y_{n-1})^{(i)}. \qquad (4)$$

4.3 Beat activation processing

The output of network is the beat activation function; i.e., for each video frame, the model predicts its probability of being a "beat" frame. To obtain the final beat positions, a postprocessing of the beat activation function is required. In our work we use the algorithm proposed by Krebs et al. [35], which is based on HMM decoding.

5. EXPERIMENTAL SETUP

We report performance results by using several beat tracking metrics typical of music and by following the practice described in Davies et al. [58]. For our experimental evaluation, we make use of the `mir_eval` [59] software package [5].

For the evaluation we consider the first 420 frames (7 s) of each video. In addition, the first 1 s of the predicted beat sequence is discarded when computing the performance results.

[5] https://github.com/craffel/mir_eval

5.1 Model selection

In order to select the best-performing configuration of the model, we conduct hyperparameter grid-search on the number of stacks $N_{\text{stack}} \in \{3, \ldots, 12\}$ and the number of convolutional features $N_{\text{feat}} \in \{32, 64, 128, 256\}$. Since no pooling is involved in the TCN architecture, the number of convolutional features is kept constant among the entire stack. The extreme values (minimum and maximum) of these hyperparameters are chosen in a way that the model would respectively under-fit and over-fit the validation dataset.

The training is stopped when the loss on the validation dataset does not decrease for 30 successive epochs. According to the considered performance metric, the best-performing model on the validation dataset is selected. This model is then evaluated on the test dataset.

The hyperparameter grid-search reported that $N_{\text{stack}} = 7$ and $N_{\text{feat}} = 128$ yields, in the majority of the cases, the best TCN. The evaluation is done for both "dancer" and "music" data splits. We denote this configuration as TCN$_{128}^7$ and we use it as our baseline.

5.2 Periodicity loss ablation study

With the purpose of assessing the usefulness of the proposed periodicity loss term (L_p), we conduct an ablation study using TCN$_{128}^7$ as the baseline.

Additional hyperparameter grid-search is done for finding the best value of α, see equation (3). This parameter weights the contribution of L_p to the overall loss and must be carefully chosen by empirical evaluation. The tested values are: $\alpha \in \{0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1\}$. The grid-search is done for both "dancer" and "music" data splits by training the TCN$_{128}^7$ according to the procedure previously described.

6. EXPERIMENTAL RESULTS

In the first part of this section we report the baseline performance of TCN$_{128}^7$. We also compare the baseline performance between TCN and LSTM architectures and show that the TCN architecture is the best in our application. Finally, we elaborate on the results of the ablation study of the periodicity loss term by showing its effectiveness.

We report the performance in terms of different metrics. More specifically we consider: F-measure (F), Cemgil's score (Cem), and continuity base scores [58]. The continuity scores are: Correct Metrical Level continuity required/not required (CML$_{c/t}$), and Allowed Metrical Level continuity required/not required (AML$_{c/t}$).

6.1 Baseline loss

Table 2 reports the performance results of TCN$_{128}^7$ model trained with L_{ce}. Results are subdivided according to the "dancer" and "music" data splits and are reported as percentages correct.

Examining the overall results, we acknowledge at first look the difficulty of this new task. A similar conclusion

Split	CML$_c$	CML$_t$	AML$_c$	AML$_t$	Cem	F
Dancer	44.28	46.93	47.27	49.04	52.92	55.02
Music	40.14	39.71	44.84	47.53	47.43	53.02

Split	CML$_c$	CML$_t$	AML$_c$	AML$_t$	Cem	F
Dancer	38.66	41.49	56.23	53.03	32.17	46.56
Music	27.62	32.45	43.13	46.32	28.35	39.18

Table 3. bLSTM$_{128}^4$ results trained with the baseline loss.

about music beat tracking is drawn in when percussion is not present in the analyzed audio signal. We find that in a dance, the body movements cannot stress the tempo as efficiently as percussive sounds do. Therefore, a lower performance is reasonably expected in dance beat tracking than in music beat tracking (Section 6.3).

In addition, we notice that the performance on the dancer data split is $\approx 4\%$ higher (for all the metrics) than the performance on the music data split. The dancing style that characterizes each dancer seems to be easier to capture by the network, while the difference in choreographies for the same music piece is less effectively captured by the model.

In more detail, for both of the data splits, we see that the continuity scores obtain lower performance. Specifically, CML is the least performing metric and is followed by AML. The performance gap between CML and AML ($\approx 3\%$ for dancer and $\approx 6\%$ for music) suggests that the model tends to detect beats at half or double the correct tempo. An improvement of CML/AML scores is achieved when continuity is not required (CML$_t$ and AML$_t$). The F-measure attains the highest performance for both of the data splits, while the Cemgil's score shows a slight decrease, which is more evident for the music data split. This performance decrease indicates that the model tends to detect beats with a slight offset with respect to the ground truth position.

The main conclusions of this experimental section are as follows. (1) Detecting beats is more difficult for the "music" split. (2) Detected beats are prone to errors such as beat positions with less continuity, with a half or double tempo, and with a small deviation from the correct beats.

6.1.1 Comparison with LSTM

We provide a baseline comparison with a bidirectional LSTM RNN, whose performance results are reported in Table 3. Also in this case, we conduct similar hyperparameter grid-search as done for the TCN. In particular, we tested $N_{\text{stack}} \in \{1, 2, \ldots, 6\}$ and $N_{\text{units}} \in \{32, 64, 128, 256\}$, and found that in average for the different performance metrics, the best performing configuration is $N_{\text{stack}} = 4$ and $N_{\text{units}} = 128$. We refer to this model specification as bLSTM$_{128}^4$.

From Table 3 we notice that for both "dancer" and "music" data splits the bLSTM$_{128}^4$ performs worse than the

Loss	CML_c	CML_t	AML_c	AML_t	Cem	F
L_{ce}	44.28	46.93	47.27	49.04	52.92	55.02
$L_{ce}+\alpha L_p$	**53.05**	**54.30**	**55.23**	**57.64**	**59.02**	**61.20**

Table 4. Performance results for the "dancer" data split using the proposed loss with $\alpha = 0.05$.

Loss	CML_c	CML_t	AML_c	AML_t	Cem	F
L_{ce}	40.14	39.71	44.84	47.53	47.43	53.02
$L_{ce}+\alpha L_p$	**46.50**	**48.33**	**48.27**	**50.87**	**54.27**	**58.25**

Table 5. Performance results for the "music" data split using the proposed loss with $\alpha = 0.1$.

TCN^7_{128} in terms of almost all the considered metrics. The performance gap is quite significant for Cemgil's score and the F-measure. Notably, the AML scores are comparable, or even better ("dancer" split), than the TCN. In this particular instance, the recurrent nature of the tested model is helpful in detecting beat locations that are regularly spaced according to musical metric (half/double).

6.2 Proposed loss

From Tables 4 and 5 we assess the benefit introduced by the proposed periodicity loss term. Indeed, the proposed loss considerably improves each of the performance metrics and does so for both of the data splits. The improvement averages $\approx 7.5\,\%$ points for the dancer split and about $\approx 5.5\,\%$ points for the music split. We found by means of grid-search that the best value for the hyperparameter α is: 0.05 for the "dancer" split and 0.1 for the "music" split.

The performance gap between "dancer" and "music" data splits is also present in this case. Moreover, a similar trend of the performance scores also occurs in the combined loss experiments. In fact, sorted in ascending order of the achieved performances, the metrics are: CML, AML, Cemgil's score, and F-measure.

In the case of the "dancer" data split (see Table 4), the continuity metrics are the most improved metrics. With an improvement of $\approx 8\,\%$ points, the periodicity loss term is beneficial for detecting beats at the correct time spacing. Although less improved, Cemgil's score and the F-measure still indicate an important boost in performance by $\approx 6\,\%$ points. This means that the proposed loss is helpful for obtaining more accurate detection of beats.

In the case of the "music" data split (see Table 5), the performance improvement, although slightly less evident than in the case of the dancer split, is still consistent. For the music data split, the proposed loss improves all the performance metrics by an average of $\approx 5.5\,\%$ points. The behavior similar to the results of the dancer data split is also observed in this case. However, for the music data split we see that improvement for AML metrics is relatively low: $\approx 3\,\%$ points. In this case CML and AML results are more aligned, with the latter being $\approx 2\,\%$ points better.

To summarize, the main conclusions of this experimen-

CML_c	CML_t	AML_c	AML_t	Cem	F
81.34	81.34	94.27	94.89	73.78	88.98

Table 6. Average performance results on the audio clips.

tal section are as follows. (1) The proposed loss based on periodicity improves performance considerably. (2) The proposed loss helps in detecting beat locations which are more aligned with the correct music metric (or half/double of it). (3) The performance gap between the two data splits is still present, although slightly mitigated.

6.3 Audio-based music beat tracking

In Table 6, we report the beat tracking performance achieved on the audio clips of the AIST Dance Video Database [1] for comparison. We use the model of Böck et al. [34] in combination with the same HMM postprocessing module used for dance beat tracking.

Since the results are much better than those in Tables 4 and 5, music beat tracking is an easier task than dance beat tracking in our experiments. This is expected since the audio clips chosen for the dancing purpose have usually distinctive beats.

7. CONCLUSION

Our main contributions are as follow. (1) We propose the task of dance beat tracking which is characterized by the novelty of using visual information, in the form of motion patterns, for detecting musical beats. (2) We provide a baseline evaluation on the AIST Dance Video Database [1] considering data splits based on "music" and "dancer". By comparing the results based on those data splits, we gain deeper insights about the dance beat tracking task. In addition, we also provide a performance comparison of deep learning architectures commonly used for time series classification. In this regard, we show that TCNs outperform bidirectional LSTMs for dance beat tracking. (3) We propose the periodicity loss term, which is scaled and added to the baseline cross-entropy loss. This novel loss term takes into account motion repetitions in relationship to beats and considerably improves the beat tracking performance.

Detecting musical beats from video frames revealed to be a challenging task, and it encourages further research in this direction in order to improve the performance results. In fact, the relationship between dancer body movements and musical beats is difficult to capture due to high variability of motion patterns among different dancers and different choreographies. This challenge is similarly faced in MIR when trying to detect beats from non-percussive music. In future work we plan to investigate deep learning architectures that can directly process video frames without needing to extract the body keypoints ahead of time. Future work will also include investigation of whether it is possible for human beings to visually track beats of a dance video without listening to the accompanying sounds, and will compare machine and human performances.

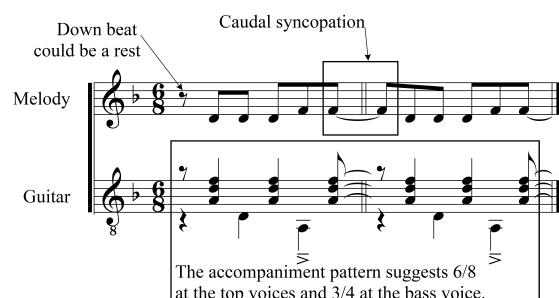
ABSTRACT

The bambuco, one of the national rhythms of Colombia, is characterized by the presence of sesquialteras or the superposition of rhythmic elements from two meters. In this work, we analyze sesquialteras in bambucos from two perspectives. First, we analyze the perception of beat and meter by asking 10 Colombian musicians to perform beat annotations in a dataset of bambucos. Results show great diversity in the annotations: a total of five different meters or meter combinations were found in the annotations, with each bambuco in the study being annotated in at least two different meters. Second, we perform a beat tracking analysis in a dataset of bambucos with two state-of-the-art algorithms. Given that the algorithms used in the analysis were designed to deal with the rhythmic regularity of a single meter, it is not surprising that tracking performance is not very high ($\simeq$42% mean F-measure). However, a deeper analysis of the onset detection functions used for beat tracking, indicate that there is enough information on the signal level to characterize the bi-metric behavior of bambucos. With this in mind, we highlight possibilities for computational analysis of rhythm in bambucos.

1. INTRODUCTION


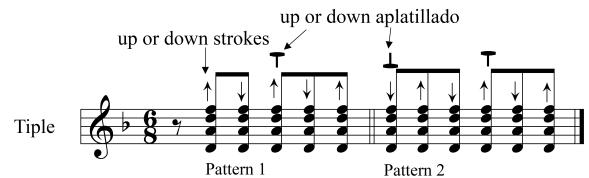
The focus of this work is the bambuco, one of the national rhythms of Colombia characterized by the superposition of musical elements in two meters, 3/4 and 6/8. This phenomenon is called *sesquialtera*, and while it is not unique to the bambuco [1, 2], this work focuses on perceptual and computational aspects particular to the Colombian bambuco. Our goal is to better understand how meter in bambuco is perceived by cultural insiders. To do so, we conducted a study where Colombian musicians were asked to

tap the beat of a selection of bambucos (Section 2.1). We then investigate whether computational tools can help ethnomusicological investigations on tendencies of bambucos to follow a given meter. We extracted beat information from a bambuco dataset using state-of-the-art algorithms and evaluate tracking performance (Section 2.5).

The contributions of this work are summarized as follows: (1) To the authors' knowledge, this paper presents the first study on meter perception in bambucos. (2) We present an objective evaluation of computational tools for rhythm analysis on bambucos, and highlight analysis possibilities for future research. (3) All the data including audios, transcriptions, annotations, and code have been made publicly available to enable future research on the topic.

1.1 The bambuco

There are references about the presence of bambuco in Colombia dating back to the mid 19th century; however, despite numerous discussions about its origin and musicological characteristics, there is no clarity today about the real origin of this music: Is it indigenous, African or Hispanic? Is it urban or peasant mestizo? Despite this uncertainty, the reality is that little by little bambuco became a regional and musical symbol of identity. Like all the great Latin American genres that fulfilled this purpose towards the end of the 19th century and the first half of the 20th (e.g. Habanera, Tango, Chacarera), to become a worthy representative of this imagined regional identity and of those who coined it, the bambuco had to undergo a

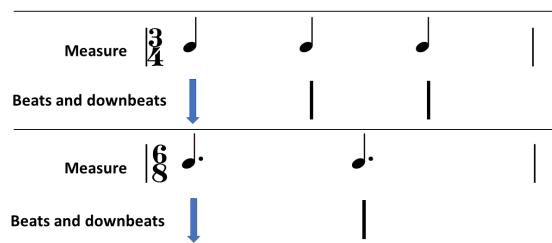
Figure 1: Bambuco example showing the downbeat, caudal syncopation and a guitar accompaniment pattern.


transformation process referred to as "whitening" [3]. This whitening can be understood as a progressive adherence to the bourgeois ideal of chamber music. This particular process has been studied by the Colombian ethnomusicologist Santamaria in [4]: "When relocating to the city since the mid-19th century, the bambuco progressively stopped being popular dance music and became music to be performed and listened to in an atmosphere of literary or concert gatherings".

Bambucos show musical elements typical of ancient Spanish-Iberian and Colombian peasant dances, typified as sesquialteras, whose main characteristic is a bi-metric behavior (3/4 - 6/8) within the melodic line or between the melodic line and the bass line. This behavior can be observed in the example in Figure 1 where the guitar accompaniment has elements from both 6/8 and 3/4. Another characteristic element of bambucos is the presence of *caudal* syncopation in its phrases (sixth eighth note tied to the first eighth note of the following measure -see Fig. 1) which can result in the perception of a delay or a harmonic anticipation [5]. Another element of bambucos which adds to its rhythmic complexity is the characteristic accentuation of the third pulse in the accompaniment patterns in 3/4, which leads to the perception of a downbeat that is not the first pulse of the bar.

Of the instruments that usually participate in the performance of this type of bambucos [1] (such as guitars, tiples, and bandolas [2]), the main role of the rhythmic accompaniment is usually delegated to the tiple. The tiple is a plucked string instrument slightly smaller than a guitar, with 12 strings grouped in four tripled courses. One of the instrument's most characteristic idiomatic playing techniques is the *aplatillado* which is achieved by bringing the nails closer to the strings to alter their timbre. With an alternating up and down strumming and the *aplatillado* (see Figure 2), textural elements are generated that can sometimes interfere with rhythm perception. This is similar to what happens in the charango (traditional string instrument) in certain Bolivian music [6].

Ramón y Rivera [7], proposed the term "free rhythm" in the context of Latin American music to refer to a certain elasticity in the unit of time, in breathing and in the execution of rhythmic groups, as opposed to a rhythmic reference subject to a measure or bar. This rhythmic freedom is observed in the set of recordings that are part of this study and that account not only for particularities of the genre, but also for a historical moment of the recordings not rigorously subject to a metronomic guide. Additionally, tempo and micro-timing in bambuco appear to work in general in a flexible way, with even subtle differences between timing of the melody and that of the various elements of the accompaniment. These freedoms could be associated with the rubato of European music or with the floating rhythm of jazz; however, it is a different phenomenon that contributes to the rhythmic complexity of bambuco and its per-

Figure 2: Tiple accompaniment patterns


ception [3].

The different levels of complexity described in this section become critical elements when developing computational tools for musicological analysis of these music traditions.

1.2 Beat and meter perception

The perception of meter and beat in music is directly associated with the perception of regularity. It is precisely this regularity that allows the listener to create expectations about the musical events in a given time span [8]. While beat perception is mostly linked to a perceived periodicity, meter is additionally linked to an accentuation pattern that differentiates, for example, beats from downbeats. Based on these ideas, Western music theory defines a hierarchical relationship between beats, measures (bars), and meter (see Figure 3). For certain musical traditions where a unique meter cannot always be clearly defined (such as the bambuco but also Bolivian Easter songs [6], the Southern Eve dance drumming of the Guinea Coast [2], among others), Western music theory (and music notation) can often fall short in providing an accurate representation of these traditions. In the particular case of the Colombian bambuco, its correct music notation has been the source of many academic discussions [3]. Besides the superposition of 3/4 and 6/8 meters, bambuco's characteristic accentuation pattern (due to caudal syncopation and the accentuation of the third beat in 3/4 by the accompaniment - see Section 1.1) adds another layer of complexity as the traditional definition of downbeats (Figure 3) do not hold in the case of bambuco.

Of particular interest in this context is the work by Stobart et al. [6] on rhythm perception of Bolivian Easter songs. The study outlines how cultural outsiders perceived

Figure 3: Hierarchical relationship between meter, measures (bars) and beats as defined in Western music theory. In both 3/4 and 6/8, the beats are indicated with vertical lines, and the downbeat with a blue arrow.

these songs as anacrustic 6/8 rhythms, while footfalls of locals dancing to the rhythm of the music indicated a 2/4 rhythmic perception. The authors highlight that accentuation patterns of the charango (traditional string instrument) accompaniment as well as stress patterns in the local language *Quechua* in which the songs are sung, are possible causes of the differences in perception.

1.3 Music Information Retrieval (MIR) approaches for rhythm analysis

The computational analysis of musical beat has been widely addressed in the literature, predominately applied to Western popular music [9] but also applied to non-Western music [10, 11]. While beat tracking accuracy for Western popular music can already be very high, beat tracking of non-Western music presents many more challenges, and performance highly depends on the rhythmic complexity of each music tradition. In the particular case of Latin American music, work on computational analysis of rhythm has either focused on understanding characteristic patterns in micro-timing that implant local rhythms their unique rhythmic feel (e.g. Brazilian Samba [12], and Uruguayan Candombe [13]), on using rhythmic pattern templates for beat tracking (e.g. Afro-Cuban rhythms [14], and Uruguayan Candombe [15]) or on genre classification [16].

To the authors' knowledge, an in-depth computational analysis of rhythm in the Colombian bambuco has never been performed. This motivated the preliminary beat tracking evaluation where the goal was to understand how state-of-the-art tools for beat tracking perform when meters superpose in music. However, we approach this evaluation not with the expectation that the algorithms will succeed in tracking rhythmic patterns they were not originally designed to track; we approach this evaluation with the goal of understanding the potential of these techniques to be expanded into meaningful musicological analysis tools for bambucos and music from the Andes in general.

2. BAMBUCO ANALYSIS

2.1 Dataset

The data used in this study is part of the ACMUS-MIR dataset (V1.1),[3] a collection of annotated music from the Andes region in Colombia [17]. To evaluate beat tracking performance, all the bambucos in the **Rhythm Set** of the ACMUS-MIR dataset were used (N=73). From the 73 bambucos, a smaller selection of 10 bambucos were used in the perceptual study (see Table 1 for details).[5] The 10 bambucos in the perceptual study were chosen as they clearly exemplify the bi-metric behaviour of the bambuco genre, and include a diversity of instrumental formats (duets, trios, wind orchestra). Additionally, the majority of the tracks were composed by Luis Uribe Bueno, a representative composer and performer of bambuco in Colombia.

2.2 Participants

A total of 10 Colombian participants took part in the perceptual study (8 male, 2 female, ages 25-50), all of whom had been exposed to bambuco music throughout their lives (cultural insiders). All the participants had musical training, and were either university music students or professional musicians: five guitarists, two bandola players, two pianist, one flutist, one singer. The majority of the participants had previous experience performing bambucos within their musical practices.

2.3 Survey

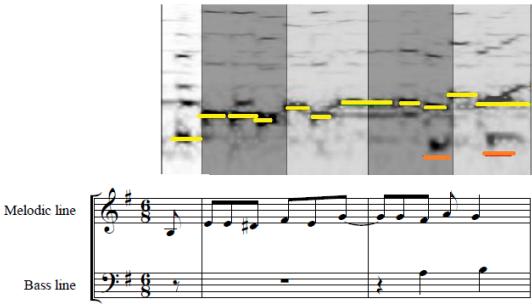
As part of the perceptual study, each participant also answered a short survey consisting of three questions: (1) Which musical elements guided you when tapping the beat? (2) Was there any element that made the annotation process difficult? and (3) Do you have any observations about the tempo in these bambucos?[1]

2.4 Annotations

2.4.1 Beat

For the perceptual study, the 10 participants were asked to tap the beat to the selection of 10 bambucos using the computer keyboard in Sonic Visualiser.[4] Participants were given freedom to tap the beats that felt more natural to them. No indications about meter were given to the participants to avoid biasing them. Two sets of annotations were recorded: (1) Beat annotations tapped while listening to the audio (without any visual information) without allowing corrections by the participants (***Audio Only***). (2) Participants were allowed to modify their initial beat annotations in Sonic Visualiser using both audio information and a visual representation of the audio waveform. Participants were allowed to make as many corrections as necessary for them to be satisfied with their annotations (***Audiovisual + corrections***). If participants were satisfied with the ***Audio Only*** annotations, the correction step was not performed.[5]

For the computational beat tracking analysis, the annotations from the **Rhythms Set** of the ACMUS-MIR (V1.1) dataset[3] were used. With the awareness that in many cases a unique meter in bambucos cannot be defined, beat annotations in the dataset were performed independently for the two predominant meters, 3/4 and 6/8. For the 73 bambucos, these two sets of annotations were used, each assuming a unique underlying meter [17].

2.4.2 Melody, bass and chord annotations


The melody line and the bass of each bambuco in the perceptual study were transcribed by four professional musicians in Colombia. The transcriptions in MIDI format were manually aligned to the audio signal resulting in time-aligned transcriptions. The chord progression of each bambuco was also annotated (see Fig. 4 for an example).[5]

Table 1: Selection of bambucos from the ACMUS-MIR dataset used in the perceptual study. Each segment corresponds to a complete musical idea or phrase taken from the original recording. Due to the superposition of 3/4 and 6/8 meters in these bambucos, tempo annotations for both meters are presented.

Figure 4: Example transcription of the first two measures of track rh_0067. Conventional music notation and their MIDI representation is displayed.

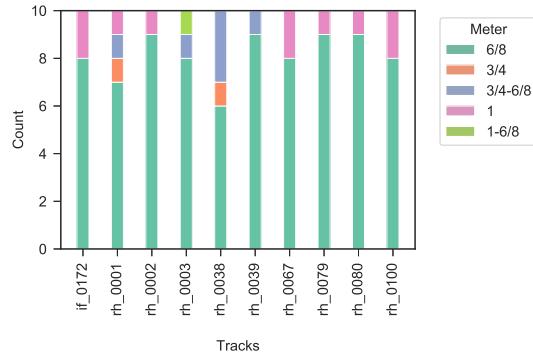
2.5 Automatic beat tracking

For beat tracking evaluation, two state-of-the-art algorithms were used to predict the beat positions. The first set of beat tracking estimations was obtained using Madmom. [6] In the context of the Madmom library, we specifically used a multi-model approach that uses recurrent neural networks to track beats [18]. The second algorithm used for beat estimation was the Multi-Feature Beat tracker (MultiBT) [19] implemented in Essentia. [7] This algorithm selects between beat estimations from a single beat tracking model with diverse input features. Given the bi-metric characteristics of bambucos, independent ground-truth annotations assuming either a 3/4 or 6/8 meter were used (see Section 2.4.1).

For evaluation we use a subset of metrics from the standard evaluation methods described in [20]. Among all the proposed metrics, we chose the F-measure (F1), along with the continuity measures originally defined in [21, 22]. This allows us to analyze both the ambiguity associated with the annotated metrical level and the continuity in the beat estimates. The F-measure (F1) is a generic score often used in information retrieval. For beat tracking, it is common practice to use a ± 70 ms tolerance window around annotations to consider a beat prediction as correct. The F-measure takes into consideration the number of correct beats, the

number of false positives (extra detections), and the number of false negatives (missed detections). Under this metric, completely unrelated beat sequences typically score around 25% by virtue of beats arbitrarily falling within the range of tolerance windows.

Continuity-based evaluation considers regions of continuously correct beat estimates relative to the length of the audio signal. This is the case of the Correct Metrical Level Continuity (**CMLc**) measure, which computes the ratio of the longest continuously correct segment to the length of the input. By definition, continuity is defined using a tolerance window of $\pm 17.5\%$ around each annotation, considering an estimation as correct if it falls within this window. To include the effect of beats in other segments, a less strict measure considers the total number of correct beats at the correct metrical level without the continuity criteria (**CMLt**) [20]. Lastly, to account for ambiguity in the metrical level, two additional metrics consider beats tapped at double or half the annotated metrical level, with the same continuity criteria as before. This conditions are considered *allowed* metrical levels resulting in the Allowed Metrical Level Continuity (**AMLc**) metric and its less strict alternative (**AMLt**) [20]. [8]

3. RESULTS AND DISCUSSION


3.1 Meter perception in bambucos

The beat annotations obtained from the 10 participants (Section 2.4.1) were analyzed by three musicologists in Colombia to determine the underlying meter(s) perceived by each participant in each track. [5] Even though participants were given freedom to tap beats that felt natural to them, each annotation can be directly mapped back to a given meter. This can be understood by looking at Figure 3: If a participant taps three beats per bar, these annotations are mapped back to a 3/4 meter. Conversely, if a participant taps two beats per bar, the underlying meter is assumed to be 6/8. In total, five different meters or meter combinations were observed: 3/4 meter, 6/8 meter, a combination of 3/4 and 6/8, "one count" annotations where participants annotated the first beat of the measure (blue arrows in Fig. 3

(a) Perceived meter aggregated per track

(b) Perceived meter aggregated per participant

Figure 5: (a) Perceived meter aggregated per track over the 10 participants. (b) Perceived meter aggregated per participant over the 10 tracks. Five distinct meters or meter combinations were observed.

which correspond to the downbeats in Western traditions but are not the accentuated beat in bambucos), and a combination between 6/8 and "one count" annotations. These five alternatives are denoted "3/4", "6/8", "3/4-6/8", "1", and "1-6/8", respectively.

Figure 5a shows a summary of the annotations aggregated per track from the revised annotations (*Audiovisual + corrections*). It can be seen that for each of the 10 bambucos, at least two different meters or meter combinations were perceived. The 6/8 meter proved to be predominant in the annotations. It should be noted, that as of today, bambuco is written as a convention in 6/8, and hence, there might be a tendency in trained musicians to default to 6/8.

Similarly, Figure 5b shows a summary of the revised annotations aggregated per participant. It can be seen that five of the 10 participants annotated all the tracks in 6/8 meter. Two of the participants perceived "6/8" and the "3/4-6/8" combination, and two participants perceived a "3/4" meter. Of particular interest in participant eight (p8), who predominantly annotated the bambucos in "1". This is interesting in the sense that this is the only type of annotation that removes the ambiguity in meter perception as the first beat coincides in "6/8" and "3/4" (see Fig. 3). The practice of counting music in "1" is often related to music in fast tempi, where counting all beats in a bar might no longer be comfortable. However, this is not the case here. Table 1 shows the tempo distribution of our bambuco dataset. The fastest bambuco in our dataset is rh_0003, which is mostly annotated in "6/8", with p8 choosing the "1-6/8" alternative in this case. Participant p8 annotated seven bambucos in "1", all of them with slower tempi than rh_0003.

From the 100 annotation instances in this study (10 tracks x 10 participants), a total of 10 instances showed different meters when comparing the (*Audio Only*) annotations with the revised annotations (*Audiovisual + corrections*). Three instances were modified from "3/4-6/8" to "6/8", two instances were modified from "6/8" to "3/4-6/8", two from "3/4" to "6/8", two from "6/8" to "1", and one from "6/8" to "3/4". These results further indicate the dynamic nature of meter perception in bambucos.

The responses from the participants in the survey show
	Algorithm	F1	AMLc	AMLt	CMLc	CMLt
$\frac{3}{4}$	Madmom	75.06	60.76	77.05	50.89	64.27
	MultiBT	42.79	23.32	25.24	12.43	14.33
$\frac{6}{8}$	Madmom	41.13	9.23	10.71	5.64	5.72
	MultiBT	45.15	42.87	51.76	32.38	35.54

Table 2: Beat tracking evaluation metrics obtained with Madmom and MultiBT. Results are presented using two sets of ground-truths: 3/4 and 6/8. All metrics presented have a maximum score of 100%.

a tendency to use harmony, as well as a tendency to rely on parts of the musical discourse that are close to their personal experience (guitar or tiple players, for example, focused more on the accompaniment patterns of the guitar and the tiple). According to the participants, the main difficulties of the analysis process, in addition to flexibility in tempo, were the conception of the phrasing present in the sample, the ritardandos and accelerandos performed between different parts of the musical texture (melody and accompaniment), and the quality of the recordings. Finally, the participants observed that the tempo in these recordings behaves in an organic way, far from the metric rigor typical of the practices of current academic musicians. This is no longer frequent in the way the bambuco is performed today. This transformation could be related to the changes in recording techniques and the prescriptive function of the academic institutions and the musical events in which this type of music circulates.

3.2 Beat tracker performance on bambucos

Two independent evaluations are presented in Table 2 for each of the two beat tracking algorithms. The top row presents results obtained when ground-truth annotations assuming an underlying 3/4 meter are used. The bottom row presents results with ground-truth annotations in 6/8. Metrics that enforce continuity (CMLc and AMLc) are in all cases lower than their less strict counterparts (CMLt and AMLt). Additionally, metrics that allow estimation in different metrical levels (AMLc and AMLt) are also higher than the ones that enforce a correct one (CMLc and CMLt).

Figure 6: Onsets detection function extracted using *Superflux* on a segment of track rh_0002. Ground-truth annotations in 3/4 and 6/8 are shown, as well as beat estimations obtained with Madmom and MultiBT.

These results indicate that in certain occasions, the algorithms are tracking a higher metrical level, detecting the first beat of the bar as the underlying beat (similar to the "1" annotations in the perceptual study). As previously mentioned, this is the only beat where 6/8 and 3/4 coincide. When focusing on those metrics that only consider the correct estimations and not the false positives and false negatives, namely AMLc, AMLt, CMLc and CMLt, Madmom appears to be consistently better at estimating beats in 3/4 than in 6/8. In contrast, MultiBT shows better performance for 6/8 for the same set of metrics.

Evaluation results confirmed our initial hypothesis that the bi-metric nature of our dataset can be challenging for the beat tracking algorithms. However, to better understand the potential of beat tracking algorithms when working with our dataset, we analyzed the onset detection functions, as obtained by the spectral flux or the superflux, [6] of the 10 bambucos in our dataset. [8] Onset detection functions are intermediate signal representations often used in beat tracking algorithms that highlight time instants of the signal where onsets might be present. A peak in the onset detection function suggests that there is a high probability of an onset occurring in that position. With this analysis, the goal was to understand whether enough information could be found on the signal level to characterize the bi-metric behaviour of bambucos. Figure 6 shows a segment of the onset detection function obtained with Superflux on track rh_0002. The ground-truth beat annotations in 6/8 and in 3/4 are also displayed for reference. It should be noted that the annotations in 3/4 and 6/8 were extracted independently by different annotators, and hence the downbeats (which in theory should coincide) do not exactly overlap in all cases. Strong peaks in the onset detection function can be observed in most beat positions from the ground-truth annotations (solid orange line (3/4) and solid green line (6/8) lines). This suggests that regardless of the rhythmic complexity, there is information that can be exploited to characterize the metric behavior of bambucos. For reference, the beat estimations obtained by Madmom

and MultiBT (dashed lines) are also shown in the figure. The complexity of the task is further confirmed by the fact that, not surprisingly, the estimations obtained by the Madmom and MuiltiBT also tend to overlap with peaks in the onset detection function.

4. CONCLUSIONS

This work presented an analysis of beat and meter in the Colombian bambuco, a rhythm characterized by the presence of musical elements from two different meters. Our perceptual study confirmed that even for human listeners, there is not an unique understanding of the rhythmic structures of the genre. Even though current conventions assume a 6/8 meter when writing bambucos, our perceptual study confirmed that reality is much more complex than that. A total of five metric alternatives were found in the annotations produced by the participants in the study. Not surprisingly, results from the computational analysis confirmed that beat tracking models developed to deal with the regularity of a unique meter, do not fully characterize the complex rhythmic interactions in bambucos. However, our analysis of onset detection functions suggests that there is relevant information in these signal representations that could be leveraged for musicological analysis of bambucos. It is clear from the findings in this study that the development of tools for rhythm analysis of bambucos –or of any other music tradition that shares similar rhythmic properties– cannot be approached from a binary decision (right/wrong) perspective. This calls for rhythm analysis tools with an exploratory nature, where the existence of several truths is permitted, and the choice of the most relevant one is both task- and context-dependent. Our hope is that this study as well as the data and annotations collected in it, will serve as a preliminary step in the development of computational tools for musicological analysis of bambucos and Andean music.

ABSTRACT

When making judgements, humans are known to be better at choosing a preferred option amongst a small number of options, rather than giving an absolute ranking of all the options. This preference-based judgment rank-ordering method is called Best-Worst Scaling (BWS). Inspired by this concept, we propose a preference-based framework to generate a relative rank-ordering of singing vocals, and therefore, singers. We adopt a twin-neural network (Siamese) that learns to choose a preferred candidate in terms of singing quality between two inputs. With a few such pairwise comparisons, this method generates a relative rank-order of a complete list of singers. Additionally, we incorporate a knowledge-based musically-relevant pitch histogram representation, as a conditioning vector, to provide explicit musical information to the network. The experiments show that this method is able to reliably evaluate singing quality and rank-order singing vocals, independent of the song or the singer. The results suggest that the twin-neural network learns the underlying discerning properties relevant to singing quality, instead of being specific to the content of a song or singer.

1. INTRODUCTION

Singing is a popular form of entertainment and a desirable skill to develop [1]. In recent times, many online applications that provide a platform to showcase singing talent as well as socially engage through music have become popular, such as Smule Sing! [1] , Starmaker [2] , Quanmin K Ge [3] , and SoundCloud [4] . With high volumes of singing performances on such online platforms, there is a need to explore automated methods of assessing the quality of singing for the purpose of identifying singing talent as well as providing meaningful feedback to amateur and aspiring singers.

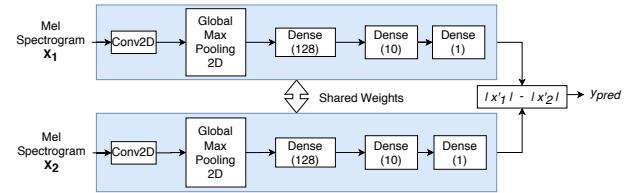
[3] https://kg.qq.com/
[4] https://soundcloud.com/

For example, such an automated evaluation method would be useful for screening of the singers for popular singing talent reality shows such as American Idol and The Voice. In this work, we provide a data-driven and preference-based framework for evaluating singing quality.

Previous work on automatic singing quality evaluation has focused on comparing a test singing rendition against the known musical notes of the song [2, 3] or against an ideal singing rendition of the song by a professional singer [4–6]. These methods extract audio features such as pitch contour and mel-frequency cepstral coefficients that are relevant to perceptual parameters used by music experts to evaluate singing quality such as intonation accuracy, rhythm consistency, and timbre brightness [7,8]. However, such methods are constrained by the need for a reference or ideal singing rendition for every song. Moreover, the choice of an "ideal" reference singer introduces a bias of subjective choice.

Another approach is the assessment of singing quality without a reference singer. Studies have shown that music experts can evaluate singers with a high level of consensus even when the song is unknown to them [9, 10], which implies that there are underlying inherent characteristics of singing quality that differentiate between preferred and amateur singing. Previously, Nakano et al. [10] designed features such as pitch interval accuracy that measure the offset of the pitch contour from the musical semitone grid to evaluate singing quality without a reference rendition. Gupta et al. [11, 12] designed hand-crafted features that characterize the shape of the pitch histogram and inter-singer distances to evaluate singing quality without a reference. Such methods provide insight and explanation to the objective evaluation, such as the measurement of the sharpness of peaks in a pitch histogram correlating with the consistency of hitting musical notes. However, such hand-crafted features provide an approximate representation of singing quality, that depend on manual thresholds that are determined empirically. They do not capture all aspects of singing and therefore are limited.

Previously in [11], the authors showed that since a song can be sung correctly in one or a few similar ways, but incorrectly in many different and dissimilar ways, it implies that the quality of a singer is proportional to his/her similarity with other singers. However, to obtain a relative rank-order based on this idea, they needed to calculate the

distance of every singer in the dataset with respect to every other singer, which becomes computationally demanding as the size of the dataset increases. Moreover, this distance calculation made sense only if the singers were singing the same song, making the algorithm song-dependent.


Humans are known to be better at relative judgments, i.e. choosing the most preferred singer among a small set of singers, than giving an absolute rating [13, 14]. This is the basis of the best-worst scaling (BWS) method used for consumer value preference surveys [15]. Motivated by this human behavior, we would like to develop a singing evaluation framework that is song-independent. The task is to rank-order a list of singing vocals without the need of any singing reference. We achieve a rank-ordering of a long list of candidates through a number of pairwise decisions.

2. TWIN-NETWORK FOR RELATIVE SINGING QUALITY EVALUATION

Twin-neural networks (or Siamese networks) have been previously used to measure similarity between two audio inputs, for example for vocal imitation [16–18], singing style identification [19, 20], and singing query retrieval [21]. The idea behind using twin-neural network for the task of singer style identification is to map different singing and song renditions of the same singer closer to each other than those of different singers. However, to the best of our knowledge, twin-neural network has not be explored for the task of singing quality assessment.

In this work, we modify a twin-neural network such that it learns which of the two given singing inputs is *more preferable* in terms of singing quality. We then obtain the rank-ordering of singing vocals by counting the number of times a singing input is preferred in many such pairwise comparisons across different singers, based on the concept of BWS. A similar approach has been discussed by Niu et al. [22] where a twin-neural network is applied for the task of image quality assessment. The network learns to rank the quality scores between the two input image patches, where it applies cross entropy as the loss function. Our work differs from [22] in that we propose a novel and intuitive preference metric and comparative loss function for training a siamese neural network to predict ranking.

Additionally, we include explicit musical knowledge in this framework, by using the pitch histogram as a conditioning vector. The two arms of the twin-network share the same architecture as well as parameters, i.e., the two inputs pass through exactly the same networks for feature learning. Singers share a similar underlying singing vocal production mechanism, however they differ in quality due to prosodic characteristics such as the ability to consistently hit the right notes. We hypothesize that the two arms of the network should be able to project each singing vocal to a compressed latent space that only represents the discriminatory singing quality properties independent of the song or the singer, thus making it suitable for the task of singing quality comparison of two singing vocals. Furthermore, BWS rank-ordering method is known to provide a reliable rank-ordering with fewer number of comparisons,

Figure 1. Twin-neural network modified for preference-based singing quality judgment.

which is helpful when the dataset size increases.

2.1 Model

A twin neural network consists of two identical sub-networks that have the same configuration with the same parameters and shared weights. During training, the parameter update is mirrored across both the sub-networks. The two sub-networks extract features from the two inputs, and then similarity between the two feature vectors is computed by a distance metric. In general, in a twin neural network, for a pair of inputs (x_1, x_2), the distance metric of the output of the two sub-networks $f(x_1)$ and $f(x_2)$ is given by Euclidean distance

$$D = ||f(x_1) - f(x_2)||_2 \qquad (1)$$

The contrastive loss function, that needs to be minimized, is defined as

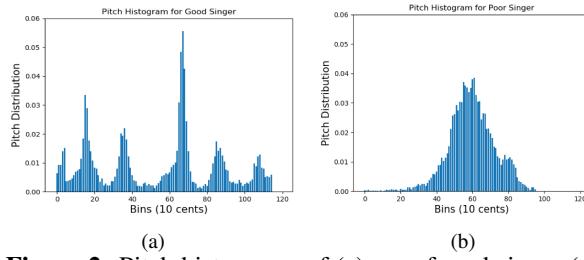
$$L = y_t \cdot max(1 - D, 0)^2 + (1 - y_t) \cdot D^2 \qquad (2)$$

where y_t is the ground truth label, such that $y_t = 1$ whenever x_1 and x_2 are from the same class and $y_t = 0$ otherwise. This framework has been successfully used for similarity detection tasks such as sound search and vocal imitation detection [16, 18].

We modify this framework such that it learns to choose the better singer amongst the two input singers, as shown in Figure 1. To do this, we propose to replace (1) the distance metric with a *preference metric*, and (2) the contrastive loss with a *comparative loss*.

2.2 Preference Metric

We define the preference metric as the difference between the L1 norm of the feature vectors,

$$D_p = |f(x_1)| - |f(x_2)| \qquad (3)$$


where $|f(.)|$ is the L1 norm of the feature vector. This provides a direction to the comparison, i.e. if $D_p \geq 0$ implies singer 1 input rendition x_1 is better than or similar to singer 2 input rendition x_2, and $D_p < 0$ implies singer 2 is better than singer 1. In contrast, a distance metric can only provide the magnitude, but not the direction of the difference.

2.3 Comparative Loss

Given the preference metric D_p, we compute the comparative loss function to be minimized, as

$$L_c = y_t \cdot max(1 - D_p, 0)^2 + (1 - y_t) \cdot (D_p + 1)^2 \quad (4)$$

where, y_t is the ground truth label, such that $y_t = 1$ whenever x_1 is better than or similar to x_2, and $y_t = 0$ otherwise. Note that the modification in comparative loss compared to contrastive loss is to accommodate for the directional or signed property of the preference metric D_p. Let's

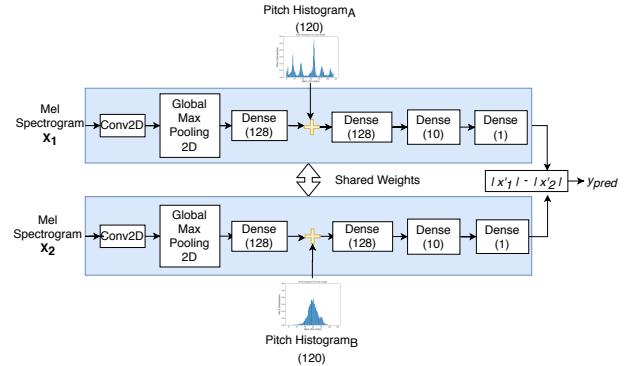
(a)   (b)

Figure 2. Pitch histograms of (a) a preferred singer (rank 1) and (b) an amateur singer (rank 99) from the song *Let it go* of dataset 1 (Section 4.1.1). (1 bin = 10 cents).

examine this equation closely. If x_1 is better than x_2, then $y_t = 1$, so equation 4 will become

$$L_c = max(1 - D_p, 0)^2 \qquad (5)$$

Minimizing this loss function, makes the preference metric D_p close to 1. On the other hand, if x_2 is better than x_1, then $y_t = 0$, so equation 4 will become

$$L_c = (D_p + 1)^2 \qquad (6)$$


For this loss function to be zero, the preference metric D_p should be optimized to -1, thus preserving the signed property of the preference metric D_p.

3. HYBRID TWIN-NEURAL NETWORK WITH PITCH HISTOGRAM CONDITIONING VECTOR

We use mel-spectrogram as the input time-frequency representation of the input audio waveforms. However, measuring pitch correctness is a vital component of singing quality evaluation. Therefore, we condition the twin-network with pitch information in the form of pitch histogram. This unburdens the network from learning pitch-related information from the input representation.

The pitch histogram represents the distribution of pitch values in a sung rendition [23]. As demonstrated by [11], a pitch histogram is a strong indicator of the quality of singing. A pitch histogram is computed as the count of the pitch values (calculated in the unit of cents) folded on to the 12 semitones in an octave, where one semitone represents 100 cents on equi-tempered octave. The melody of a song typically consists of a set of dominant musical notes (or pitch values). These are the notes that are hit frequently in the song and sometimes are sustained for long duration. In the pitch histogram of a preferred singing rendition, there are several narrow, sharp, and well-defined spikes that indicate that the dominant notes are hit repeatedly and consistently (Figure 2(a)). On the other hand, an amateur singing rendition has a dispersed distribution of pitch values, that reflect that the singer is unable to hit the dominant notes of the song consistently (Figure 2(b)).

Due to its strong relevance to singing quality, we condition the twin-neural network by concatenating the pitch histogram vectors of the two inputs, ph_A and ph_B to the output vector of their respective sub-network intermediate layer, as shown in Figure 3. Such a configuration, called the hybrid twin-neural network, improves the performance

Figure 3. Hybrid Twin-neural network conditioned on pitch histogram.

of the network for singing quality evaluation, by providing explicit pitch-related information to the network releasing degrees of freedom to the network to learn other non-pitch related properties.

4. EXPERIMENTAL SETUP

We conduct experiments to evaluate the performance of the twin-neural network and the hybrid twin-neural network for the task of automatic rank-ordering of singing vocals. We analyse the performance of the framework when the input pair of singing vocals belong to the same song, as well as when they belong to different songs. We also compare the performance and capabilities of this framework with previous similar work in literature.

4.1 Dataset

4.1.1 Singing voice dataset 1

We use the subset of DAMP dataset[5] that was curated by [11] for the purpose of singing quality evaluation. It consists of solo-singing recordings (16 kHz sampling rate, mono) of 4 popular Western songs each sung by 100 unique singers (50 male, 50 female). There were no common singers across different songs. The selection of songs was based on the available number of unique singers in the DAMP dataset, and equal distribution between males and females, to avoid gender bias. The 4 popular songs are *Let it go (Idina Menzel), Cups (Anna Kendrick), When I Your Man (Bruno Mars), Stay (Rihanna)*. All the songs are rich in steady notes and rhythm, as summarized in Table III of [11].

We use one 20-30 seconds long snippet from each singing rendition. This snippet is a common section of the song for all the singers singing that song. The ground-truth subjective ranking provided with this dataset was a BWS score obtained through a crowd-sourcing platform by asking listeners to choose the best and the worst amongst a few singers singing the same song. This score resulted in a rank-order of the singers of each song from 1 to 100, where rank 1 means the best singer, and rank 100 means the worst singer. We divide this dataset into a train set that has 80%, i.e. 80 singers per song, and validation and test sets, each

---

Dataset	Division	#songs	#singers per song	#singer pairs per same song	#singer pairs singing same+different songs
1	Train	4	80	4 x 80 x 79 = 25,280	80x4=320 singers 320x319=102,080 pairs
	Validation	4	10	4 x10 x 9 / 2 = 180	10x4=40 singers 40 x 39 / 2 = 780 pairs
	Test	4	10	4 x 10 x 9 / 2 = 180	10x4=40 singers 40 x 39 / 2 = 780 pairs
2	Test	2	10	2 x 10 x 9 / 2 = 90	10x2=20 singers 20 x 19 / 2 = 190 pairs

Table 1. Summary of the number of singer pairs from the different datasets used in this work.

consisting of 10%, i.e. 10 singers per song. To ensure similar distribution of singing quality in all of these subsets, we pick the singers with ranks [1,11,21,...91] for the test set, [2,12,22,...92] for the validation set, and the rest for the train set. Note that the test set consists of singers that are not present in training or validation sets. However, the songs in all three sets are the same.

4.1.2 Singing voice dataset 2

To test the trained models on unseen songs, we use a small test dataset provided by [4] that consists of solo-singing recordings (16 kHz sampling rate, mono) of 2 Western pop songs (*I have a dream (ABBA), Edelweiss (Sound of Music)*) each sung by 10 singers. Since this dataset was recorded in a lab-controlled environment, the entire spectrum of singing ability - from amateur singers to professionally trained excellent singers - was covered. The ground-truth singing quality annotations provided in this dataset are absolute ratings on a scale of 1-5, 5 being the best, provided by professional music teachers and/or performers in a lab-controlled environment. Additionally, the music experts evaluate and score the quality of pitch and rhythm separately.

4.1.3 Singer pair inputs

The number of singer pairs singing the same song and different songs in the two datasets is summarized in Table 1. There exist a total of 25,280 ordered pairs of singers singing the same song in the training set, and 102,080 ordered pairs of singers singing different as well as same song. We treat ordered pairs, i.e. singer pairs (A,B) and (B,A) as different training samples for the purpose of data augmentation. Also this is helpful because the preference metric is asymmetric. The validation set consists of 180 unordered pairs of singers singing the same, 780 unordered pairs of singers singing the same and different songs. We have two test sets, one each from singing vocals datasets 1 and 2. The number of pairs in test dataset 1 is same as the validation set. The test dataset 2 consists of 90 unordered pairs of singers singing the same song, and 190 unordered pairs of singers singing the same and different songs.

4.1.4 Ground-truth Labels

The ground-truth label for each pairwise comparison of singers is derived from the human scores provided in the singing datasets 1 and 2. In dataset 1, the BWS score b provided for every singer that ranges between -1 and 1 is first normalized between 0 and 1. We then label a pair of singers A and B as

$$y_{true} = \begin{cases} 1, & \text{if } b_A \geq b_B \\ 0, & \text{otherwise} \end{cases}$$

which implies that if singer A is better or similar to singer B, the label is 1, and it is 0 otherwise. Similarly, in dataset 2, the absolute human ratings between 1 and 5 is normalized between 0 and 1, and the same method is applied to give a binary label every pair of singers.

4.2 Setup

The overall structure of the twin network is shown in Figure 1, and the hybrid twin network is a modified version of the twin network, as shown in Figure 3.

4.2.1 Pre-processing

Both the input audio waveforms are converted to the 2-D mel-spectrogram representations with 96 mel-bins over the frequency range of 0–8 kHz, a window length of 512 and a hop-size of 256. The input waveforms are singing vocal snippets of approximately 20 seconds in duration. The number of frames of the two inputs are made equal by appending zeros to the shorter spectrogram.

4.2.2 Twin-network

Each arm of the twin network consists of a 2D Convolutional Neural Network (CNN) with 1 convolutional layer having 64 filters with a kernel size of 3x3 and stride size of 1x1, followed by a sigmoid activation function. They are then each followed by a 2D global max-pooling layer, and three fully-connected dense layers. There are 128 neurons in the first dense layer, 10 in the second layer, and 1 in the third. The sigmoid activation function is used in all of these layers, as it squashes the output of the layers between 0 and 1. Empirically, we observe that applying the sigmoid activation at all the layers results in convergence while training.

The preference metric is computed using the outputs of these two arms, as discussed in Section 2.2. This value is viewed as the preference judgment value between the input singer pair, i.e. which of the two singers is better.

4.2.3 Hybrid twin-network

In order to incorporate musical relevance into the network, we concatenate the normalized 120 dimensional pitch histogram vectors of the two inputs, at the output of the first dense layer in both the arms of the twin network. We chose to inject the pitch histogram information here because of the comparable number of dimensions of the latent space and the histogram. Empirically, an additional fully-connected layer was needed to gradually project the dimensions of the output to 1, and for training to converge.

4.2.4 Training

Training the network requires positive (singer A better than or similar to singer B) and negative pairs (singer B better than A) of singer inputs. In our training, the ground truth label is 1 for positive pairs and 0 for negative pairs.

The loss function we minimize is the comparative loss which is a function of the probability output of the network and the binary ground-truth label, as given in equation 4. We use the Adam optimization algorithm [24]. The learning rate is 0.0001. The batch size is 10. Maximum number of epochs is set to 250, though early stopping based on training loss with patience of 5 epochs is employed for training termination. Back-propagation is car-

ried out through the twin-net arms. We choose the model that shows minimum loss in the validation set.

4.2.5 Prediction

The preference judgment value, i.e. the preference metric D from equation 3 of the twin network lies between -1 and 1. If this value is >=0, it implies singer A is preferred over singer B, thus the verdict is 1, and vice versa.

After all the pairwise comparisons, the singers can be rank-ordered according to the aggregate scores of each singer, given by the BWS score defined as

$$B = \frac{n_{best} - n_{worst}}{n} \qquad (7)$$

where n_{best} and n_{worst} are the number of times the singer is marked as preferred and not preferred respectively, and n is the total number of times the singer appears.

4.3 Evaluation Metrics

We use three kinds of metrics to evaluate the performance of the framework with respect to the human ground-truth labels as described in section 4.1:

Pair prediction accuracy: This is defined as the percentage of input singer pairs for which the preference prediction from the network is correct.

Pearson's Score Correlation: This is the correlation between the machine BWS scores and human BWS scores.

Spearman's Rank Correlation: This is the correlation between the machine and human annotated singer rank-orders based on the respective BWS scores.

5. EXPERIMENTS AND RESULTS

The inter-judge correlation between ratings from music experts is 0.82 [4], which means that experts do not always agree with each other, and there is, in general, an upper limit of the achievable performance of any machine-based singing quality evaluation.

5.1 Twin-Net vs. Hybrid Twin-Net

We test our hypothesis that twin neural network can be applied for the task of learning singing quality preference in pairwise comparisons of singers to predict rank-ordering of singers. We train the twin-network and the hybrid-twin network on the 25,280 *same song* singer pairs from the training set of dataset 1. Since the two singers sing the same sequence of words, the twin arms focus on learning the discriminatory characteristics from the input representations which lie in the differences in the prosodic properties such as pitch harmonics of the two singing renditions. The hybrid network further helps in this process as the pitch histogram provides a direct singing quality discriminatory representation, as discussed in section 3.

From Table 2, we see that the both the twin-networks are able to converge on the training dataset with a high pair prediction accuracy and score correlation with humans. This validates our hypothesis and technique of the adaptation of a Siamese network for preference-based judgment and hence rank-ordering of singers. We also observe that the hybrid-twin network outperforms the twin-network on the test set from dataset 1. This implies that conditioning

Dataset	%Accuracy		Pearson Corr.	
	Twin	**Hybrid**	**Twin**	**Hybrid**
Train	88.3	81.3	0.91	0.82
Validation	73.8	73.3	0.63	0.62
Test Dataset 1	72.7	76.1	0.61	0.68

Table 2. Performance of twin-network and hybrid twin-network in terms of pair classification accuracy and Pearson correlation between machine BWS scores and human BWS scores. All correlation values are statistically significant with $pvalue \ll 0.05$.

the network on pitch histogram frees degrees of freedom to model non-pitch related information via the network.

5.2 Comparison with Prior Studies

The prior studies that are closest to this work are the ones by Gupta et al. [11] and Pati et al. [25]. In the former, the authors studied various hand-crafted features to generate rank-ordering of singers, such as pitch histogram-based absolute measures and inter-singer distance based relative measures. They also performed late-fusion of these ranks to get a good correlation with human annotations. Pati et al. trained a supervised regression DNN model that uses mel spectrograms of pitched wind instruments as input representation to predict their subjective human scores.

In this experiment, we compare the performance of our proposed hybrid twin-network against the relative measures performance of [11]. Both these techniques involve same-song pair comparisons, and hence are conceptually similar. Additionally, we train the absolute score prediction network of [25] on our dataset. The ground-truth, in this case, are the raw human BWS scores of every singer that was provided with this dataset. This prediction network is similar to the absolute measures prediction from [11] in the sense that both involved direct assessment of singers. Finally, in late-fusion, we compute the average of the rank-order obtained from our hybrid twin network and the absolute score prediction network, similar to [11].

In Table 3, we see that the proposed hybrid-twin network performs better than the relative measures of [11]. Moreover, hybrid-twin outperforms the absolute score prediction network. This implies that pairwise comparisons in combination with pitch histogram representation results in better modeling of singing quality, than hand-crafted features. The late-fusion performances are comparable.

The inter-singer distances of relative measures in [11] compare the features from one singer with that of the rest of the singers in the dataset singing the same song. Thus, the major drawback of this method is that the relative measures will make sense only if all the singers are singing the same song. Moreover, for a new unseen song, there needs to be a large number singers singing that song for the thresholds designed for relative measures to be reliable. The above drawbacks make the relative measures highly song dependent. Moreover, any new test singer needs to be compared to all the singers in the dataset to get a reliable ranking. This becomes computationally cumbersome with increasing size of dataset. In the next sections, we show how our proposed framework overcomes these drawbacks.

Gupta et al. [11]		This work	
Framework	Corr	Framework	Corr
Relative Measures	0.64	Hybrid Twin-network	0.68
Absolute Measures	0.48	Absolute score prediction network [25]	0.62
Late-Fusion	0.71	Late-Fusion	0.71

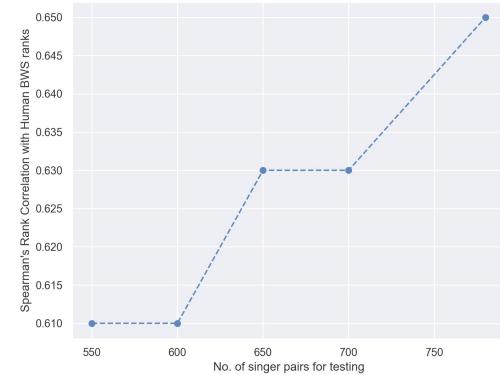
Table 3. Comparison of the Spearman's rank correlation performance of the proposed hybrid twin network on dataset 1 with that from a recent previous work on the same dataset. All correlation values are statistically significant with $pvalue \ll 0.05$.

Framework	%Accuracy	Pearson's Score Corr	Spearman's Rank Corr
Twin-net	65.9	0.39	0.41
Hybrid twin-net	77.7	0.63	0.65

Table 4. The performance of twin-net and hybrid twin-net models on unseen songs from test dataset 2. The models are trained on the same song input training pairs from dataset 1. All correlation values are statistically significant with $pvalue \ll 0.05$.

5.3 Performance on Unseen Songs

To test the performance of the trained model on unseen songs, we evaluate its performance on test dataset 2 (Table 1). These songs and singers were not present in training set. The dataset consists of 90 same song singer pairs. From Table 4, we observe that the hybrid twin net outperforms the twin-net by a significant margin. This shows that the pitch histograms are a powerful representation of singing quality that reduces the dependency of the network on the identity of the song, thus confirming that our proposed framework can reliably evaluate unseen songs.

5.4 Comparing Different Songs


We further test if our proposed framework can compare singing vocals of different singing content. For this, we train the hybrid-twin net singer pairs singing same as well as different songs, for which we use the 102,080 ordered singer pairs of the training dataset (Table 1). In Table 5, we observe the performance of this model on the different song singer pairs from both test dataset 1, where the songs are seen by the trained model, and test dataset 2, where the songs are not seen by the trained model. Rank-ordering singing vocals with different-song singer-pair inputs (Table 5, row 1 and row 3) shows comparable results to same-song singer-pair comparisons (Table 3 row 1 and Table 4 row 2). Moreover, when rank-ordering is done using both different-song and same-song pair comparisons, the results on unseen songs (Table 5, row 4) significantly outperforms that from the same-song pair trained model (Table 4 row 2). This experiment shows that our proposed preference-based framework is able to learn discerning properties of singing quality such that given any two singers singing the same or different songs, it learns to choose the better singer.

5.5 Effect of Number of Comparisons

BWS method is known to be able to reliably rank-order with fewer number of comparisons. We tested this idea by

Test Dataset	No. of diff. songs singer pairs	No. of same songs singer pairs	%Accuracy	Pearson's Score Corr	Spearman's Rank Corr
1	600	0	72.3	0.64	0.64
	600	180	72.7	0.65	0.65
2	100	0	77	0.68	0.68
	100	90	78.6	0.70	0.73

Table 5. Performance of hybrid twin network trained on the same and different song input pairs. All correlation values are statistically significant with $pvalue \ll 0.05$.

Figure 4. Spearman's rank correlation as the number of pairwise comparisons is reduced.

reducing the number of paired comparisons in the test set, while ensuring that each singer appears at least once. Out of the 780 pairs, we randomly selected x number of unique pairs three times, and calculated the average of the performance of the three random trials. These average values of Spearman's rank correlation are plotted in Figure 4, where the number of pairs selected ranged from 550 to all of the 780 pairs. We observe that for a reduction of 30% in the number of pairs for comparison, there is a very small drop in the correlation value, approximately 6%. This computational advantage will become more significant when the size of the dataset increases.

6. CONCLUSIONS

In this work, we propose a preference-based framework in which we adapt the twin neural network (Siamese) such that given two input singers, it learns to choose the better singer. We incorporate structural changes in the Siamese network framework such as preference metric instead of distance metric and comparative loss instead of contrastive loss, so that it is able to learn a preference instead of similarity. We show that with a few pairwise comparisons, this modified Siamese network effectively gives a reliable rank-order of singers. We also incorporate the musically relevant pitch histogram representation in a hybrid twin network framework, which shows to provide reliable singing quality predictions in a singer and song independent way on unseen data.

ABSTRACT

Music producers who use loops may have access to thousands in loop libraries, but finding ones that are compatible is a time-consuming process; we hope to reduce this burden with automation. State-of-the-art systems for estimating compatibility, such as AutoMashUpper, are mostly rule-based and could be improved on with machine learning. To train a model, we need a large set of loops with ground truth compatibility values. No such dataset exists, so we extract loops from existing music to obtain positive examples of compatible loops, and propose and compare various strategies for choosing negative examples. For reproducibility, we curate data from the Free Music Archive. Using this data, we investigate two types of model architectures for estimating the compatibility of loops: one based on a Siamese network, and the other a pure convolutional neural network (CNN). We conducted a user study in which participants rated the quality of the combinations suggested by each model, and found the CNN to outperform the Siamese network. Both model-based approaches outperformed the rule-based one. We have opened source the code for building the models and the dataset.

1. INTRODUCTION

The emergence of digital audio editing techniques and software such as digital audio workstations (DAWs) has changed the way people make music. In a DAW, producers can easily produce music by making use of pre-existing audio as loops. Loops are used in many styles, especially Electronic and Hip-Hop music. Perhaps noticing the business value of such loop-based music, many companies such as Splice and LANDR have built up databases of loops. Community efforts have flourished too, including Looperman, an audio community that provides free loops for music producers to use. But having so many resources to choose from leaves a separate problem: how to navigate the library efficiently and how to choose which loops to combine. These tasks require human practise, expertise, and patience: to recognize the characteristics of the

loop and to determine whether it is suitable for their song. However, thanks to recent advances in music information retrieval (MIR), we believe it is possible to make loop selection from large-scale loops database easier.

A few existing systems could potentially solve this problem. Kitahara *et al.* [1] presented an intelligent loop sequencer that chooses loops to fit a user-defined 'excitement' curve, but, excitement only accounts for part of what makes two loops compatible. The AutoMashUpper system [2] could also be applied to the loop selection process: it involves estimating the 'mashability' of two songs (i.e., how compatible they would be if played at the same time). It is a rule-based system that computes the harmonic and rhythmic similarity and spectral balance, and it has proven useful in other applications [3,4]. However, AutoMashUpper has two limitations that could be improved by current machine learning methods. First, it regards the harmonic and rhythmic similarity as part of mashability, while it is actually possible that two music segments match perfectly despite having different harmonies and rhythms. Second, hand-crafted representations cannot fully describe all features in the music segment.

To capture the more complicated compatible relationship between two music segments, we propose to employ modern machine learning models to learn to predict the compatibility of loops. A major obstacle preventing the development of such a model is the lack of a dataset with sufficient labelled data. While there are many datasets of loops, none provide ground truth compatibility values.

We make two main contributions. First, we propose a data generation pipeline that supplies labelled data for model-based compatibility estimation (see Section 3). This is done by using an existing loop extraction algorithm [5] to yield positive examples of loops that have been used together in real loop-based music. We also propose procedures to ensure the quality of the positive data, and investigate different strategies to mine negative data from the result of loop separation.

Second, we develop and evaluate two neural network based models for loop compatibility estimation (see Section 4), one based on convolutional neural network (CNN) and the other Siamese neural network (SNN) [6]. The two approaches perform loop compatibility estimation using different approaches: the CNN directly evaluates the combination of loops in a time-frequency representation, whereas SNN processes the two loops to be evaluated for compatibility separately. We report both objective and sub-

jective evaluations (see Section 5) to study the performance of these approaches, and to compare the model-based approaches with AutoMashUpper.

The audio data we employ to build the neural network is from the Free Music Archive (FMA) [7] (see Section 3.1), which make data re-distribution easier. Moreover, we have open-sourced the code implementing the proposed CNN and SNN models at `https://github.com/mir-aidj/neural-loop-combiner`.

2. RELATED WORK

Along with the growing interest in loop-based music, academic studies focusing on assisting loop-based music production have become popular. An early study [8] proposed two ways to help create loop-based music: automatic loop extraction and assisted loop selection. This laid the foundation for this field.

For **loop extraction**, Shi and Mysore [9] proposed an interface with automatic and semi-automatic modes for the producer to find the most suitable segment in a piece of music to excerpt and use as a loop, by cropping directly. These algorithms estimate similarity with handcrafted features: harmony, timbre, and energy [8, 9]. However, the segments are excerpted without any attempt to isolate one part of a potentially multi-part piece of music. One solution to this used a common quality of loop-based music—that loops are often introduced one at a time—to recover the source tracks [10], but not all pieces have this form. To tackle both problems, Smith *et al.* [5, 11] proposed to extract loops by taking into account how they repeat. The algorithm they proposed can directly extract the loops from songs using nonnegative tensor factorization (NTF).

For **loop selection**, Kitahara *et al.* [1] proposed to select the loops according to the level of excitement entered by the user. However, we see three limitations in this work. First, the study focuses on Techno music only—while excitement is certainly highly relevant to this genre, the approach may not generalize well to other genres. Second, the level of excitement has to be manually entered by a user, which limits its usability. Third, the study does not take compatibility into consideration. As a result, even though a user can find loops with the desired excitement level, the loops may not be compatible with one another.

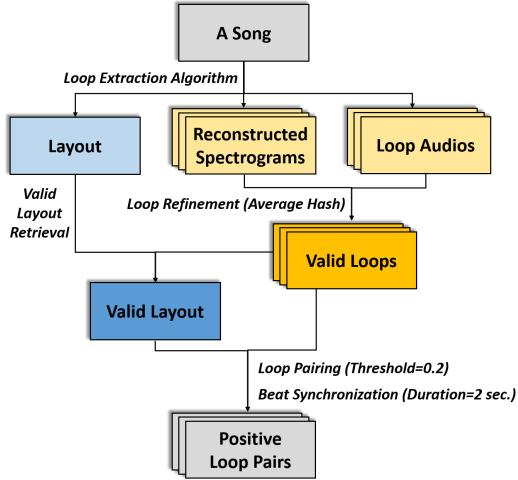
To the best of our knowledge, the work of Davies *et al.* [2, 12] represents the first study to investigate mashability estimation. Their AutoMashUpper system represents each music segment (not necessarily a loop) with a chromagram, a rhythmic representation, and a spectral band representation, each made to be beat-synchronous. Given two songs, it computes the similarity between the chromagrams and the rhythmic representations, and the spectral balance between the songs, to obtain the final mashability estimate. While AutoMashUpper is developed for general mashability estimation of longer music pieces, it can also be applied to loop selection.

Lee *et al.* [13] extended AutoMashUpper, proposing that two parts should be more compatible if they have complimentary amounts of harmonic instability. They gener-

Data type	# loops	# loop pairs	# songs
Training set	9,048	12,774	2,702
Validation set	2,355	3,195	7,06
Test set	200	100	100
$\sum$	11,603	16,069	3,508

Table 1: Statistics of the dataset, which is derived from Hip-Hop songs in the Free Music Archive (FMA) [7] using the data generation pipeline shown in Figure 1.

ated mashups that were preferred by listeners to the output of AutoMashUpper, but they focused on a particular type of mash-up (combinations of vocal and backing tracks) whereas we focus on general loop compatibility. Bernardes *et al.* [14,15] proposed several harmonic mixing approaches based on psychoacoustic principles and "tonal interval space indicators." Xing *et al.* [16] used paired audio, MIDI, and lyrics data for mashability estimation, taking into account similarity in melody, rhythm, and rhyming lyrics. Among these works, AutoMashUpper stands out as a general-purpose system requiring only audio data, so we consider it as our baseline.

3. DATA GENERATION PIPELINE


To create the labeled data needed for training our models, we obtained a dataset of loop-based music and used loop extraction [5] to obtain audio loops. We use a new loop refinement procedure to reduce the number of duplicate loops per song, and a loop pairing procedure to get pairs of loops that co-occur in songs.

3.1 Dataset

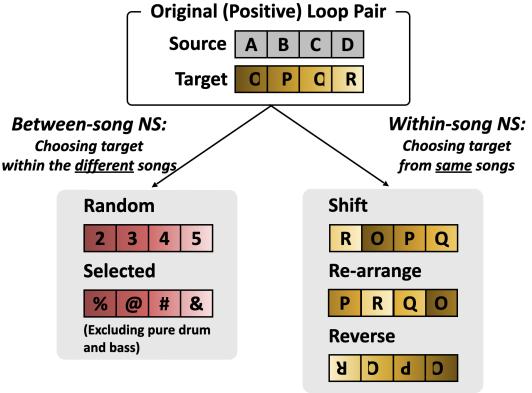
To extract a collection of loops, we first need a large set of songs that use loops. We chose to use music from the Free Music Archive (FMA) [7] so that we could redistribute the audio data. We restricted ourselves to the genre of Hip-Hop for three reasons: First, we could not manually verify whether each song used loops, so we needed to use a genre known for using loops. Second, for the loop extraction step to work, we needed the music to have a steady tempo. Third, we expected that a Hip-Hop subset would provide a useful variety of loops since the genre is known for incorporating loops from many other genres

We collected 6,868 Hip-Hop songs in total from FMA by searching for the tag "Hip-Hop." We passed these songs through the proposed data generation pipeline, and kept the 3,508 songs from which we could find at least one valid loop pair. Specifically, from these 3,508 songs, we obtained 11,603 valid loops and 16,069 valid loop pairs. From the full set of loops, we reserved 200 loops (1 pair each from 100 different songs) for the evaluations (see Section 5), and then split the rest into train and validation sets in a 4-to-1 ratio (see Table 1). [1]

---

[1] To facilitate follow-up research, we plan to share publicly the loops we extracted from FMA songs. While FMA has looser copyright re-

Figure 1: The proposed data generation pipeline for creating positive loop pairs.

Figure 2: Illustration of various loop-pair 'negative sampling' (NS) strategies explored in the paper.


3.2 Data Generation

Figure 1 depicts the overall data generation pipeline. We firstly use the algorithm proposed by Smith and Goto [5] for loop extraction. The algorithm uses NTF to model a song as a set of sound templates and rhythm templates, a set of "recipes" for combining these templates to recreate the loop spectrograms, and a loop layout that defines when each loop occurs in the song. In later work, the authors described how to choose the best instance of a loop to extract from a piece, and a second factorization step that can be applied to reduce the redundancy of the loops [11]. As a result of this process, we get out of a song the loop layout, the reconstructed spectrograms, and the audio files of loops, as depicted in the first half of Fig. 1.

Despite this extra step, we still found many redundant, similar-sounding loops from the Hip-Hop dataset. To further deduplicate the loops, we introduce a new loop refinement step. The main idea is to consider the reconstructed spectrograms obtained from the loop extraction algorithms as an image, and apply the average hash algorithm [17] used in the identification or integrity verification of images to detect the duplicate loops. We first construct the hash from each spectrogram extracted from the same song, then count the number of bit positions that are different in every pair of spectrograms. If a pair of spectrograms has fewer than five bit positions that are different, we regard them as duplicates and remove one of them.

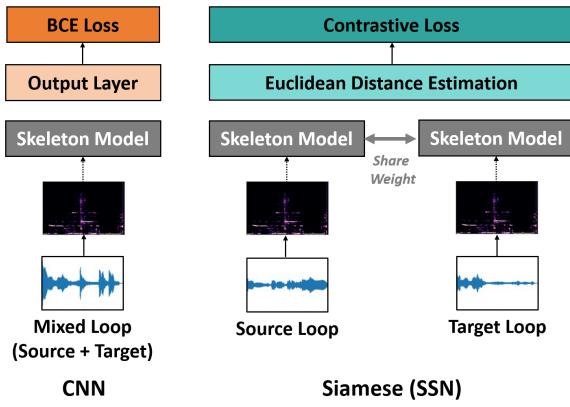
After this, we refine the loop layout by two steps. First, we combine all activation values from the duplicate loop in the loop layout into a single activation value. Second, we normalize all the activation values in each bar. This leads a valid loop layout that is ready for loop pairs creation.

Finally, we have to process the real-valued loop layout to obtain pairs of loops that do co-occur. A straightforward approach is to threshold the loop layout; we found

a threshold of 0.2 to work reasonably well. Please note that, to make all the loops in our dataset comparable, we time-stretch each to be 2 seconds long.

4. PROPOSED LEARNING METHODS

4.1 Negative Sampling Strategies

We get abundant positive data after the data generation pipeline. However, we also need negative examples (pairs of clips known to not match well) to train our mashability predictor. While there are straightforward ways to collect such examples, proper and domain-specific negative sampling has been shown to be important [18–22]. We experiment with the two types of methods of negative sampling. See Figure 2 for an overview of such methods.


4.1.1 Between-Song Negative Sampling

A naive approach to negative sampling, dubbed the **random** method, is to take any two loops from two different songs, and call that a negative pair. But, it is hard to ensure the loops collected in this way clash with one another.

We therefore also study a slightly more sophisticated method that takes *instrumentation* into account, dubbed the **selected** method. Specifically, we noted that many loops are pure drum or pure bass loops, and they tend to be compatible with any loops. Therefore, we use [23] to detect pure drum or bass loops and avoid selecting them in the process of random negative sampling. This way may help emphasize the harmonic compatibility of the loops. With this strategy, we can experiment whether putting more emphasis on *harmonic compatibility* can indeed improve the result, or other feature's compatibility is still crucial.

4.1.2 Within-Song Negative Sampling

Negative data can also be created by editing a loop in a positive loop pair. We come up with three methods for making conflicting loop pairs: 'reverse,' 'shift,' and 'rearrange.' Given a positive loop pair, we view one of them as the *source loop*, and the other as the *target loop*. With the **reverse** method, the target loop is played backward to create the rhythmically and harmonically conflict. The **shift**

Figure 3: Architectures of the CNN and SNN models studied in this paper. The CNN takes a pair of loops (in the time domain) as the input, whereas the SNN takes the two loops as separate inputs and concatenate the intermediate abstractions only in the middle of its network.

method cycle-shifts a target loop by 1 to 3 beats at random to make the source loop and manipulated target loop unbalanced. The **rearrange** method cuts the target loop into beats and reorders them randomly. The combination of the source loop and the manipulated target loop is considered as a negative loop pair. See Figure 2 for illustrations.

4.2 Model and Training

Figure 3 shows the two models (CNN and SNN) proposed to learn the compatibility of two loops. To make a fair performance comparison, we train them with the same skeleton in a different way. Therefore, we first introduce the skeleton model and then explain how it is incorporated into the specific model architectures for the training process.

4.2.1 Skeleton model

A two-layer 2-D convolutional neural network (CNN) and 3-layer fully connected neural network is the skeleton of networks used in this paper. There are 16 filters (with kernel size 3) and 4 filters (also with kernel size 3) in the first and second convolutional layers. The 3-Layer fully-connected neural network is constructed by 256, 128, 16 output features, respectively. Furthermore, batch normalization [24], 10% dropout [25], and PReLU [26] are applied to all convolutional and fully-connected layers. All the models are trained using stochastic gradient descent with batch size 128. The input for the skeleton model is a 2-second loop audio. We compute the spectrograms by sampling the songs at 44k Hz and using a 2,048-point Hamming window and 512-point hop size. We then transform the spectrograms into 128-bin log mel-spectrograms. The resulting input has shape 173 frames by 128 bins.

4.2.2 CNN Model

A convolutional neural network is well-known for its ability as feature extraction. In our system, in order to learn the compatibility of two loops, we propose to use a CNN

as a classifier by combining two loops into a single input, and then train the CNN model to learn to distinguish whether loop combinations would sound harmonious (high compatibility) or incompatible (low compatibility). For the classification purpose, we stack the skeleton model with a fully-connected output layer to get a single value as the output. Then, we compute the binary cross entropy loss (BCELoss) to update the parameters of the whole model. We note that its output is a value between 0 and 1, with values closer to 1 indicating a higher probability that the pair of loops are compatible, and closer to 0 when they are not. Therefore, we can later use its output to estimate the compatibility of any two loops.

4.2.3 Siamese Model

A Siamese neural network (SNN) [6] consists of twin networks that share weights and configurations. SNN has been shown effective in image retrieval [27] and various MIR tasks alike [4, 28–32]. Aiming to test its applicability to loop compatiblity estimation, we train an SNN using the labeled data we created through the data generation pipeline as follows. The outcome of an SNN is a mapping function from the input features to the output vectors in an embedding space. During the training process, our SNN first transforms the input Mel-spectrograms into a vector by a skeleton model and then optimize in contrastive loss [33] directly. After training, we have a mapping function that can map any loop to the embedding space. To select the compatible loops, we compute the Euclidean distance between two loops in that embedding space. If the distance for two loops is close, then we assume they may be compatible, and vice versa.

5. EXPERIMENTS AND EVALUATION

5.1 Objective Evaluation

In the objective evaluation, we aim to evaluate the performance of different combinations of model architectures (i.e., CNN and SNN) and negative sampling methods. In doing so, we consider two types of objective metrics.

The first type of evaluation entails a *classification* task. It assesses a model's ability to distinguish compatible loops from incompatible ones. To create a test set for this evaluation, we used the positive data from the validation data and collected the negative data by using all the negative sampling methods equally, in order not to favor any of them in this evaluation. To make the test set balanced, we set the ratio of negative to positive data to 1:1.

The second type of evaluation, on the other hand, involves a *ranking* task. Given a query loop and a certain number of candidate loops, a model has to rank the candidate loops in descending order of compatibility with the query. We created the set of candidate loops for a query loop such that we knew one and only one of the candidate loops formed a positive loop pair with the query loop. We could then evaluate the performance of a model by checking the position of this "target loop" in the ranked list. The closer the rank is to 1, the better. This evaluation task

Model	Negative sampling	Classification-based metric		Ranking-based metric			
		Accuracy	F1 score	Avg. rank	Top 10	Top 30	Top 50
CNN	Random	0.60	0.59	43.0	0.13	0.35	0.59
	Selected	0.59	0.59	43.1	0.13	0.29	0.62
	Reverse	**0.63**	**0.62**	41.2	0.19	0.42	0.62
	Shift	0.57	0.56	49.0	0.11	0.34	0.54
	Rearrange	0.57	0.57	47.7	0.10	0.31	0.57
Siamese NN	Random	0.51	0.47	**34.2**	**0.27**	**0.52**	**0.74**
	Selected	0.52	0.47	42.8	0.18	0.39	0.59
	Reverse	0.53	0.48	42.7	0.16	0.37	0.62
	Shift	0.53	0.52	43.0	0.16	0.41	0.65
	Rearrange	0.53	0.53	44.2	0.16	0.40	0.60

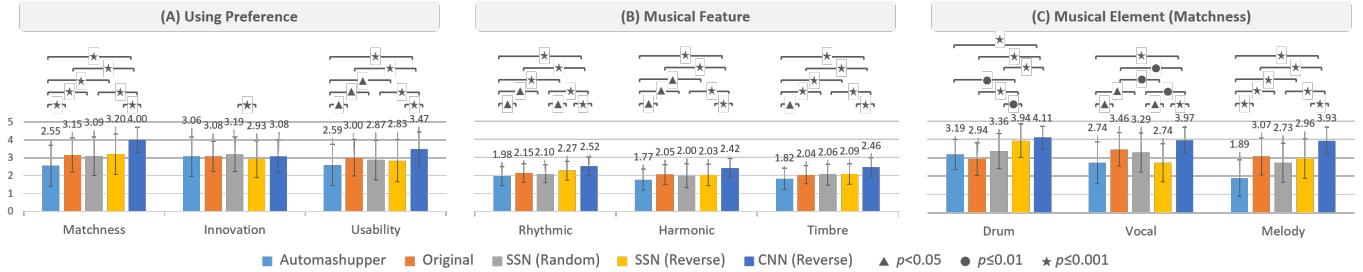
Table 2: Objective evaluation result of different combinations of models (CNN or SNN; see Section 4.2) and negative sampling strategies (see Section 4.1). We highlight the best result for each metric in bold.

aligns well with the real-world use case of the proposed model: to find loops compatible with a query loop from a pool of loop libraries. However, we note that it may not be always possible to rank the target loop high in this evaluation, because the other loops in the candidate pool may also be compatible with the query.

In our experiment, we set the number of candidate loops to 100. We computed four metrics for the ranking task: top-10 accuracy, top-30 accuracy, and top-50 accuracy—which evaluate whether the target loop was placed in the top-10, top-30, and top-50 of the ranked list, respectively—as well as the average rank. We report the average of these values for the 100 different query loops.

Classification Result—Table 2 shows that, regardless of the negative sampling method, the CNN models outperform the SNN models for the classification-based metrics. While the CNN learns to rate the compatibility of the loop combinations directly, the SNN learns to place the loops in a space, with nearby loops being more compatible. The training data were the same, so the difference in performance suggests that the space learned was not effective for the classification task.

Ranking Result—Table 2 also shows CNN and SNN models seem to perform comparably with respect to the ranking-based metrics. Yet, the best scores in the four ranking-based metrics are all obtained by SNN with 'random' negative sampling. When an SNN is used, there appears to be a large performance gap between 'random' and all the other negative sampling methods. This suggests that focusing on harmonic compatibility alone (e.g., as done by using the 'selected' negative sampling method) is not optimal; compatibility in other dimensions of music is also important. On the other hand, when a CNN is used, 'reverse' appears to perform the best among the five negative sampling methods.

5.2 Subjective Listening Test


We note that even if a model obtains the highest classification or ranking result, we still cannot guarantee that the model also works well in real-world applications. Accordingly, we deployed a user study by releasing an online questionnaire to get user feedback. As the users' time is

precious, it is not possible to test the result of all combinations of the models and negative sampling methods. Therefore, we considered the result of the objective evaluation and picked five methods for subjective evaluation:

- 'CNN + reverse', 'SNN + random,' and 'SNN + reverse,' three instances of the proposed methods that performed well in the objective evaluation;
- 'AutoMashUpper' [2], as it represents the state-of-the-art for the task. Our implementation is based on the open source code from `https://github.com/migperfer/AutoMashupper`. As the rhythmic compatibility part of [2] is missing in this repo, we implement it ourselves following [2].
