- 'Original,' which stands for the real loop combinations observed in FMA and extracted by the procedures described in Section 3.2. Specifically, an 'original' loop combination is one of the 100 positive loop pairs from the 'test set' listed in Table 1.

The loop combinations, or *test clips*, presented to users for evaluation are created as follows. As in Section 4.1.2, for each positive loop pair, we view one as the source loop, and the other as the target loop. Accordingly, we have 100 source loops and 100 target loops in the test set. A test clip is a combination of two loops. For the 'original' method, we pair the source loop with its true target. For the other methods, the 99 target loops (excluding the true target) are ranked, and the one predicted to match the source best is combined with it to form a test clip. The 5 resulting test clips for each source loop were considered as a *group*. This way, we have 100 groups in total. Among them, we picked 6 groups for evaluation: they have 2 vocal loops, 2 drum loops, and 2 loops of instrumental melody as the source loop, respectively.

We designed a subjective listening test that could be administered to users through an anonymous online questionnaire, and advertised it on social media websites related to EDM and Hip-Hop. A participant was randomly directed to a questionnaire containing one group of test clips, and was then asked to listen to the 5 test clips and rate each clip, on a 5-point Likert scale, in terms of: i) whether they sounded *matched*, ii) whether they were an *innova-*

Figure 4: The subjective evaluation results of comparing the preference, musical feature and musical element among 5 methods. A method is considered to show low abilities to manipulate loops if its MOS is under 3 in (A) 'using preference'-related and (C) 'musical elements'-related metrics, and under 2 in (B) 'musical feature'-related metrics.

tive combination, iii) and whether they were *usable* in future compositions (see Figure 4A). They were also asked to indicate whether the loops matched according to 3 musical features: rhythm, harmony, and timbre (see Figure 4B). Finally, to see how consistent the models are at recommending loops given different query types, Figure 4C breaks down the results for Matchness (Figure 4A(i)) according to source loop type: drum, vocal or melody loop.

5.2.1 Subjective Evaluation Result

Data from 116 Taiwanese participants were collected, and all of them were included for analysis. The participants self-reported the gender they identified with (36 female, 80 male) and age (19–33). 50% said they listened to loop-based music more than 5 days a week, 54% had classical musical training, and 42% had experience composing loop-based music. Overall, the responses indicated an acceptable level of reliability (Cronbach's $\alpha = 0.778$).

Figure 4 indicates the mean opinion score (MOS). A Wilcoxon signed-rank test was conducted to statistically evaluate the comparative ability of the 5 methods.

Overall, we observe that AutoMashUpper performs least well in almost all the evaluation metrics. Outside of the *Innovation* (Figure 4A) and *Drum* metrics (Figure 4C), AutoMashUpper is significantly worse than almost all the other methods. This suggests that, in loop selection, considering only loop similarity and spectral balance (as assumed by AutoMashUpper) is not enough—perceptually compatible loops are not necessarily similar in content.

On the other hand, we note that 'CNN with reverse negative sampling' performs the best in almost all of the evaluation metrics. To our surprise, the loop combinations picked by the CNN are preferred even to the original loop combinations extracted from FMA songs. The performance difference between 'CNN + reverse' and 'Original' is significant (p-value < 0.001) in terms of several metrics, including *Matchness* and *Usability*. In contrast, there is no significant performance difference between 'Original' and the two SNN models.

One finding was surprising: The MOS obtained by 'CNN + reverse' for *Matchness* is 4.0, higher even than the MOS of 3.15 obtained by 'Original.' I.e., the loop combinations proposed by the system were found to match better than the original combinations. We are not sure how to ac-

count for this success. One might conjecture that the quality of the 'Original' pair suffers from the imperfect loop extraction algorithm, but since all the loops were extracted the same way, they should be on equal footing. Alternatively, the novelty of the non-original mash-ups could be more interesting to the listeners than the originals; however, there was no clear difference among the systems in terms of 'Innovation.' We can only conjecture that 'CNN + reverse' found better loop combinations than human-made ones because the model-based method could examine all the possible loop combinations, while humans cannot.

We found that SSN methods, despite their performing better in ranking-based objective metrics than the CNN method, did not create perceptually-better loop combinations. This suggests a discrepancy between the objective and subjective metrics. And lastly, while it seems fair to say that CNNs outperform SNNs in the subjective evaluation, it is hard to say whether 'reverse' is the most effective negative sampling, because we were not able to evaluate all the possible methods here. This is left as a future work.

6. CONCLUSION AND FUTURE WORK

In this paper, we have proposed a data generation pipeline and several negative sampling strategies to address the need of ground-truth labels for building a machine learning model for estimating the compatibility of loops. We have also implemented and evaluated two different network architectures (CNN and SNN) to build such models. Our objective evaluation shows that a CNN does well in classifying incompatible loop pairs and an SNN is good at imitating how producers combined loops, and our subjective evaluation suggests the loop combinations created by a CNN are favored over those created by an SNN and even, in some aspects, real data from FMA. Both CNNs and SNNs outperform the rule-based system AutoMashUpper.

We have two plans in place for future work. First, as we see some inconsistency between the results of objective and subjective evaluations, we plan to investigate other objective metrics for performance evaluation. Second, we plan to exploit the loop layouts estimated by the loop extraction algorithm [5] to study further the relationship between loops and their arrangement, which may aid in the automatic creation of loop-based music.

ABSTRACT

In this paper, we describe a workflow of successive corrections on Optical Music Recognition (OMR) generated MusicXML files and their respective outputs under Music Information Retrieval (MIR) tasks. The original OMR-generated files of six Mendelssohn String Quartets were initially corrected by individual members of this interdisciplinary group, then reviewed by others to further standardize the quality and music analysis priorities of the team. Four MIR tasks are applied to each round of corrections on this collection: cadence detection, chord labeling, key finding, and monophonic pattern discovery. We measure changes in the outputs of these four MIR tasks from one round of corrections to the next in order to evaluate the impact of corrections. Results show that expert revision is more beneficial to some MIR tasks than to others. The resulting corpus of curated MusicXML files is available as an open-source repository under a Creative Commons Attribution 4.0 International License for further MIR research.

1. INTRODUCTION

Music Information Retrieval (MIR) algorithms that analyze symbolic music require high-quality data to produce accurate results. When building symbolic music corpora for MIR research, manually transcribing data using music notation software is expensive [1].

A faster option might be to use Optical Music Recognition (OMR) software on existing images of printed scores as an initial step. For example, Condit-Schultz et al. [2] worked on automated harmonic analysis of 571 chorales by Johann Sebastian Bach and Michael Praetorius. OMR was used in the process of creating symbolic encodings, with the results reviewed and manually corrected by a human annotator. Cumming et al. [3] created symbolic corpora of Renaissance music using OMR-generated scores as the first step and followed strict guidelines of manual corrections for the retention, addition, or removal of specific notations such as ties and fermatas. Although the performance of OMR applications has been improving over the years [4], extensive manual revisions are still required to ensure data quality and consistency for MIR analysis. This expensive and time-consuming task is especially relevant for OMR-induced errors since small ambiguities can lead to substantial variation in analytical output [5]. *What are the impacts of expert curation on data for MIR analysis tasks?*

We answer this question using files produced in the process of building a symbolic corpus of Mendelssohn string quarters. The OMR-generated passed through three iterations of increasingly-stringent manual corrections without additional annotations. We measured the impact of each round of corrections on four MIR analysis tasks (key finding, chord labeling, melodic pattern discovery, and cadence detection) through the changes between each iteration. Expert analysis of the scores exposes the types of errors to which these tasks are sensitive, demonstrating the need to tune corpus content to the anticipated analyses.

2. CORPUS CREATION

2.1 Mendelssohn String Quartets

Our corpus consists of the string quartets of Felix Mendelssohn. The Classical string quartet is a particularly relevant genre for computer-assisted analysis of music. In contrast to piano repertoire, where voice leading is often obscured by the limitations of the performer's hands and by what can be notated on the grand staff, a string quartet score preserves the independent parts of four separate instruments, allowing attribution of the role of each part (such as melody, bass, accompaniment, leading and imitative voices, etc.). The Classical aesthetic is characterized by a very clear harmonic, melodic, and formal organization, so it is not surprising that Beethoven's and Mozart's string quartets have already been encoded and annotated [6,7] for music analytical purposes. Mendelssohn's string quartets are a natural next step; his works have Classical characteristics that place them in the tradition of Beethoven's late quartets [8].

Specifically, we encoded quartets Op. 12, Op. 13, and Op. 44, Nos. i, ii, and iii, all composed between 1827 and 1847, and *Four Pieces for String Quartet*, Op. 81. [1] The initial OMR encodings of these 24 movements were generated from scans of the 1875 edition published by *Breitkopf und Härtel*, available as PDF files on IMSLP. [2]) Although not part of the set studied in this paper, an additional quartet, Op. 80, is incorporated in our final published corpus. It had been previously encoded in MusicXML [3] by user *Musemeister*.

2.2 The CTS Team

An interdisciplinary team of nine people collaborated to create this corpus, with members from music technology, music theory, string performance, and music cognition. Each member brought unique viewpoints, skillsets, and objectives to the project. Whether they were interested in a specific MIR task or the applications of MIR to music theory, cognition, or pedagogy, team members refined encoding objectives together to satisfy their varied interests during the iterative correction and cleaning of OMR-generated symbolic music files.

2.3 From PDF to MusicXML

The first step in building the corpus was to transcribe the PDF files into a symbolic, machine-readable format. We used the commercial OMR software PhotoScore to analyze the original score images in PDF. It first detected the position of each staff on the page and we ensured that these detected positions were correct, adjusting as necessary. We also manually corrected the key and time signatures. The OMR results were then exported to MusicXML because the format is widely supported by music notation software. These files formed the Corrections 0 dataset "C0",

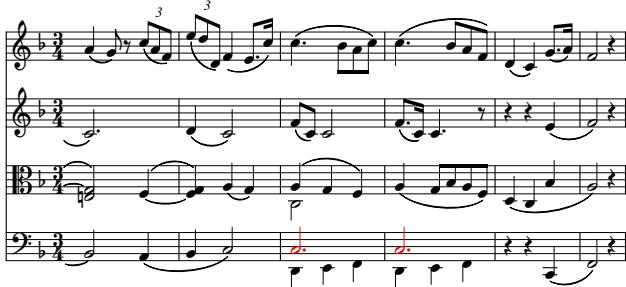
---


Figure 1. Measures 60-62 of Op. 44, No. iii, Mvt. 4. The upper system is initial OMR output (C0) and the lower system is after three rounds of manual corrections (C3).

with no additional manual corrections of score information. All subsequent corrections were made using MuseScore v2.3.2.

2.4 OMR Corrections

Starting from these initial OMR-generated music files (C0) we applied three successive stages of manual corrections: "C1", "C2", and "C3". The goal of each stage was to improve the accuracy of the previous stage(s) and to ensure that all information necessary for the MIR algorithms was included. The original C0 files included score elements both unlikely to be used by existing symbolic MIR algorithms and deemed by the team's music theorists to be less essential for the specific analytical approaches that we chose. Many of these score elements—for example, hairpin dynamics—were ignored or removed during the rounds of corrections (for a full list, refer to the supplementary materials).

The focus of C1 was accuracy of pitch and rhythm, while elements such as dynamic markings and articulations were largely ignored in the interest of time. As work progressed, it became clear which errors were most common in the OMR output. For example, there were many misaligned or missing notes in passages with higher note density (see Figure 1). The OMR software frequently encoded ties as slurs and *vice versa*. Despite their visual similarity, these curved lines produce different rhythmic values of notes, with consequences for our MIR analysis algorithms. Mendelssohn's scores also included many detailed performance instructions, prompting lengthy discussions about what information should be preserved in the final dataset

---

Figure 2. Measures 14-19 of Op. 13, Mvt. 2.

and what should be left out. With a more rigorous protocol in place, we reviewed each other's work to produce C2. The main purpose of this phase of review was to ensure that no errors had been missed in the previous round of revision. Again, during C2, details of the score came to light that necessitated further discussion, and the varied perspectives of the multidisciplinary team informed decisions about how to proceed. For example, double-stops, where more than one string is played at once, posed a recurring challenge. While chords on a staff line can be encoded in most analysis systems, Mendelssohn wrote many passages with moving lines against held notes (see Figure 2). This texture is easily misinterpreted by algorithms unfamiliar with the particularities of string music. Ultimately, note accuracy and articulation of onsets (namely, ties, slurs, and staccatos) were prioritized, while most indications of dynamics and ornamentation were excluded: a trade-off between comprehensiveness and machine interpretability.

Finally, the last round of corrections (C3) was a review to align all the encodings according to the conclusions of discussions during C2 and to standardize formatting and metadata. A full account of the score elements preserved in the final dataset is included in the supplementary materials. For consistency, a single person reviewed all the movements in preparing C3. Further discussion is provided in Section 4.1.

2.5 Differences between Correction Rounds

Besides a qualitative report on the amount of corrections we made in each round, quantitative measurement of the scale of changes is possible on these digital files. As the ideal MusicXML tool [9] is not publicly available with open source code, we used the more generic `SequenceMatcher.quick_ratio()` from Python's `difflib` library to produce percent differences. The median and range of similarity scores between C0 and C1, C1 and C2, and C2 and C3 are shown in Table 1.

Interpreting these numbers directly is difficult as MusicXML files include a plethora of elements beyond the focus of our corrections. Still, it is reassuring to see the median difference between successive corrections decrease by an order of magnitude each round. If all file modifications had the same impact on the MIR analyses, their outputs would show a similar pattern of decreasing impact.

Comparison Pair	Percent Difference median [min, max]
C0 to C1	10.0% [2.8%, 21.8%]
C1 to C2	1.3% [0.0%, 7.3%]
C2 to C3	0.2% [0%, 1.3%]

Table 1. Percent difference for each comparison pair. The results are medians across all 24 movements, with maximum and minimum values indicated in brackets.

3. MIR ALGORITHMS

Four symbolic MIR algorithms were applied to each version of the Mendelssohn String Quartet Corpus. These algorithms were chosen because they were either designed or extensively used by members of the CTS team. Without ground truth annotations to assess the *accuracy* achieved by each MIR tasks, the corrections were evaluated through their *perceivability* to the algorithms in output *changes* between successive versions. [4] For two of the tasks that produce sequences of annotations, results from different versions of the same movement had to be aligned to one another before comparison; this procedure is detailed in the supplementary materials. In total, 96 evaluations per task were performed as each analysis algorithm was applied to all four versions of the 24 movements in the corpus.

3.1 Key Analysis

A recent key-finding algorithm [10] provided two predictions: global key per movement and local key per onset slice. We ran the algorithm using the default parameters provided in the implementation. Between C0 and C1, predictions of global key changed in 3 of the 24 files tested. There was no change in prediction between C1, C2, and C3. Predictions of local key changed substantially between C0 and C1 across all files, and changed much less between C1 and C2, and between C2 and C3, as shown in Table 2.

Comparison pair	Changes in local key annotations median(%) [min(%), max(%)]
C0 to C1	46.8% [9.9%, 71.1%]
C1 to C2	0.4% [0.0%, 9.8%]
C2 to C3	0.0% [0.0%, 3.0%]

Table 2. Percent differences in local key annotations for each comparison pair. The results are medians across all the 24 movements with minimum and maximum values indicated in brackets.

3.2 Chord Labeling

The automatic chord labeling model [11] was applied to each stage of the dataset, predicting chords for every onset slice of the piece.

---

[4] E.g. comparing the outputs of a key-finding algorithm applied to C0 and C1.

Comparison Pair	Changes in chord labels median(%) [min(%), max(%)]
C0 to C1	69.1% [17.5%, 96.7%]
C1 to C2	0.7% [0.0%, 41.1%]
C2 to C3	0.0% [0.0%, 12.5%]

Table 3. Percent difference in chord annotations for each comparison pair, shown as medians across all the 24 movements with minimum and maximum values indicated in brackets.

Each chord is labelled according to its root (C, F♯, B♭, etc.) and its quality (major, minor, fully diminished seventh, dominant seventh, etc.), with no mention of its inversion or its harmonic function (Roman numeral analysis).

The results are shown in (Table 3). We can see differences between C0 and C1 were substantial (median 69.1%), while the percent change between C1 and C2 was much smaller (median 0.7%). The majority of the movements showed no change in chord labels between C2 and C3 (median 0.0%). Such results indicate that chord labelling is not sensitive to local differences.

3.3 Monophonic Pattern Discovery

The SIARCT-C Algorithm [12] was used on each version of each movement to discover sets of repeating patterns. A "pattern" here refers to a set of excerpts of a piece that are all nearly identical in pitch and rhythm under transposition. While the algorithm is capable of operating on polyphonic music, here we focus on finding monophonic patterns between voices. To this end, each MusicXML file was transformed into point sets of (onset time in quarter notes, morphetic pitch) pairs; for example, the first measure of the first violin's part in Figure 1 is notated as the sequence `(69, 0) (69, 1) (71, 2) (71, 2.75)`. Dynamics, articulatons, and durations are discarded. Some algorithmic pattern discovery methods do use this kind of information, such as the Automatic Time-span Tree Analyzer [13], but the majority use only rhythmic and pitch-related data, partially due to the computational complexity of the problem. The four voices in each file were concatenated into one sequence for the purpose of evaluation.

We searched only for patterns that were at least eight notes long that occurred at least five times within each movement, allowing for a small amount of variation. These parameters were chosen as a compromise in light of the number of movements we had to analyze and the running time of the algorithm; searches for short patterns take significantly longer than searches for long patterns. We illustrate the effect of iterative corrections by their impact on descriptive statistics of these results: the number of unique patterns detected, the coverage of these patterns over all notes in the music, and the median cardinality (i.e., number of instances) of each pattern discovered. [5]

Table 4 shows how these statistics change between versions. Many more patterns were found in C1 than in C0 (median 85%, maximum 2100%), with a small amount of gain and loss from C1 and C2, and no change in total from C2 to C3. Coverage also grew substantially from C0 to C1, including more than twice the number of notes after this first round of corrections for more than half the movements. In contrast, the median cardinality did not change as drastically for those patterns detected in these different versions, and no apparent changes occurred during the last round of corrections.

Comp. Pair	Magnitude Increase, median [min, max] (%)		
	Num. Patterns	Coverage	Cardinality
C0 to C1	85% [16%, 2100%]	110% [21%, 1100%]	8.3% [-22%, 29%]
C1 to C2	0.0% [-5.1%, 7.1%]	0.041% [0.85%, 9.8%]	0.0% [-3.4%, 3.5%]
C2 to C3	0.0% [0.0%, 0.0%]	0.0% [0.0%, 0.0%]	0.0% [0.0%, 0.0%]

Table 4. Median magnitude increase in three statistics taken on the sets of discovered patterns over the course of the corrections. Minimal and maximal values for change are shown in brackets.

Comparison pair	Change in PACs detected	New PACs detected	PACs lost
C0 to C1	154.5% 22 to 56	177.3% 39	22.7% 5
C1 to C2	-3.6% 56 to 54	1.8% 1	5.4% 3
C2 to C3	1.9% 54 to 55	3.7% 2	1.9% 1

Table 5. Change in the number of PACs detected. 'New PACs detected' report the number of PACs detected in the latter that were not in the former. 'Lost PACs' is the number of PACs that were in the former but not the latter. As the number of PACs detected is quite small, both relative changes and exact numbers are given.

3.4 Cadence Detection

Finally, the cadence detection algorithm introduced by Bigo et al. [14] was used to detect perfect authentic cadences (PACs) [6] throughout the corpus. Each beat was evaluated as a potential point of cadential arrival using a Support Vector Machine. As there are only few cadences within single movements, Table 5 reports the results of

---

[5] Comparing sets of discovered patterns is difficult because of their highly heterogeneous structure, with individual patterns spanning a wide

range of cardinalities and number of notes per instance. While it is possible to devise a more direct evaluation based on similarities between individual patterns, we used an approach based on descriptive statistics for the sake of brevity and interpretability.

[6] Too few cadences of other types, such as half cadences, were successfully detected to interpret sensibly in this context.

this evaluation as a count of cadences detected rather than percent change. As expected, the model benefited greatly from the initial round of corrections: twice as many cadences were identified in C1 files as in C0 files. Additional rounds of reviews had little impact on the total number of PACs detected. Close investigation of the differences between detected cadences in C1, C2 and C3 revealed that some changes in the algorithm's output were due to corrections in notated pitch.

4. DISCUSSION

The different rounds of corrections prompted a wide range of considerations for the group, which are discussed below. Proofreaders with different kinds of expertise, whether in MIR, music theory, string musicianship, or the use of the chosen music notation software, communicated various concerns and discoveries relating to their respective tasks. Finally, special situations are discussed, in which music theoretical and analytical considerations collide with MIR objectives in notable ways.

4.1 MIR Significance of Correction Rounds

Using OMR to create datasets of symbolic music is an attractive proposition. Our results suggest that there is significant variation in the quality of the output between files when using software like PhotoScore. No task evaluated here was able to totally overcome the errors introduced by OMR, with all of the results seeing some amount of change after the first round of corrections, and the degree of change in this initial round varied widely between tasks. Global key estimations changed for only 3 of the 24 movements, while the discovered patterns on the raw OMR output bear little resemblance to those discovered after just one round of corrections. However, these findings cannot be extrapolated directly to other algorithms that perform the same tasks; different machine-learning methods may cause models to become more sensitive to some errors and less sensitive to others. For the specific algorithms applied here, we may consider this as evidence that the underlying symbolic-musical structures they use to make judgments are affected by errors in the OMR process to different magnitudes. For most tasks, though, initial correction is necessary when using OMR to create datasets, given the current capabilities of commercially-available OMR software.

For subsequent rounds of corrections, the sizes of changes shrink dramatically but still vary between tasks. In particular, the discovered patterns barely change at all after the first round of corrections; this is likely due to the fact that the algorithm uses only onset times and morphetic pitch, thus ignoring some pitch changes with harmonic consequences.

4.2 Experience of Doing Corrections

For the members of our team with solid experience in copying music, correcting OMR required an average time of 30 to 45 minutes per printed page depending on the variety and amount of errors. To review Mendelssohn's complete string quartets (C0 to C1) thus took approximately 75 to 110 hours. Even though the standardization step (C1 to C2) in itself was much shorter (5 to 15 minutes per printed page, or an approximate total of 25 hours), discussions concerning what should be kept and what should be ignored lasted over a month. Finally, checking the consistency represented 30 additional hours (C2 to C3). While the dataset at C3 was standardized to meet the requirements of our analysis tasks, one might wonder whether investing this amount of time was necessary.

Different movements, and different passages within individual movements, required vastly different degrees of effort to correct. In some sections, only corrections to articulations and accidentals were needed, whereas other sections needed to be completely rewritten. The first round of corrections (C0 to C1) was the most difficult, involving many decisions about which elements of the score to preserve. Some time-consuming corrections had to be rolled back after standardization protocols had been decided on. This round of corrections was particularly difficult for proofreaders who had never used MuseScore. Certain features of the program, such as the addition of key signatures, introduced multiple additional errors when used incorrectly, while some features that might have saved time, such as batch addition of articulation marks, went unused through much of the correction process. There were a few musical situations that tended to produce predictable errors in the OMR encoding. Errors frequently arose when the OMR software missed or misplaced rests, and proofreaders quickly learned that passages with higher note density required much more effort to correct.

4.3 Musical Considerations

Figure 1 gives a general sense of the differences between the initial (C0) and final (C3) stages of the correction process. These differences fall into two broad categories: "pitch-rhythm" differences in the vertical (pitch) or horizontal (rhythm) placement of notes and "notational" differences in articulations, ornaments, and other non-pitch elements of the score. Pitch-rhythm differences had a large effect on the outcomes of analysis tasks. Pitches that were incorrect (Vla., m. 61), misaligned (Vln. 1, m. 62), missing (Vla., m. 62), or extraneous (Vln. 2, m. 61; Vc., m. 60) affected all four analysis tasks. Notational differences in tremolos (Vln. 2 & Vla., mm. 60-62), and slurs (Vln. 1, m. 60) had a smaller effect on the outcomes of analysis tasks, but could be disruptive in MIR tasks that make use of recurring notational cues, especially for pattern finding or cadence detection. For example, Mendelssohn often uses slurs, staccatos, and dynamic markings such as hairpins to highlight recurring motives. When these motives are transposed or altered non-uniformly, as in the tonal answer of a fugue or the development section of a sonata-form movement, they may become undetectable by pattern-finding algorithms that rely exclusively on pitch and rhythm. An analyst relying on these results may be led to misinterpret larger tonal, hypermetric, and formal structures if, for example, the algorithm fails to detect a main theme at the

beginning of a returning section. Algorithms that also consider articulations and dynamic markings might perform better in situations like these. One other complication is that PhotoScore sometimes generates hidden rests (Vla. m. 61), slowing the correction process by making the score less readable to humans.

Extraneous or incorrect clefs were found in four of 24 movements during the final round of corrections (C3). In the fourth movement of Op. 44 No. iii, an incorrect (French violin) clef in the first violin transposed the part up by a major third. This error persisted through several rounds of correction because it was obscured by system breaks. Incorrect clefs had a large effect on key-finding, chord-labeling, and cadence-detection tasks, but not on the transposition-invariant pattern discovery task.

Another recurring issue concerns multiple voices within a single staff (i.e., "double-stops" on a string instrument). While this is possible to encode in MusicXML format, it is often unreadable to the software used for analysis tasks. In these cases, the encoder must decide which voice to keep and which to discard, which can result in the loss of information. In Op. 13, Mvt. 2, mm. 16-17 (see Figure 2), the cello plays both a held C (in red) along with a moving line D-E-F. Without the moving line, the C becomes a pedal at the bottom of the texture, changing the harmonic and cadential sense of the music. In Op. 13, Mvt. 3, mm. 143-53, the cello and violin II have melodic lines below a harmonic pedal resulting in two-note chords for each of them. Choosing one voice or the other is difficult: keeping the pedal tones preserves the harmony, allowing for the detection of cadences and chords; keeping the melodic motives allows for the discovery of more patterns throughout the movement. Deciding what to keep depends on the type of analysis to be carried out.

4.4 Implications for OMR

The initial errors in OMR files disproportionately impacted these tasks: a 10% change in the MusicXML files produced a 47% change in local key judgments and a 69% change in chord labels. This proportion of incorrect results underlines how this commercial software struggled with these scores. One cause was missing notes: runs of sixteenths and eighths typical of this genre of music were often dropped, when the dense or complicated stemmings were incorrectly interpreted. The numerous articulation and ornamentation markings were often misinterpreted as notes, suggesting poor recognition of shapes within staves. There was also confusion between parts in the four staff systems, with notes and text annotations packed more tightly in vertical arrangements than in other genres and publication styles. Software tuned to this era and style of work would hopefully reduce the amount of information lost. However, given the variety in performance quality across these scores, human supervision is highly recommended.

5. CONCLUSION

This project is a case study in how human corrections on OMR can influence MIR analysis results. The range of outcomes across these analyses suggests that the value of human correction time depends on the MIR task. If some noise in the results is permissible and one is only interested in large-scale qualities like global key, the raw OMR files may suffice, but anything closer to the notes would benefit from some review and correction. Without human intervention, half of the outputs for local key detection and chord labeling were corrupted, while monophonic pattern discovery and cadence detection missed substantial portions of the relevant material in most pieces.

The second and third rounds of corrections had progressively smaller effects on the aggregate results of these analyses, as expected, but there are instances when these smaller changes were crucial for the type of analysis at hand. Passing the symbolic music files between multiple reviewers minimized the impact of human error. Some of the changes in these later rounds were motivated by new understanding of the music, music encoding limitations, and what could be used by our MIR algorithms.

This project is not representative of all symbolic music corpus-building with OMR. PhotoScore was not necessarily the best OMR processor for string quartet music printed in 1875. The sensitivity of these MIR analysis tasks on changes in symbolic music information is also specific to their implementations; a study of monophonic patterns that included articulation or dynamics would tell a different story from that above. However, the novel comparison process across iterations of corrections highlights the importance of expert musical care in the developing of symbolic music corpora, as well as the need for explicit acknowledgement of the types of score information preserved therein.

Discussions between team members about the potential relevance of ornamentation and articulation to each analytical objective resulted in a set of files that contained more information than could be used by the algorithms applied here. At the same time, important layers like dynamics were removed because of the difficulty of producing machine-interpretable encodings. We hope to see that the retained layers of performance information are used in future work with this collection of symbolic scores, and that symbolic music encoding and analysis tools continue to progress towards capturing a richer range of musical information. The final version of this Mendelssohn String Quartet Corpus, a pedagogical, scholarly, and artistic resource for musicians, composers, and music researchers alike, can be downloaded from: `https://github.com/DDMAL/felix_quartets_got_annotated`.

While OMR can be a helpful tool for corpus building, such projects still require human expertise in both the music represented and in its intended uses. For MIR-related research, some tasks benefit from manual review more than others.

ABSTRACT

Deep representation learning offers a powerful paradigm for mapping input data onto an organized embedding space and is useful for many music information retrieval tasks. Two central methods for representation learning include deep metric learning and classification, both having the same goal of learning a representation that can generalize well across tasks. Along with generalization, the emerging concept of disentangled representations is also of great interest, where multiple semantic concepts (e.g., genre, mood, instrumentation) are learned jointly but remain separable in the learned representation space. In this paper we present a single representation learning framework that elucidates the relationship between metric learning, classification, and disentanglement in a holistic manner. For this, we (1) outline past work on the relationship between metric learning and classification, (2) extend this relationship to multi-label data by exploring three different learning approaches and their disentangled versions, and (3) evaluate all models on four tasks (training time, similarity retrieval, auto-tagging, and triplet prediction). We find that classification-based models are generally advantageous for training time, similarity retrieval, and auto-tagging, while deep metric learning exhibits better performance for triplet-prediction. Finally, we show that our proposed approach yields state-of-the-art results for music auto-tagging.

1. INTRODUCTION

Learning a good representation, or embedding space, is a key goal in deep learning and is central to music classification and retrieval tasks. An important quality of a good representation is its generalization capability, i.e., its applicability to a diverse set of downstream tasks, including those relying on small datasets in a transfer learning setting [1–3]. While numerous representation learning methods have been explored to date, two learning

Figure 1. A disentangled music representation space. The green dot depicts a query song, the black dots depict retrieval songs, the red and yellow dots depict centroids of musical concepts, the gray arrows depict multidimensional axis, and the blue arrows depict retrieval methods.

paradigms are particularly common: deep metric learning and classification-based representation learning. The former is based on deriving similarity scores (or distances) between examples, while the latter is achieved via a cross-entropy loss over similarity scores between example and class centroids.

While both paradigms share the goal of learning a generalizable representation, the results from each approach are generally different. For example, a learned representation optimized via a classification task may perform poorly on a similarity-search task, and vice versa. While recent studies have elucidated the theoretical relationships between these paradigms and validated them through experimental findings [4], these developments have not been explored in the music domain. Furthermore, the relationship has not been explored for multi-label data, which is central to many music information retrieval tasks.

Beyond seeking a representation that generalizes across tasks, the emerging concept of disentangled representations [5,6] is of great interest for music applications. Music is often labeled with multiple semantic dimensions simultaneously (e.g., genre, mood, and instrumentation) and learning a representation that can capture this structure is advantageous. We often need to search for music that is similar along a particular semantic dimension in one ap-

plication (e.g., a music playlist with lighthearted mood), while requiring music similar along a different semantic dimension for another application (e.g., era for musicological analysis). Disentangled representations allow us to address both problems with a single model, and were recently proposed for audio-based music similarity search [7]. However, this study only explored disentanglement via a single deep metric learning approach, and the applicability and performance of more recent metric- and classification-based learning methods is yet to be explored.

In this paper, we present a unified representation learning framework that elucidates the relationship between metric learning, classification, and disentanglement. First, we outline past work on the relationship between metric learning and classification. We then extend this relationship to multi-label and multi-concept data (common to music applications) by exploring three different learning approaches and their disentangled versions – two of which are novel to this work. Finally, we evaluate all models against four tasks (training time, similarity retrieval, autotagging, and triplet prediction) and compare various aspects of the learned representations.

2. RELATED WORK

2.1 Metric Learning and Classification

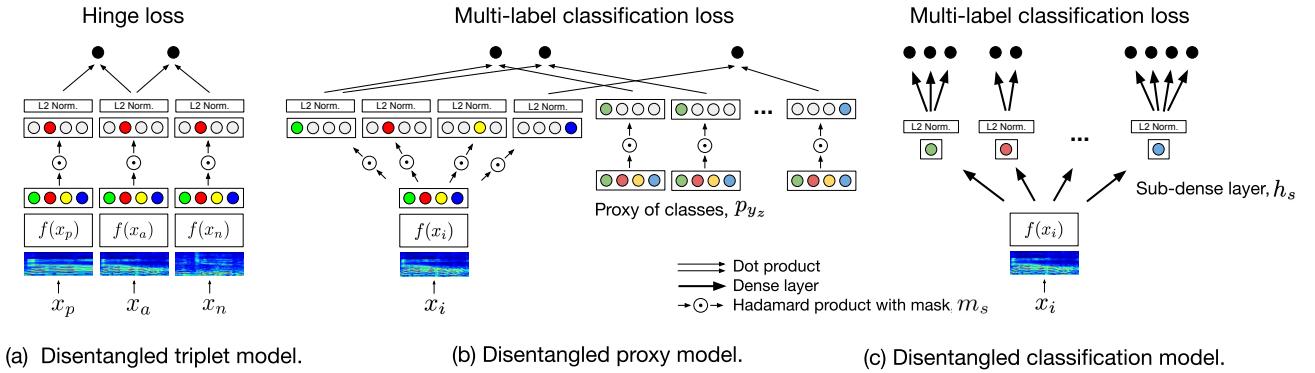
The goal of distance metric learning is to obtain an embedding space where similar items are close together and dissimilar items are far apart. A common strategy is to use pairwise [8, 9] or triplet-based samples to train a model [10–13]. An important advantage of deep metric learning is that it can efficiently model an extremely large number of classes (e.g., for face recognition) [12]. However, training models using this strategy are relatively slow as models operate on triplets of input samples [14]. Recently, more efficient sampling techniques have been proposed to speed up convergence, including hard negative mining, semi-hard negative mining [12], distance weighted sampling [15], and proxy-based training [14]. Proxy-based training [14] assigns one or several proxies to each class (given by per-class embedding centroids) and optimizes the learned space by comparing embedded input samples to proxies instead of directly comparing them to positive and negative samples. This reduces training time significantly while improving retrieval performance on images.

Classification models, on the other hand, are typically trained such that classes are linearly separable in the embedding space of the last hidden layer of the deep neural network. Since classification models are not optimized based on distances in the learned embedding space, they may not perform well when directly used for similarity-based retrieval. To overcome this, recent work proposed the application of a normalization layer over the embedding space during training, and showed that this simple technique increases model performance on similarity-based image retrieval [4].

Recent and parallel advances in both paradigms (metric- and classification-based learning) have shown that there is an inherent link between them [4, 16, 17]. The per-class embedding centroids used in proxy-based training are, in fact, equivalent to the per-class vectors obtained from the linear transformation in the last hidden layer of a classification model [16]. Further, a recent comparative study demonstrated that the loss function of a triplet-based model is equivalent to that of a classification model up to a smoothing factor for single-label, multi-class data [16]. These findings suggest that deep metric- and classification-based learning are not as different as initially thought and we could, potentially, use either to learn a representation that generalizes well to both similarity-based retrieval and classification tasks.

2.2 Disentangled Representation Learning

Another important measure of representation learning is *disentanglement* [18]. Recently, Lee et al. adapted Conditional Similarity Networks (CSN) applied to triplet-based deep metric learning to the music domain [7, 19]. The main idea in CSN is to apply a masking function over the embedding space, where each mask corresponds to a different semantic dimension of similarity corresponding to musical notions such as genre, mood, instrument and tempo. They showed that the disentangled music representation not only enables multidimensional music search via its sub-dimensions, but also improves general music retrieval performance when all embedding dimensions are used. However, CSN for disentangled music representation learning was only explored using a deep metric learning strategy, and classification-based approaches were not studied. Considering the close relationship between the two, we propose to study disentanglement under classification, particularly for multi-labeled music data, and compare and contrast it to disentanglement via metric learning.

3. DISENTANGLED LEARNING MODELS


In this section, we introduce three disentangled learning methods, which are triplet-based, proxy-based, and classification-based models. The first model was previously developed [7], and the latter two are novel contributions. The overall architectures are illustrated in Figure 2. In the following descriptions, x denotes a data point, $f(\cdot)$ a nonlinear embedding function, y a multi-hot class label, and s a category (or a similarity notion such as mood, genre or instrumentation) of y. For example, if y_z is *rock*, then s_{y_z} is *genre*.

3.1 Triplet-based Model

Disentangled triplet-based models were recently proposed in [7, 19]. We first define a triplet as $t = (x_a, x_p, x_n; y_z)$, where x_a is the anchor sample, x_p is the positive sample, and x_n is the negative sample. x_a and x_p are sampled to have the same positive label y_z, while x_n is negative for y_z. Then, the basic triplet loss is defined as

$$L(t) = \max\{0, D(f(x_a), f(x_n)) - D(f(x_a), f(x_p)) + \Delta\},$$
$$(1)$$

where $D(f(x_i), f(x_j)) = cos(f(x_i), f(x_j))$ is a distance metric, and Δ is a margin value [11]. To disentangle the

Figure 2. A unified framework for disentangled triplet- and proxy-based metric learning and multi-label classification.

embedding feature of size d, a masking function $m_s \in \mathbb{R}^d$ is applied. The number of masks corresponds to the number of similarity notions s and each mask occupies certain dimensions of the $\mathbb{R}^d$ space evenly as illustrated in Figure 2 (a). Thus, when the $t = (x_a, x_p, x_n; y_z)$ is used, a mask for the similarity notion s_{y_z} is applied to the embedding feature space. The loss for training the model is given by:

$$L(t) = \max\{0, D(f(x_a) \circ m_s, f(x_n) \circ m_s) \\ - D(f(x_a) \circ m_s, f(x_p) \circ m_s) + \Delta\}, \quad (2)$$

where $\circ$ denotes the Hadamard product.

3.2 Proxy-based Model

The core idea of proxy-based metric learning is that proxy embeddings are learned and assigned to each class and used to measure the distance to an anchor data point instead of directly measuring distances to pairs or triplet data samples [14]. This can be interpreted as a supervised clustering algorithm, where proxies play a role of class centroids. In this approach, the distance metric becomes

$$D(f(x_i), p_{y_z}) = cos(f(x_i), p_{y_z}) = \frac{f(x_i)}{||f(x_i)||} \cdot \frac{p_{y_z}}{||p_{y_z}||}, \quad (3)$$

where x_i is a data point, p_{y_z} is a proxy for class y_z, and $\cdot$ is the dot product. If the data is single-labeled (multiclass), one can apply triplet loss, Neighborhood Component Analysis (NCA) loss [20], or Softmax loss over the above distance metric [14, 16], but with our multi-labeled data, it is not directly applicable. To address this, we replace these losses with a multi-label classification loss, i.e., binary cross entropy. The prediction score for each class becomes

$$\hat{y_z} = sigmoid(D(f(x_i), p_{y_z})), \quad (4)$$

and the loss is

$$L(x_i) = \sum_z [-y_z log(\hat{y_z}) - (1 - y_z) log(1 - \hat{y_z})]. \quad (5)$$

However, from our preliminary experiments, we found that the sigmoid function with cosine similarity score causes numerical problem in optimization. We speculate that the reason for this is that the cosine similarity score (bounded between -1 to +1) only activates the linear regions of the

downstream sigmoid activation, reducing model capacity. [1] Therefore, we modify the distance metric to be

$$D(f(x_i), p_{y_z}) = \frac{f(x_i)}{||f(x_i)||} \cdot p_{y_z}, \quad (6)$$

to ensure that both the learned embedding space is normalized and the sigmoid activations can have nonlinear properties.

From this basic multi-label proxy-based model, we expand the model by applying the masking function as used in the disentangled triplet-based model. Then, the prediction score for each class is updated to

$$\hat{y_z} = sigmoid(D(f(x_i) \circ m_s, p_{y_z} \circ m_s)), \quad (7)$$

as illustrated in Figure 2 (b).

3.3 Classification-based Model

Classification-based metric learning has recently been explored [4, 16]. The core idea is to apply a normalization layer on the embedding feature space. This simple technique ensures that the learned representation has unit length and makes similarity-based retrieval more effective compared to the vanilla classification model. Therefore, the prediction score of classification-based metric learning model for each class is

$$\hat{y_z} = sigmoid(\frac{f(x_i)}{||f(x_i)||} \cdot c_{y_z}), \quad (8)$$

where c_{y_z} is a centroid for each class (parameters of the last hidden layer). [2] At this stage, we observe that the distance metric inside the sigmoid function of Equation 8 is equivalent to that of our modified distance metric in Equation 6 of the proxy-based model.

As for triplet-based metric learning, we extend classification-based metric learning to learn a disentangled embedding space. We begin from the disentangled distance metric, which is

---

[1] In proxy-triplet loss, this type of numerical problem does not occur because they are relative comparison based losses. In proxy-NCA or proxy-Softmax loss, some of the previous works encountered similar problem, and solved the problem by applying a smoothing factor over the similarity score [4, 16, 21]. We also tested applying a smoothing factor, but for our multi-label classification problem, it turns out that the proposed modified distance metric is more effective.

[2] In our preliminary experiments, we found that removing the bias term does not decrease the model performance, so we did not include it in the Equation 8.

$$D(f(x_i) \circ m_s, c_{y_z} \circ m_s) = \frac{f(x_i) \circ m_s}{||f(x_i) \circ m_s||} \cdot (c_{y_z} \circ m_s)$$
$$= \frac{1}{||f(x_i) \circ m_s||} \cdot (f(x_i) \circ m_s) \cdot (m_s \circ c_{y_z}). \quad (9)$$

From the above equation, if we split $f(x_i)$ into the nonlinear function $f_{n-1}(x_i)$ and the embedding feature layer h (here, h layer includes nonlinear activation), then the equation becomes

$$= \frac{1}{||f(x_i) \circ m_s||} \cdot (f_{n-1}(x_i) \cdot h \circ m_s) \cdot (m_s \circ c_{y_z})$$
$$= \frac{1}{||f(x_i) \circ m_s||} \cdot f_{n-1}(x_i) \cdot h \circ m_s \cdot m_s \circ c_{y_z}. \quad (10)$$

In this equation, $(h \circ m_s \cdot m_s \circ)$ is actually a sub-dense layer that has the same dimensionality as the disjoint mask m_s, which is applied when $y_z \in s$. Henceforth, we denote the sub-dense layer h_s. Now, $||f(x_i) \circ m_s||$ can be replaced to $||f_{n-1}(x_i) \cdot h_s||$. Finally, the disentangled distance metric becomes

$$= \frac{1}{||f_{n-1}(x_i) \cdot h_s||} \cdot (f_{n-1}(x_i) \cdot h_s) \cdot c_{y_z}. \quad (11)$$

This is the same formula for multi-task learning in the multi-label classification problem formulation, surprisingly, proving a previously unknown link between the two concepts. We illustrate this disentangled classification-based model in Figure 2 (c). Through experimental evaluation, we further verify that this multi-task learning-based classification model is equivalent to the disentangled proxy-based model while being much simpler to implement and benchmark.

4. EXPERIMENTS

4.1 Dataset and Input Features

For our experiments, we use the Million Song Dataset (MSD) [22] and Last.FM tag annotations associated with MSD tracks, which have been previously grouped into different categories [23], resulting in 28 genre tags, 12 mood tags, 5 instrument tags, and 5 era tags. We treat each category as a similarity notion s. We use these tags for evaluating similarity-based retrieval, auto-tagging, and triplet prediction tasks. The data are split into 201680, 11774, and 28435 samples for the train, validation, and test sets, respectively, following a previous auto-tagging benchmark [24]. For triplet prediction evaluation, we follow the same procedure as in [7], albeit switch one similarity notion (era replaces tempo) to match auto-tagging benchmarks. We sample 40,000 triplets per each similarity notion (genre, mood, instruments, era, track) and use a cleaned version of the *dim-sim* dataset to evaluate the models on human-annotated triplets.

The input to the embedding function $f(\cdot)$ is 3-second excerpts represented as a log-scaled mel-spectrogram S, extracted with librosa [25]. We use a window size of 23 ms with 50% overlap and 128 mel-bands, resulting in input dimensions of 129×128 as in [7]. The input features

are z-scored standardized using fixed mean and standard deviation values of 0.2 and 0.25, respectively.

4.2 Backbone Model and Training Parameters

For the embedding function or backbone model $f(\cdot)$, we use the same architecture as described in [7], which is an Inception-based model [26]. The model is comprised of a convolution layer with 5×5 sized 64 filters followed by 2×2 strided max-pooling, followed by six Inception blocks. Each Inception block consist of two Inception modules, a *naïve* module and *dimension reduction* module, which are applied in sequence. Both of the modules include filters of mixed size, but the *naïve* module has 2×2 strides in the last convolution layers of the module, so that the spatial feature map is reduced, and the *dimension reduction* module has a fixed number of filters in the last convolution layers of the module, so that the feature map is fixed to 256 in the intermediate layers. At the end, one fully connected layer with 256 units is added, except for the disentangled (multi-task learning) classification-based model, which uses sub-dense layers instead of a single fully connected layer. We use ReLU nonlinearities for all layers.

Since our embedding dimensionality is 256 and we consider four music similarity notions (genre, mood, instruments, era), each has a disjoint subspace of size 64. For the disentangled (multi-task learning) classification-based model, the sub-dense layers are also 64 units each. We use the Adam optimizer [27] for training. We initialize the learning rate to 0.005 and reduce it by a factor of 5 when the validation loss does not decrease for 10 epochs, up to 5 times, after which we apply early stopping. The margin for the triplet-based models is set to 0.1.

4.3 Evaluation Tasks

Our learned representations can be utilized for many applications, so there are many aspects to consider when evaluating representation learning models. Therefore, as a unified evaluation framework, we evaluate the models on four tasks: training time, similarity-based retrieval, auto-tagging, and triplet prediction.

4.3.1 Training Time

We first measure the overall training time to see the efficiency of the representation learning model. The training time is calculated as the total number of epochs multiplied by the time consumption of 1 epoch. Then, we report the value as a ratio to the shortest training time.

4.3.2 Similarity-based Retrieval

For the similarity-based retrieval evaluation, we use the recall@K (R@K) metric to measure retrieval quality following the standard evaluation setting in image retrieval [4, 14–16, 30]. This metric is useful for evaluating a search system because it measures the quality of the top K retrieved results, which are more important than long-tail retrieved results. The definition of the standard recall@K that is used for single-label problems is as follows. A query song is used to search a test set of recordings and retrieve

Models	Normalization	Disentanglement	Training time ratio	Similarity-based retrieval				Auto-tagging AUC
				R@1	R@2	R@4	R@8	
Triplet	✓	✗	1.87	31.8	45.2	59.9	73.0	0.815
Triplet	✓	✓	2.37	36.5	50.5	64.1	76.0	0.825
Triplet + track reg.	✓	✓	3.05	33.9	47.5	61.9	74.3	0.813
Proxy	✓	✗	1.11	**45.0**	**58.5**	**71.0**	80.9	**0.890**
Proxy	✓	✓	1.29	44.7	58.2	70.7	80.6	**0.890**
Classification	✗	✗	**1.00**	6.1	11.5	21.1	35.9	0.887
Classification	✓	✗	**1.00**	43.8	57.8	70.3	80.3	0.887
Classification	✓	✓	1.27	44.7	58.4	70.7	**80.9**	**0.890**

Table 1. Results for training time, similarity search, and auto-tagging.

Model	AUC
CRNN [23]	0.850
Self-attention [28]	0.881
Sample-level ReSE-2 [29]	0.885
Multi-level & multi-scale [24]	0.888
Proposed Model	**0.890**

Table 2. Auto-tagging SOTA comparison.

similar sounding results. If one of the top K retrieved results has the same class label as the query song, the recall@K is set to 1, otherwise it is set to 0. This process is repeated for all samples in the test set and then averaged.

Our data is multi-labeled, however, so we adapt the standard single-label (multi-class) R@K metric to create a multi-label variant. Our definition is

$$R@K = \frac{1}{N} \sum_{q=1}^{N} \frac{n(y^q \cap (\cup_{i=1}^{K} y^i))}{n(y^q)}, \qquad (12)$$

where N is the number of test samples, y^q is the ground truth labels of a query, and y^i is the ground truth labels of the top K retrieved results. And, $n(\cdot)$ denotes the number of the elements of a set. In this setup, if the set of labels of the top K retrieved results contains all the multiple labels of the query song, the recall@K is set to 1, otherwise it is set to the correct answer ratio. We report R@K when K is 1, 2, 4, and 8.

4.3.3 Auto-tagging

Music auto-tagging has been extensively studied in the literature with diverse model architectures [3]. As such, we follow standard benchmarking and evaluation criteria, and report area under the receiver-operator curve (AUC) to measure tag-based retrieval performance.

Unlike the proxy-based and classification-based approaches, the triplet-based model doesn't directly predict a class (or several classes) for a given input. Thus, we use the concept of prototypes to obtain classification result from the triplet-based models [31]. We first average all the embedding features of the training samples that are assigned to each class label to construct prototype (or centroid) of each class label. Then, we measure a distance between these prototypes and embedding feature of each sample and regard it as a prediction score for classification, which itself is directly used for AUC evaluation.

4.3.4 Triplet Prediction

Triplet prediction score is simply measured by counting the number of correct predictions among all test triplets. Here,

it is regarded as correct if the distance between the embedding features of the anchor and the positive is smaller than that of the distance between the anchor and the negative.

5. RESULTS

In Table 1, we present the results for training time, similarity-based retrieval, and auto-tagging. We compare a total of eight models, which are categorized into three learning methods: triplet-based, proxy-based, and classification-based models. "Disentanglement" indicates whether a CSN masking function is applied to each learning method, and "Normalization" indicates whether a normalization layer is applied to the model's embedding layer. "Track regularization" (track reg.) indicates whether, in addition to tag-based triplets, we also sample triplets by taking the anchor and positive from the same track and the negative from a different track, as proposed in [7].

First, we see that the training time, represented as the ratio between each model's training time and the training time of the fastest approach, is significantly reduced for the proxy-based and classification-based models compared to the triplet-based models. This is because each training sample for the triplet model is actually composed of 3 inputs (anchor, positive and negative) or even 5 when track regularization is also applied, whereas the proxy-based and classification-based approaches only require one input per training sample.

Second, for similarity-based retrieval, we see that the vanilla classification model without a normalization layer exhibits poor performance. This confirms our conjecture that using the representation learned by the classification model without normalization layer directly is not optimal for similarity-based retrieval, as the model is not optimized based on distances in the learned embedding space. We also see that the proxy- and classification-based models are superior to the triplet-based models across the board. We hypothesize that this is due to the latter strategy using only a single label per training sample, whereas the former two use all (multi-)labels for each training sample, thus exploiting a richer signal during training.

Third, for auto-tagging, we see that the proxy-based and classification-based models outperform the triplet-based model by a large margin. As expected, the vanilla classification-based model performs well on this task. In Table 2, we compare our proposed classification-based disentangled model to the state of the art (SOTA) for music auto-tagging. Our model outperforms all baselines, setting

Embedding space	Models	Normalization	Disentanglement	Genre	Mood	Instruments	Era	Overall

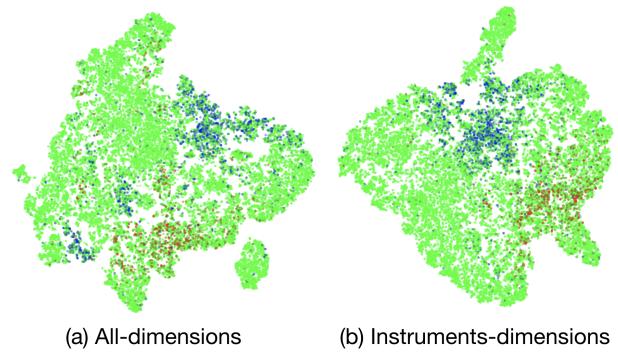
Table 4. Results on track-based & human-labeled triplets.


the new state-of-the-art for music auto-tagging.

Fourth, for triplet prediction, we report tag-based triplet results in Table 3 using different similarity dimensions (genre, mood, instruments, era), and in Table 4 the results for track-based and human-labeled triplets. The "Embedding space" column indicates whether we use the complete embedding space to measure the similarity between pairs of examples, or whether we only use the disjoint sub-space $(f(x_i) \cdot m_s$ or $h_s)$ corresponding to the similarity notion s used to sample the test triplets (genre, mood, instruments or era). In Table 4 we use the complete space.

Fifth, in Table 3 we see that while proxy- and classification-based embeddings are superior for music retrieval and tagging, triplet-based embeddings perform better (unsurprisingly) on the triplet-prediction task. It is noteworthy that while the triplet task is often used as a proxy for evaluating music similarity modelling, models that do best on this task are not necessarily the best at downstream retrieval tasks as evidenced by Table 1. In Table 4, we also see that while classification-based embeddings perform better at predicting track-based triplet similarity, triplet-based embeddings perform better when it comes to matching human judgements of triplet similarity. This is particularly true when we apply triplet learning with track regularization, in accordance with previous work [7].

6. VISUALIZATION OF DISENTANGLED SPACE

To qualitatively evaluate the disentangled representation space learned by our model, we visualize the embeddings of the test set as a t-SNE plot [32] in Figure 3. We take embeddings from the disentangled triplet model and highlight samples with the *female vocalists* and *instrumental* tags as an example. While the highlighted samples are relatively dispersed when considering all dimensions, we see that they are nicely clustered together when only con-

(a) All-dimensions   (b) Instruments-dimensions

Figure 3. t-SNE plot of test set embedding features. The blue dots are labeled positive for the female vocalists tag, the red dots are labeled positive for the instrumental tag, and the green dots are negative.

sidering the instrument sub-space of the embedding. This illustrates the benefits of a disentangled space, which supports both global similarity and specialized similarity over specific music dimensions.

7. CONCLUSION

In this paper, we presented a detailed study of metric-based and classification-based learning approaches for music representation learning. We extended both strategies to learn disentangled spaces from multi-label data, and showed both analytically and empirically that under certain conditions, proxy-based learning is equivalent to classification-based learning. We benchmark multiple variants of each strategy in terms of training efficiency and performance on music retrieval, auto-tagging, and triplet prediction tasks. Our results show that, when coupled with disentanglement and normalization, classification-based representation learning produces superior benchmark results on all tasks, except for triplet prediction where triplet models are (predictably) strong performers, indicating that triplet prediction is not necessarily a reliable proxy for real-world retrieval performance. Our best performing disentangled model obtains state-of-the-art results for music auto-tagging, outperforming all previous baselines. Finally, we complement our quantitative analysis with qualitative results that further illustrate the benefits of learning a disentangled music embedding space.

ABSTRACT

While many researchers have proposed various ways of quantifying recommendation list diversity, these approaches have had little input from users on their own perceptions and preferences in seeking diversity. Through an exploratory user study, we provide a better understanding of how users view the concept of diversity in music recommendations, and how they might optimise levels of intra-list diversity themselves. In our study, 17 participants interacted with and rated the suggestions from two different recommendation systems. One provided static top-7 collaborative filtering recommendations, and the other provided an interactive slider to re-rank these recommendations based on a continuous diversity scale. We also asked participants a series of free-form questions on music discovery and diversity in semi-structured interviews. User-preferred levels of diversity varied widely both within and between subjects. Although most users agreed that diversity is beneficial in music discovery, they also noted a risk of dissatisfaction from too much diversity. A key finding is that preference for diversification was often linked to user mood. Participants also expressed a clear distinction between diversity within existing preferences, and outside of existing preferences. These ideas of inner and outer diversity are not well defined within the bounds of current diversity metrics, and we discuss their implications.

1. INTRODUCTION

As music consumption has moved from physical media to digital collections to streaming, people have changed the way they discover new music. As with other forms of consumption which have made the shift to digital media and marketplaces such as movies, television, and consumer products, data on music listening habits is more prevalent than ever. Accordingly, systems which use this data to market or recommend new content to users have become ubiquitous. These *music recommender systems* aim to provide satisfying music recommendations to users across a wide variety of contexts [23].

One common way of recommending music is to create a ranked list where the items are formed by the top-*n* recommendations, as produced by the used recommendation algorithm, sorted by recommendation relevance. To judge the quality of recommendations, various forms of accuracy metrics have been proposed. Typically borrowed from the field of *information retrieval*, these accuracy measurements aim to quantify how well a recommendation (or set of recommendations) aligns with a user's known preferences, or in some cases how satisfied a user will be with those recommendations [10].

In addition to accuracy, various other metrics have been proposed [10, 12]. These aptly named *beyond-accuracy* metrics include novelty, coverage, serendipity, and diversity [10]. Novelty relates to items which are unknown to the user, coverage relates to the proportion of items that can be recommended (item coverage) or to the proportion of users for which at least one recommendation can be made (user coverage), serendipity relates to the unexpectedness of a recommendation, and diversity relates to the dissimilarity of recommended items [10]. We focus our attention to diversity as it is well researched, and easily understood for music [10, 12, 25].

Diversity in *music recommender systems* is well researched, but we are unaware of any research which specifically explores user provided perceptions of diversity. Additionally, most implementations of diversity treat the metric as a static variable between or within users. We argue that desire for diversity in recommendations may instead be situationally dependent so we present users with an interactive system which allows them to select diversity as a continuous trade off against accuracy across numerous personalized recommendation lists. Here, alongside a live user study using this prototype system, we present the results of semi-structured interview questions in order to address the following research questions:

- RQ1: How do users feel about diversity in personalized music recommendation lists?

- RQ2: How might users optimise their own level of diversity in personalized recommendation lists?

We found that users presented a range of definitions for diversity, linked ideal diversity levels to their mood, and distinguished between what we call inner and outer diversity. When asked to optimise their own level of diversity using our system selections differed greatly within and between subjects.

2. BACKGROUND & RELATED WORK

2.1 Diversity in Recommender Systems

Alongside novelty, coverage, and serendipity, diversity has long been identified as an important metric in providing satisfying automated recommendations to users across varying domains [12]. Diversity in this context traces back to information retrieval tasks, where it was used to resolve ambiguity in search queries [3]. Within recommender systems, diversity prevents over-personalization of recommendations to users, thereby increasing user satisfaction with recommendations [12, 13]. Research on diversity in recommender systems is extensive, and numerous different definitions have been proposed [13]. More generally, recommender system diversity has been described as the opposite of *similarity* [1, 10]. Among the most commonly researched and implemented definitions of diversity in *music recommender systems* is intra-list diversity (ILD) which measures the average pairwise dissimilarity of items using some chosen similarity metric; typically calculated using content features [1, 32].

2.2 Optimising for Diversity

Research on selecting optimal levels of diversity for recommender systems is extensive. In their original paper defining diversity as the opposite of similarity, Bradley and Smyth show that traditional recommender system outputs are not diverse, and diversity, in one metric, can be increased with minimal negative impact on accuracy [1]. Ziegler et al. further showed that user satisfaction with recommendation lists relies on more than accuracy by computing precision, recall, and satisfaction curves in a large user study [32]. Studies following this theme of incorporating existing diversity metrics with minimal negative impact on accuracy and/or satisfaction are plentiful [21, 31]. Whereas these works applied a global level of diversity to recommendations, recent work has focused on selecting levels of diversity on a per-user basis through user modeling [5, 8, 17, 18]. Interactive systems which allow users to explore recommendations through diversity have been explored outside of the music domain, but these systems aim to abstract diversity into a user interface rather than allow for user selection of existing diversity metrics [22, 27, 30].

Differences in user perceived diversity levels have been identified across varying recommendation algorithms [6], and varying levels of intra-list diversification [29]. Finally, user listening habits on diversity have been extracted from social networks [7] and playlists [20].

We are not aware of any research which explores user provided perceptions of diversity in personalized music recommendations, or allows them to directly modify existing diversity metrics on the fly. We begin to fill in this gap by providing knowledge on how well formalizations of diversity align with user perceptions of diversity.

3. METHODOLOGY

To control all aspects of recommendation and diversity inclusion, and to minimise restricting participants' consumption method, we implemented a collaborative filter recommender. We used Last.fm as a source of raw listening data, and presented song previews in the form of standardised 30 second track previews from Spotify.

3.1 Interactive Recommendation Lists

3.1.1 Data

We collected a total of 341,764,569 unique listening events (LEs) from 51,669 unique users whose region was set to North America using the Last.fm API. Users were found by crawling the Last.fm social graph using the *user.getFriends* endpoint. We had a limit of 10,000 LEs accepted per user, and only accepted LEs between January 12, 2019 and when we collected them in February 2020. The median number of LEs per user is 7744, 25th percentile is 3502, and 75thth percentile is 9842.

We used a simple key consisting of artist and track name tuples in order to identify individual tracks. The final user-track-interaction matrix, used to generate recommendations (see Section 3.1.2), contains 141,205,668 non-zero entries (play counts) across 12,300,857 unique artist-track tuples, resulting in a 51,669x12,300,857-sparse matrix. This system does not account for potentially inaccurate metadata obtained from Last.fm, but does account for the same track across different releases. Entries in this matrix are integers which correspond to the number of unique times a user (row) played the track (column). An anonymized version of this data is available upon request.

3.1.2 Collaborative Filtering & Diversity

For generating recommendations we used an Alternating Least Squares (ALS) matrix factorization algorithm which is designed specifically for implicit feedback data sets [8, 11]. This algorithm results in one vector for each user consisting of a non-negative real number (recommendation relevance) for each track in the database; higher numbers are considered more relevant recommendations. The ALS collaborative filter recommender was implemented using the *Implicit* python library [9], and was trained using the dataset described in Section 3.1.1. Hyperparameters were optimised using 5-fold cross-validation and Mean Average Precision for top-10 recommendations (MAP@10) over 60 iterations of randomized search resulting in 160 factors, 28 iterations, a scaling factor of $\alpha = 774$, and regularization term of $\lambda = 1$.

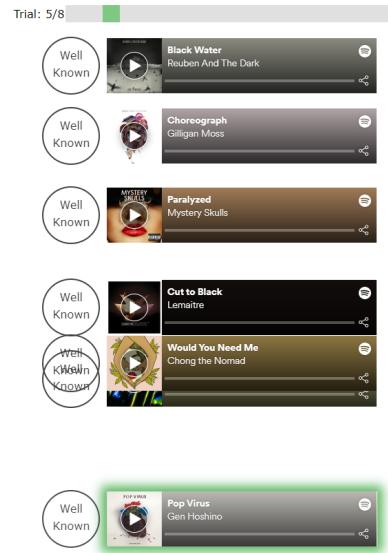
The trained collaborative filter recommender was used to generate top-400 track recommendation lists for a single Last.fm username (see Section 3.2). To facilitate multiple recommendation lists per-user we split this list evenly into four smaller lists of 100 tracks each. Each track within each of the four lists was assigned a rank from 1-100 with one being the most relevant. In order to measure diversity we used the latent vectors generated for each track during matrix factorization as descriptors. Similar to previous work [8, 29], we calculated a form of ILD (d_i) by summing the Euclidean distance of one track's descriptors (v_i) from all other descriptors (v_j) in each top-100 list.

$$d_i = \sum_{\substack{j=1 \\ j \neq i}}^{n} ||v_i - v_j|| \tag{1}$$

This calculation differs from previous work in that diversity is only calculated once and not as part of a greedy diversification algorithm. Higher values of d_i correspond to more diverse tracks in relation to others in the list. Tracks are assigned additional ranks from 1-100 where rank one is the most diverse. We are left with four unique top-100 recommendation lists for a given user where each track is assigned a rank for relevance (R_i), and diversity(D_i).

The final ranking (F_i) is calculated as a trade off between relevance and diversity controlled by a convex combination of both ranks, with a diversity parameter β.

$$F_i = (1 - \beta) * R_i + \beta * D_i \qquad (2)$$

The user interface, shown in Figure 1, displays the top-7 tracks of each top-100 recommendation list based on F_i in the form of 30 second previews using Spotify Play Button widgets. [1] We chose to use top-7 recommendation lists to ensure user study session times under 70 minutes (see Section 3.2). An interactive slider that controls the value of β is situated above the song previews. The left of this slider corresponds with $\beta = 0$ and the right side corresponds with $\beta = 1$ with a step size of 0.001. A *Well Known* button appears to the left of each song preview allowing users to remove songs which are not new to them.


Due to differences in the music collection available on Spotify and our own music database, as well as to avoid false-positives in retrieving song previews, we omitted all songs which did not match exact artist and song string queries to Spotify. This typically resulted in final recommendation lists of 95-100 tracks each.

3.2 User Study

Participants were recruited on the University of Waterloo campus through internal email lists and posters. After completing a digital information consent form participants were asked to complete a brief survey. As part of this survey they were asked to provide their Last.fm usernames, or alternatively were provided instructions on how to set up a Last.fm account and record their listening events to it. We required that participants had a minimum of 5 hours of LEs recorded before continuing to the interactive portion.

The interactive portion of the study involved a pre-interaction interview, two conditions of 4 trials using four unique recommendation lists, and a post-interaction interview. Interviews were semi-structured. Pre-interaction interview questions focused on the importance of music discovery to the participant, how the participant finds new music, and what a diverse list of personalized recommendations means to them. Post-interaction interview questions focused on the perceived effect of the slider on recommendations, the static or variable nature of their selections across trials, and positives and negatives of diversity in music recommendations.

Trials 1-4 consisted of static top-7/100 recommendation lists each corresponding with one evenly split quarter of

[1] https://developer.spotify.com/documentation/widgets/generate/play-button/

Figure 1. The mid-motion user interface state directly after moving the diversity slider seen at the top. The top 7/100 songs as ranked by Equation (2) are displayed as 30 second song previews. As the slider is moved the songs shift from the old order to the new order over a period of 2 seconds. Songs which leave the top 7 move off the bottom and new songs appear from the bottom highlighted in green for 5 seconds. The circular *Well Known* buttons on the left remove songs from the list entirely.

their top-400 recommendations as ranked only by recommender output (relevance) (see Section 3.1.2). The user-interface was similar to Figure 1 but without the slider. Participants were asked to listen to each preview, remove well known tracks, mark if they were familiar with the artist, and rate the recommendation on a four-point Likert scale of 'Strongly Dislike', 'Dislike', 'Like', or 'Strongly Like'. Only once every track was rated could the participant move to the next trial.

Trials 5-8 consisted of the same ranked lists as trials 1-4 (minus tracks marked as well-known) with the addition of the interactive slider to re-rank the larger hidden list based on the participants' selected level of diversity (see Section 3.1.2). The user-interface can be seen in Figure 1. Participants were not told what the slider did and were instructed to find the position on the slider that resulted in the most satisfying recommendation list as a whole while removing tracks that were well known to them. Once the participant locked in this position they were again asked to mark if they were familiar with each song's artist, and rate each individual recommendation on the same four-point Likert scale before moving to the next trial.

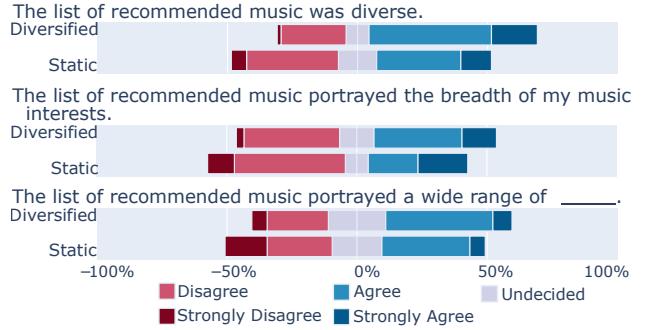
Between each trial participants completed a survey with questions on their satisfaction with the final recommendation list, the level of diversity in the recommendation list, and how well the recommendation list portrayed the definition of diversity they provided in their pre-interview survey. Participants were paid $10 CAD upon completing the interactive portion of the study.

Pre- and post-interaction interviews were transcribed, and comments were then sorted into three categories: in-

teraction, music discovery, and diversity. Similar to other qualitative music consumption studies we extracted individual ideas as statements from transcriptions and proceeded to build connections and groupings through affinity diagramming [2, 19]. Main ideas were highlighted and categorized into groupings of similar themes, and finally counts of each theme were collected. We specifically focused on responses regarding diversity.

4. RESULTS

We recruited 18 participants, and removed one participant for marking all recommendations as *Well Known*, leaving 17 total participants. The median participant age was 23; the oldest was 29 and the youngest 19. Each user session took 50-70 minutes inclusive of interviews. Some sessions were completed face to face, and others involved the users connecting remotely to the interactive system.

4.1 Music Discovery


When asked how they discovered new music, 9 said they used Spotify, 9 used YouTube, 5 used movies and/or television, 4 relied on friends, 3 used radio, and 4 used some other online service such as Amazon or Soundcloud. The importance and frequency of finding new music varied significantly from user to user, and no clear patterns were observed. Some users noted that the primary reason they use music services such as Spotify is to enable easier music discovery. When asked how important finding new music is to them, one user reported previously spending 5 hours per week looking for new music, but added:

> "While it's still very important to me, I basically don't do it very often on my own anymore; I rely on Spotify to do almost all of it for me."

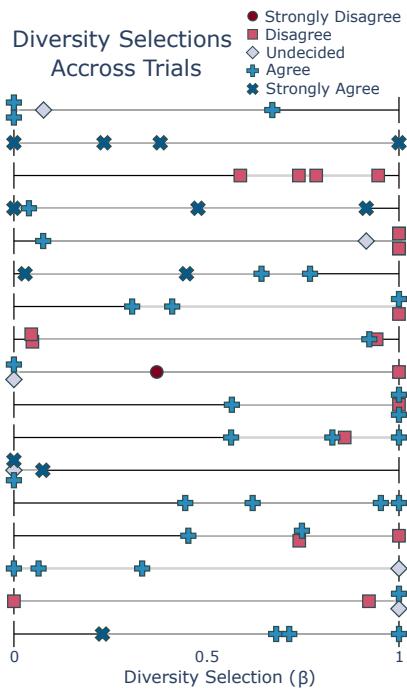
4.2 Recommendations

None of the participants had an existing Last.fm account, and the length of time during which users recorded their listening histories to Last.fm varied from one to three weeks. The median percentage of user LEs which existed in our CF database was 95%, with a max of 100% and a min of 65%. Median LE counts per-user used for recommendation generation were 256, with a max of 1156 and min of 86. All users marked and removed fewer than 100 tracks as well known across all trials, with the exception of one user who marked and removed 208.

When asked to rate individual recommendations on a 4-point Likert scale (Strongly Dislike, Dislike, Like, Strongly Like) 72.69% of songs were rated as 'Like' or 'Strongly Like' after locking in the diversity slider, and 74.79% in static lists. In addition to rating individual songs, participants were asked if they were satisfied with the list of recommended music for every trial. On a 5-point Likert scale (Strongly Disagree, Disagree, Undecided, Agree, Strongly Agree) 75% of diversified recommendation lists resulted in a positive response, with 50% for static recommendation lists.

Figure 2. Responses to Likert questions completed after every recommendation list, split between static lists and lists which were selected using the diversity slider. The final question was customized for each individual using their own definition of diversity obtained during the pre-interaction interview (see Section 4.4).

4.3 Interactive Diversity

In addition to the task of selecting an optimal position for the diversity slider, participants were asked a series of questions on how diverse they felt each recommendation list was. Responses to these questions can be seen in Figure 2. In order to visualise how participant responses on diversity align with their diversity selections, Figure 3 shows all 17 user's diversity selections coded with their Likert response on diversity. User selections varied greatly between their own recommendation lists and between other users'. Likert responses for perceived diversity did not fall in line with levels of β.


As a part of the post-interaction interview participants were asked to identify what they thought the slider was changing within their recommendation lists. Of the 17 participants, 5 identified it to increase diversity directly, 3 identified some change in genres, and 4 had no explanation. The remaining participants identified the slider to change the perceived gender of vocalists, increase 'newness', increase distaste, increase quality, and decrease quality. In one case where a participant identified the slider to effect genre they stated:

> "I noticed initially that the first side of the slider was giving me a bunch of songs from different genres. The more I was sliding it the more it was giving me the songs. . . from the genre which I like."

In another case where a participant was unable to identify the effect of the slider and was asked what they would like the slider to do they answered:

> "The way I imagined it was. . . less diverse on the one side and more and the other side. That's something I could definitely use."

When asked about their experience using the system some users expressed difficulty in remembering which locations of the slider they preferred most, and frustration over which songs remained on the list and which were moved off. In total, 10 users preferred interacting with the static list, and 7 preferred using the interactive slider.

Figure 3. All user selections for diversity using the slider found in Figure 1. The legend corresponds to Likert responses to: "The list of recommended music was diverse."

4.4 User Perceptions of Diversity

During the pre-interaction interview participants were asked what they would mean if they were looking for diverse recommendations. In addition to their open ended responses, they were challenged to come up with a single word or idea that could be used in place of diversity. Of the responses to this question, 13 answered a difference in **genres**, 2 answered **cultural differences**, and the remaining participants responded with **originality**, **variety**, and differences in **artists**. [2] These definitions were used to complete the third question in Figure 2.

Coding of participants' comments on diversity in their own personalized music recommendations resulted in two primary themes which we labeled **diversity meaning**, and **listener mood**. Comments which we classified under **diversity meaning** are deeply intertwined with personal definitions of diversity, and can be more specifically categorized into what we identify as **inner and outer diversity**; that is music within the bounds of existing preferences, and music outside of these bounds. In answering the interview question on the meaning of diverse recommendations, 8 participants made reference to a preference for this idea of inner or outer diversity. Participant comments expressing a preference for inner diversity include:

> "Diverse in the–within the boundaries of the things that I like."

> "I like a playlist which recommends me songs on the genre I like. . . the important thing is to get diversified music in my genre only. . . to stay in the same genre but diversity in artists."

[2] One participant was unable to choose between genre and culture.

> "A diverse music recommendation I think should still be within the category of music that I usually listen to, but it should be different artists or different albums that I haven't listened to so far."

Comments expressing a preference for outer diversity include:

> "[Diverse recommendations are] something new, something exciting. Something that I'm not used to, like I've never heard before."

> "[Diverse recommendations] would be music from other genres that maybe I haven't listened to very much, but still somewhat akin to the ones that I have listened to."

Secondary in frequency of occurrence to diversity meaning, **mood** was explicitly mentioned by 7 participants. Only 2 participants mentioned context. Participants referenced mood as a primary factor in how much diversity they want in their music recommendations at any given time. Notable comments on mood include:

> ". . . depending on my mood–whether I'm looking for more of the same things that I already like–I could set that slider to show me less diverse music–if I'm in the mood."

> "[I] like a piece of music right now because of the mood that I am in, but I might not like it while I'm listening to a very different kind of music. So diversity is good but I think in a weird way the recommender system should know when to recommend it."

> "Sometimes you're in the mood of listening to one specific–like you don't want [a] diverse playlist. You just want to listen to sad songs. You just want a playlist that has a sad song. You don't want diversity"

> "If you're in a melancholic mood and then you don't have a very diverse playlist of melancholic music then you'd be happy about your music because that's your mood."

Participants also provided their thoughts on the positives and negatives of diversity in personalized recommendations, and a summary of these thoughts can be found in Table 1. Participants generally felt that while diversity could enable music discovery, it also increased the risk of disliking some recommendations.

5. DISCUSSION

In this study we provided a primary analysis of user perceptions on diversity in personalized music recommendations. We also provided users an opportunity to directly optimise a diversity metric which until now had been algorithmically optimised for them. Although our results do not hold statistical power due to the small sample size, our semi-structured interviews facilitated valuable insights and answers to our posed research questions. These insights add to the growing number of other qualitative works in Music Information Retrieval research [2, 14–16, 19].

	More Diversity	Less Diversity
Pos.	Music Discovery (N=11) Preference Discovery (N=4) Interesting (N=4)	Likely to Like (N=2)
Neg.	Likely to Dislike (N=8) Dissatisfaction/Annoyance (N=2)	Restrictive (N=4) Repetitive (N=2) High Risk/Reward (N=2) Unremarkable (N=2)

Table 1. Positives and negatives of more and less diversity in recommendation lists expressed by participants.

5.1 RQ1: How do users feel about diversity in personalized music recommendation lists?

Despite a large variance in user's feelings towards diversity in music recommendations, their ideas on its positives and negatives (Table 1) mostly align with the metric's purpose of reducing over-personalization. Beyond this, however, users attached more complex ideas such as personal preference discovery and interestingness to more diversity. Ideas such as this may in part explain the higher levels of satisfaction reported by users given more diverse recommendations.

The prevalence of mood in participants descriptions of diversity is especially notable when compared to the lack of references to their context. As more focus is directed towards context-aware recommender systems [24], careful attention should be paid to not assume that ideal diversity levels can be determined by context alone. Diversity optimisation may also serve as an ideal jumping off point for mood-based recommendation [4,26]. In designing systems which incorporate diversity, it is also important to note that preferred diversity levels may not remain static on an individual user basis.

Although most participants described diversity as a difference in genres, genre was not the exclusive answer. To some participants, a recommendation list which spans genre may not be considered diverse unless those genres span a range of cultures, and to other users a recommendation list which spans artists in just one genre may be considered diverse.

The occurrence of inner and outer diversity–that is diversity within the bounds of existing preference, and outside of those bounds–was an unexpectedly binary result, and neither of these ideas are well defined by existing beyond-accuracy metrics. Inner diversity is not well described as novelty, nor is outer diversity well described by serendipity. The idea of inner diversity does however align with idea of user genre coverage [28]. More research on the universality of inner and outer diversity preference is clearly required.

In their foundational paper on diversity in *information retrieval*, Clarke et al. use a query for 'jaguar' as an example to show the usefulness of diversity; a diverse response might include the cars, the cats, and the classic Fender guitar [3]. In the case of music recommendations, all diverse responses may be simultaneously correct to one user, and incorrect to another.

5.2 RQ2: How might users optimise their own level of diversity in personalized recommendation lists?

The interactive system we implemented (Figure 1) represents a first attempt in allowing users to optimise diversity metrics in line with how they are optimised in existing studies. As such, all variables other than the level of diversity (Equation (2)) were fixed. We note that in allowing users to remove well-known songs the system represents a specific use for diversity in discovering novel music.

Diversity selections across the interactive trials varied widely within and between users. Ideally in Figure 1, users' Likert ratings would be distributed with positive responses on the right ($0.5 \leq \beta \leq 1$), and negative responses on the left ($0 \leq \beta \leq 0.5$). While results do not follow this distribution, the responses in Figure 2 show that users generally found the slider system to enable more diversity. We hypothesise a combination of three reasons for these results. First, the Likert survey provided no frame of reference for diversity and participants used their own idiosyncratic definitions. Second, the users' responses were heavily impacted by music previewed before locking in a diversity value. Third, the diversity metric did not match users' models of diversity. All three of these hypotheses should be considered for future implementations.

We also note that while our selection of CF recommender and diversity metric have a basis in previous work, there are countless combinations of them which may be used to comprise of a system such as ours. Also, more recent music recommendation algorithms based on deep neural networks could be investigated [24].

6. CONCLUSION & FUTURE WORK

The work we present here provides a much needed connection between quantitative diversity metrics and user perceptions of diversity in music recommendation lists. Through analysis of semi-structured interviews with 17 participants we identified two primary themes on user selections for diversity: listener mood, and diversity meaning. More specifically many users expressed a clear distinction between diversity within the bounds of their existing preferences, and diversity outside of these preferences. This inner and outer diversity was often expressed as a binary preference. Additionally, we found that when given the ability to select their own level of diversity in recommendation lists, user selections varied widely within and between subjects.

Much future work is required in order to generalize our qualitative findings to a larger population, and further inform *music recommender systems* from the user's perspective. Additionally, we plan to explore the connection between listener mood, and their preference for inner and outer diversity. Diversity in music recommendations should have at least as solid a foundation in user perception as in *information retrieval*.

POLYPHONIC PIANO TRANSCRIPTION USING AUTOREGRESSIVE MULTI-STATE NOTE MODEL

Taegyun Kwon[1]   **Dasaem Jeong**[1*]   **Juhan Nam**[1]

ABSTRACT

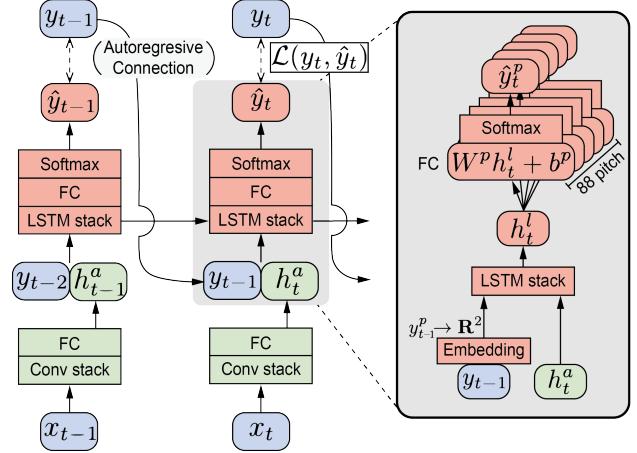
Recent advances in polyphonic piano transcription have been made primarily by a deliberate design of neural network architectures that detect different note states such as onset or sustain and model the temporal evolution of the states. The majority of them, however, use separate neural networks for each note state, thereby optimizing multiple loss functions, and also they handle the temporal evolution of note states by abstract connections between the state-wise neural networks or using a post-processing module. In this paper, we propose a unified neural network architecture where multiple note states are predicted as a soft-max output with a single loss function and the temporal order is learned by an auto-regressive connection within the single neural network. This compact model allows to increase note states without architectural complexity. Using the MAESTRO dataset, we examine various combinations of multiple note states including on, onset, sustain, re-onset, offset, and off. We also show that the autoregressive module effectively learns inter-state dependency of notes. Finally, we show that our proposed model achieves performance comparable to state-of-the-arts with fewer parameters.

1. INTRODUCTION

Automatic music transcription (AMT) refers to an automated process that converts musical signals into a piano roll or a musical score. Polyphonic piano transcription is a specific AMT task for piano music. Due to the complex nature of piano sound such as overlapping spectra and interference among notes and inharmonic overtones, most of recent approaches are based on learning algorithms such as non-negative matrix factorization (NMF) and deep neural networks (DNN) [1]. In particular, the transcription performance has been significantly improved by virtue of the representation power of DNN [2–5] and large-scale piano music data such as the MAESTRO dataset [6].

A key element in designing state-of-the-art DNN architectures is detecting multiple states of a note beyond the conventional binary states (i.e., on/off) and modeling the temporal evolution of the note states. For example, the *Onsets and Frames* model incorporated a note onset detection network into the frame-level pitch detection network [4]. This onset-aware model significantly reduced note-level false positive errors, which is critical in perceptual evaluation of the transcription. Similar multi-state note modeling approaches are found in [4, 7–10] and some detect even more phases of note envelope including onset, sustain and offset [11, 12]. As such, various versions of note state representations have been suggested so far and showed improved performances. However, the majority of them use separate neural networks for each note state. This requires to optimize multiple loss functions, progressively increasing the model complexity for more note states. Also, they handle the temporal evolution of note states by an abstract connection between the hidden layers of the state-wise neural networks [4] or using a separate neural network to model piano-roll data [2, 13, 14].

In this paper, we propose a unified neural network architecture where individual neural networks for each state and the temporal order modeling are integrated within a single neural network. We implement the all-in-one architecture by predicting multiple states of a note as a softmax output and modeling the temporal order in an auto-regressive connection in the output layer. Specifically, the architecture is composed of convolution neural network (CNN) and recurrent neural network (RNN). For each time step, the CNN module summarizes local acoustic features into a frame-level latent vector. The RNN modules predicts the note states from the softmax outputs conditioned on the latent vector and the previous outputs via an auto-regressive connection. The multi-class classification approach for note states allows the model to increase the number of note states without architectural complexity. Taking the advantage of this property, we examine various combinations of multiple states including *on*, *onset*, *sustain*, *re-onset*, *offset*, and *off* by comparing the performances and visualizing an example of the note state activations. In addition, we show that the autoregressive module effectively learns inter-state dependency by comparing it to a non-auto-regressive version. Finally, we show that the auto-regressive multi-state note model can achieve transcription performance comparable to the state-of-the-art *Onsets and Frames* model on the MAESTRO dataset.

2. RELATED WORKS


2.1 Multi-State Note Modeling

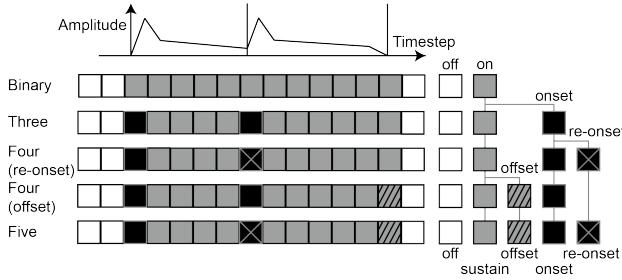
Most of recent approaches in polyphonic piano transcription are based on deep learning. The model architectures are diverse, including CNN [2, 3, 10, 12], RNN [9, 15], CRNN [4, 5, 16], and U-Net [17]. The loss function is typically the cross-entropy between predicted and ground truth labels but also includes the adversarial loss [5]. An important direction in designing a neural network architecture is detecting note onset explicitly apart from the binary on/off states [4, 9, 10, 12], considering that piano sound starts with a percussive tone but, after the attack park, it slowly decays with a harmonic tone [18]. This multi-state note modeling even including note offset was already explored before the DNN approaches become dominant [7, 8, 11]. While this multi-state note modeling has significantly improved the transcription performance, to the best of our knowledge, there has been no study that systemically compares various combinations of multi-state note representations. In this paper, we define five note states even considering the sustain pedal that globally changes the note states, and examine the different representations of temporal evolution.

2.2 Temporal Modeling of Multi-State Notes

Modeling the temporal order of note states is an essential step to improve the transcription performance [1]. A popular choice is hidden Markov model (HMM), which learns the temporal dependency of note states typically for each pitch. The note states can range from binary (on/off) [19–21] to more complete note phases (attack, decay, sustain, and release) [12]. Another approach is the autoregressive modeling which has been implemented with an RNN or its variants [2, 13, 14]. The autoregressive models can learn much wider musical context than HMM, covering inter-note and long-term dependency at the cost of sophisticated decoding algorithm [13]. Since this is analogous to the language model in speech recognition, it is also called musical language model (MLM). The MLMs are trained only with frame labels without paired audio data. This enables them to leverage large-scale symbolic data such as MIDI files. However, this decoupling from audio data may not take advantage of the synergy when the MLM is conditioned with the acoustic information, for example, using a transduction model [22, 23]. The *Onsets and Frames* model learns the temporal order of note states without an MLM by having a directed connection between different columns of neural networks that account for onsets and frames states, respectively [4]. However, this hidden-layer connection implicitly learns the temporal orders and the design choice is heuristic.

Our proposed architecture integrates the acoustic model with the MLM by conditioning the autoregressive multi-state note modeling on the acoustic latent features. Unlike the transduction models that use the pre-trained features or posterior as input [22, 23], we train the acoustic model and MLM jointly within a single neural network in an end-to-end manner. This unified approach was recently at-

Figure 1. A diagram of the proposed CRNN architecture at time step t.

tempted by the image-to-image translation model between mel-spectrogram and piano-roll [5]. However, our model has multiple states for each note and the state transitions are learned via the autoregressive connection.


3. PROPOSED METHOD

3.1 Term Definitions

In this paper, we will use frame as an unit of time. t indicates the frame index. For a given audio recording, we express its audio feature as $\mathbb{X} = \{x_t\}$, where x_t is a vector that represents local audio feature at t, and $\mathbb{N} = \{n_i\}$, where n_i denotes a musical note with index i over the frames. Each note consists of onset, offset time and pitch. We also represent notes with a piano-roll-like form $\mathbb{Y} = \{y_t^p\}$, where y_t^p denotes a frame-level state of a note with pitch p at time step t. The pitch p corresponds to each key of piano. The actual form of y_t^p are determined by the chosen note state representation and network architecture. For example, the *Onsets and Frames* model uses three parallel binary rolls $\mathbb{Y}_{onset}$, $\mathbb{Y}_{frame}$, and $\mathbb{Y}_{offset}$, as they have three columns of networks for separate detection of onset, offset and frame. In our proposed model that uses a single-column network, y_t^p is a one-hot vector of multiple states. Without the pitch superscript, y_t denotes concatenated one-hot vectors (y_t^p) for all pitches (88 keys in piano) at time step t. In Section 3.3, we explain various combinations of multiple states of a note.

3.2 Model Overview

Our proposed network architecture consists of two modules as shown in Figure 1. The first module is a CNN-based acoustic model to extract local feature h_t^a from the input x_t. The second module is an RNN-based autoregressive MLM to estimate the output y^t from the previous output y^{t-1} but it is conditioned on the extracted audio feature h_t^a. The output layer have 88 independent softmax functions, each of which corresponds to pitch p. The following equations summarize the input and output in each module.

Figure 2. Visualization of five note state representations. The idealized ADSR curve of two consecutive notes and corresponding annotations are displayed.

$$h_t^a = CNN(x_t)$$
$$h_t^l = RNN(y_{t-1}, h_t^a) \qquad (1)$$
$$\hat{y}_t^p = softmax(W^p h_t^l + b^p)$$

For the acoustic model, we borrow the CNN architecture (*convnet*) proposed in [3], which is also used in [4,5]. The acoustic model consists of three convolutional layers followed by a fully-connected layer. For the autoregressive MLM, we employ two layers of uni-directional long short-term memory (LSTM). When the one-hot vector y_{t-1}^p at the previous time step $t-1$ is used as the input of the LSTM stack, it is embedded into a two-dimensional vector with continuous values to be matched with the audio feature h_t^a, another input of the LSTM stack. Since all of note states are predicted from the single CRNN architecture, our model has fewer parameters compare to the *Onsets and Frames* model. In addition, the causal uni-directional RNN in our model enables real-time applications.

3.3 Multiple Note States

We illustrate five different note state representations in Figure 2. Our main idea is to extend the conventional binary state (*onset* and *off*) to multiple states using the states transition of note activations such as note *onset* and note *offset*. Considering that sustain pedal affects the note transition, we also add *re-onset*, the moment that a new note is played while the previously played note on the same key is being sustained with the pedal. In addition to the transition states, we distinguished *sustain* from *on*. Using the multiple note states, we examine five types of note state representations: binary, three states (*off, onset, sustain*), four states which have additional {*re-onset* or *offset*} state, and five states which utilize all local states.

We define the note state representation over the softmax output in the LSTM in contrast to other multi-note-state models which have a separate binary classifier for each state [4, 12].

$$\mathcal{L}(y, \hat{y}) = -\sum_{t=0}^{T} \sum_{p=p_{min}}^{p_{max}} \sum_{i=0}^{\#states} y_t^p(i) log(\hat{y}_t^p(i)) \quad (2)$$

We expect two advantages from this multi-class approach. When the states are explicitly defined by a single variable,

the relation among states becomes concise. This may help the autoregressive model to learn note transition patterns more easily. Also, it prevents unrealistic combination of states which can be occur in inference. (i.e. $P(onset)=1$ but $P(on)=0$). Adding *re-onset* class independently, out of onset or sustain class, is also expected to be helpful to train the neural network due to the distinct percussive timbre of piano at note attack.

3.4 Autoregressive Model

For given a audio recording, our goal is estimate the notes $\mathbb{N}$ from the acoustic features $\mathbb{X}$. In practice, it is common to estimate the frame-level note states first $\mathbb{Y}$ by computing the maximum-likelihood of $P(\mathbb{Y}|\mathbb{X})$ and then to decode the estimated $\mathbb{Y}$ into $\mathbb{N}$. In the majority of AMT algorithms, the condition probability is factorized as follows (see [2] for details):

$$P(\mathbb{Y}|\mathbb{X}) \propto P(y_0|x_0) \prod_{t=1}^{T} P(y_t|y_0...y_{t-1})P(y_t|x_t) \quad (3)$$

where $P(y_t|x_t)$ corresponds to an acoustic model and $P(y_t|y_0...y_{t-1})$ accounts for a (musical) language model. The factorization allows the MLM to be trained with large-scale symbolic data such as MIDI without paired audio recordings. However, this approach has two issues. First, the factorization may not take advantage of the synergy when the MLM is conditioned with the acoustic information as input, for example, using a transduction model [22, 23]. Second, the frame-level MLM in Equation 3 is usually set up to learn the dependency of binary on or off states over piano-rolls [2, 13]. The recurring nature of the binary representation may lead the model to play a role of smoothing, rather than learning any kind of musical structure [2, 24]. While a note-level MLM (i.e, $P(n_i|n_{\leq i-1})$) can solve this problem [14,24] (and also this learns the distribution of notes more meaningfully as notes in AMT are analogous to words in speech recognition), it requires a separate beat and meter detection algorithm to convert the time unit [25].

Our proposed method addresses the two issues by 1) jointly training the acoustic model and MLM and 2) using multiple note states. Unlike the transduction models that use the pre-trained features or posterior as input [22, 23], we train the acoustic model and MLM in an end-to-end manner through the auto-regressive CRNN architecture. More precisely, we express the condition probability by conditioning the autogressive model on the acoustic input.

$$P(\mathbb{Y}|\mathbb{X}) \propto P(y_0|x_0) \prod_{t=1}^{T} P(y_t|y_{\leq t-1}, x_{\leq t}) \quad (4)$$

Although our model maintains the frame-level MLM, the note-aware multiple state representation may mitigate the repeated patterns of the simple binary representation.

3.5 Note Decoding

Once we estimates frame-level note states, we decode them into musical notes in the inference phase. We examine two ways of note decoding. One is a simple greedy approach and the other is a global optimization strategy using a modified beam search. The simple greedy decoding samples from the most probable estimated state of $\hat{y}_t$ every frame. However, it does not guarantee global optimum over multiple time steps. On the other hand, it is intractable to examine all possible sequences especially in the high-dimensional sequence. To overcome this problem, a beam search is usually used to obtain a global optimum. For MLM, a high-dimensional beam search [22] or a hashed beam search [2] was proposed to reduce the complexity in high dimensional situation. However, their methods mainly aim to capture dependency across pitches on the binary piano-roll representation. To focus on dependency over the multiple states, we simplified the beam search to find the optimum for every pitch independently. We achieve this by examining the sub-sequences in the beam search tree only when the second-best state of a pitch has a higher possibility than a certain threshold. When such pitches and frames are detected, we perform beam-search for five more steps only with that pitch while fixing other pitches with greedy sampling. We also consider only two states with the highest probability at each frame because we expect the probability becomes negligible from the third in most cases. After the best path for the pitch is found, we proceeded to other pitches and next frame recursively. Most of the target frames were close to onset and offset. Therefore, the pitch-wise path search can be regarded as locating the onset or offset to an optimal position. This method operates like the greedy decoding if all of the estimated frames have a high confidence.

After note states are inferred by one of the decoding algorithms, we apply a simple rule to determine notes. Along with frame axis, a note is initiated if a {*onset* or *on*} state is detected after *off*. The offset of the note is determined if {*offset* or *off* } is detected after the note initialization.

4. EXPERIMENTS

4.1 Dataset

We trained our model with the MAESTRO dataset v1.0.0 [6] with the published training and test split. The dataset provides 1184 performances played in the *International Piano-e-Competition*. Both audio recordings and the corresponding aligned MIDI files captured through Disklavier are given. To compensate the effect of sustain pedal on note offsets in labeling, we elongated the offset of notes according to the sustain pedal followed by methodology in [4].

4.2 Metrics

We employed the standard frame-based and note-based metric using *mir_eval* [26] package. We report precision, recall and F1 score. We used a threshold of $50msec$ to de-

tect note onset. We counted note offset as hit when the difference is within $50msec$ or $\pm20\%$ of note duration.

4.3 Hyperparameters

We used log-compressed mel-spectrograms as input of the acoustic model. We computed the mel-spectrograms with 229 logarithmically-spaced frequency bins, a hop length of 512, an FFT window of 2048, and a sample rate of 16kHz following [4, 5]. The CNN consists of $48/48/96$ nodes from the bottom to the top layer, and the following fully-connected (FC) layer has 768 nodes. The RNN consists of two layers of LSTM with 768 nodes. The output FC layer has $(88 \times N)$ nodes where N is the number of note states. The receptive field size of the top hidden layer in the CNN is 7 frames of mel-spectrograms centered at time step t. This yields 176 msec latency when the model runs in real-time.

We used the categorical cross entropy loss and Adam optimizer for training, applying a batch size of 32 and a learning rate of $6e-4$ with a decay of 0.02 in every 10000 steps. We trained our model with the teacher-forcing method, which provides ground-truth data of the previous time step for the AR layer. We tried scheduled sampling [27] but our preliminary result showed a significant degradation in performance. We randomly segmented audio into $10sec$ while training, but the whole sequence is transcribed at once during inference. We evaluated the models after 200k steps in training. In addition to the aforementioned hyperparameters, we report the experimental result of a smaller model where the number of nodes in the LSTM is set to 256 (three times smaller than the above) to reduce the number of model parameters.

4.4 Comparative Experiments

We conducted a comparative experiment with the proposed method with the five note state representations. Also, we evaluated the same set of models without the autoregressive connection to verify the effectiveness of the autoregressive model. For the autoregressive models, we evaluated the note decoding results as well. We compared our model mainly with the *Onsets and Frames* model and its GAN-based extension [5], which is also trained on the same dataset. In addition to the reported performance, we evaluate *Onsets and Frames* model with the publicly available pre-trained model [1] and our own re-implementation.

5. RESULTS

5.1 Effect of Multi-State Note Representations

We report the averaged metrics over the test set in Table 1. Overall, the use of *onset* makes a significant improvement as seen in comparison between the 'Binary' model and other multiple models. This result is in accordance with previous studies [4]. The note-with-offset score also increases along but this might be seen as affected by the increased number of matched notes. The 'Binary' model

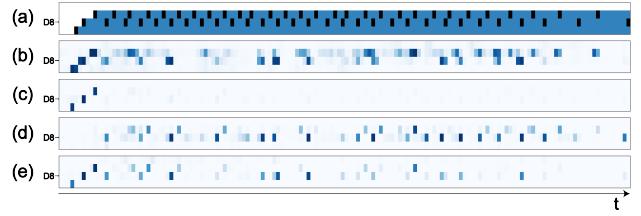
Table 1. Frame and note metrics for the five note state representations. All measures are based on decoded sequence with greedy decoding. Precision, Recall and F1 score are averaged over piece-wise results. AR stands for 'autoregressive'. Refer 4.3 for detail. * This number was estimated based on hyperparameters in the paper. †This includes a neural network to estimate note velocity.

achieves a high frame-level F1-score but at the same time it has the lowest note onset F1-score. We suspect that overlapped notes without offsets (notes with *re-onset*) were not distinguishable in the binary note state representation, thereby leading low recall in the note onset score.


The influence of *re-onset* and *offset* is observed from the note-with-offset score. The 'Four' models that have either one of the states achieve higher scores than the 'Three' model. The 'Five' model that has both states achieves a higher score than the 'Four' models, particularly with the AR connection. However, *re-onset* and *offset* do not help improving the note onset score much.

Among the five note state representations, the 'Five' model achieves slightly higher frame-level and note-level F-scores than others. We investigated the model further by downsizing the LSTM units (small). The small model has a lower F-score in the note-with-offset score but it achieves comparable F-scores to the original 'Five' model in the note onset score.

We also observed that *re-onset* in the 'Five' model estimates sharper activations compared to the common *onset* when it estimates repeated notes with extremely short intervals such as trills, as shown in Figure 3. The number of such note patterns is too small to affect overall performance but it would be helpful when detailed analysis on articulation is necessary.

5.2 Effect of Autoregressive Connection

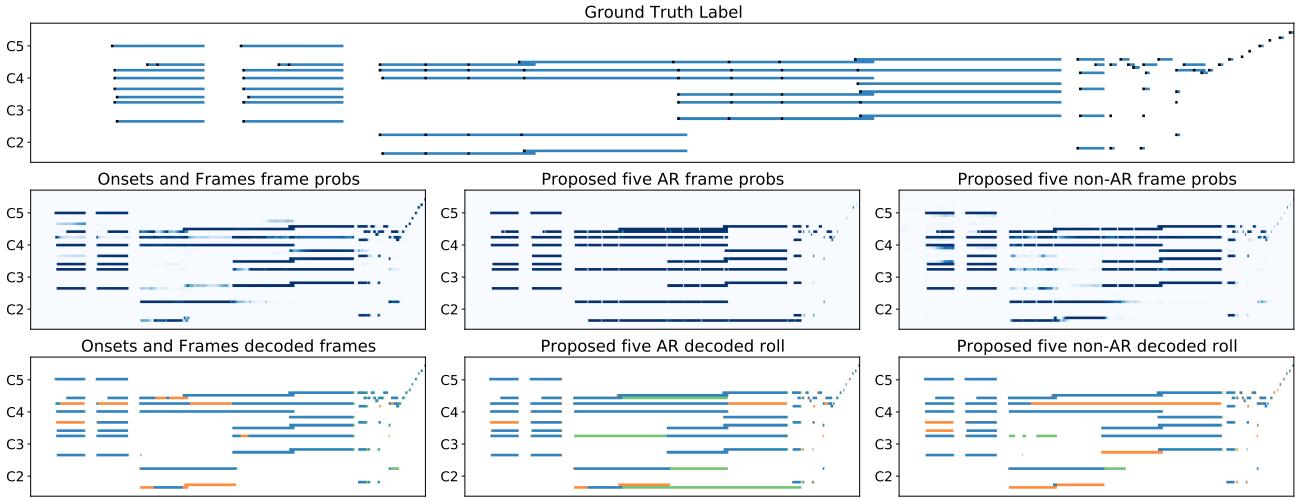
All AR models with *onset* show similar high performances in the note onset score. While the AR connection improves the F-score in both onset and offset of notes, it significantly decreases the frame-level scores. This might be because some extremely elongated note offsets are predicted by the AR model. This issue is discussed in the following section. The improvement in the note-with-offset score with *re-onset* and *offset* should be carefully understood because


Figure 3. Comparison between *onset* and *re-onset* activation on trill notes. (a) ground truth (b) onset activation of *Onsets and Frames* (c) *onset* activation of 'Five' AR model (d) *re-onset* activation of 'Five' AR model (e) *onset* activation of 'Four (offset)' AR model

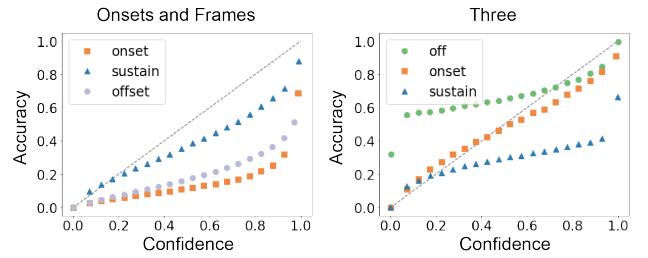
our model cannot learn state dependency backward (for example, considering that there will be an offset few frames later, the current frame is more likely to be *on*). Therefore, it is not clear why it is effective only on the AR model. Since our model was trained with a teacher-forcing scenario, we suspect that part of the benefits might be related to resilience on the noisy output, which can occur in the inference phase.

5.3 Learned State Transition

Figure 4 shows an example of frame activations and decoded piano rolls of the selected models. In the proposed 'Five' model with the AR connection, a note always starts with its onset prediction and the activation is clearly maintained with the following sustain predictions. This contrasts with the blurry activation in the *Onsets and Frames* model and the non-AR model, where some notes were estimated too short. This is identified by the short blue frames followed by the orange frames in the decoded roll in Figure 4. Estimating continuous sustain frames also has an negative effect. The AR model often fails to detect note offsets as the sustain frames are estimated too long. This is

Figure 4. Frame probabilities (or activations) and decoded piano rolls with the ground truth. The excerpt was selected from the test set. *Sustain* frames and *onset* frames are displayed in blue and black, respectively, in the ground truth. In the decoded piano rolls below, the estimated frames with {true positive, false negative, false positives} are annotated in blue, orange, and green, respectively. Best viewed in color.


Decoding	F1 score	Models				
		Five	Four (offset)	Four (re-onset)	Three	Binary
Greedy	Note Onset	0.9467	0.9416	0.9465	0.9433	0.7560
	Note w. Offset	0.7936	0.7735	0.7744	0.7593	0.5064
Beam Search	Note Onset	0.9380	0.9305	0.9361	0.9310	0.7480
	Note w. Offset	0.7886	0.7648	0.7657	0.7484	0.5035

Table 2. Summary of note decoding results. All models have autoregressive model.

identified by the green frames followed by the blue frames in the decoded roll in Figure 4.

5.4 Beam Search and Error Calibration

We summarized the comparison between the two decoding algorithms in Table 2. Counter-intuitively, the proposed beam search performed slightly worse than the simple greedy decoding method. To analyze the reason, we investigated the confidence errors of class prediction. With the greedy decoding, we regarded their softmax predictions as a confidence measure and classified each estimation according to the value. We equally divided the confidence range [0 1] into 20 bins and recorded the averaged accuracy of each bin. The empirical discrepancy between accuracy and confidence indicates the model calibration error [28]. The confidence diagram Figure 5 shows that the model is overconfident on *sustain* prediction but it is underconfident on *off* frames. We suspect this large gap between estimated probabilities leads to sub-optimal paths in the beam search. Label smoothing [29] or temperature scaling [28] may be helpful for relaxation but we leave this for future work.

Figure 5. Confidence diagrams of the *Onsets and frames* model and the 'Three' model. The dashed diagonal line in black indicates perfect calibration.

6. CONCLUSIONS

We proposed a neural network architecture for polyphonic piano transcription where the acoustic and language models are integrated in a unified manner. The architecture is designed to predict multiple note states as a softmax output and learn the dependency among note states through the auto-regressive MLM. Our comparative study shows that the *onset* state is critical to improving note onset scores and the *offset* and *re-onset* states help improving the note-with-offset score. The auto-regressive MLM provides significantly higher accuracy on both note onset and offset estimation compared to its non-auto-regressive version. The visualization of decoded piano roll shows that our models with the auto-regressive connection generates a realistic sequence of note states. We also examined a pitch-wise beam search to decode the frame-level activation but the result showed that it was not as effective as a simple greedy decoding. Finally, the evaluation on the MAESTRO dataset shows that our proposed model achieves transcription performance comparable to the state-of-the-art models even with the unidirectional RNN and fewer parameters.

ABSTRACT

Audio alignment is a fundamental preprocessing step in many MIR pipelines. For two audio clips with M and N frames, respectively, the most popular approach, dynamic time warping (DTW), has O(MN) requirements in both memory and computation, which is prohibitive for frame-level alignments at reasonable rates. To address this, a variety of memory efficient algorithms exist to approximate the optimal alignment under the DTW cost. To our knowledge, however, no exact algorithms exist that are guaranteed to break the quadratic memory barrier. In this work, we present a divide and conquer algorithm that computes the exact globally optimal DTW alignment using O(M+N) memory. Its runtime is still O(MN), trading off memory for a 2x increase in computation. However, the algorithm can be parallelized up to a factor of min(M, N) with the same memory constraints, so it can still run more efficiently than the textbook version with an adequate GPU. We use our algorithm to compute exact alignments on a collection of orchestral music, which we use as ground truth to benchmark the alignment accuracy of several popular approximate alignment schemes at scales that were not previously possible.

1. INTRODUCTION

The go-to algorithm for computing alignments between two audio clips is Dynamic Time Warping (DTW) [1, 2], and DTW and its variants have seen wide application in music processing applications [3]. However, the textbook version of exact DTW has quadratic memory constraints. While some MIR applications, such as cover song identification, can get away with coarse, beat-synchronous features [4] to remain in a low memory regime, other applications may require finer scale features and can quickly explode in memory requirements. For instance, in orchestral music, onsets are weak, so one must often revert to frame-level features for satisfactory alignments. Singing voices also present unique challenges in this regard [5], and both stringed instruments and singing voices have precise, expressive attacks at sub-beat scales.

In this work, we present a simple divide and conquer variant of DTW to compute a globally optimal alignment between two audio sequences with linear memory. Our contributions are as theoretical as they are practical; though there are many approximate algorithms that work well in practice (Section 2), we are not aware of any other linear algorithms for DTW with this guarantee. A related advantage is that there are no approximation parameters to tune; there is only one exact cost (with some caveats on numerical precision in Section 4.2).

Once we establish the algorithm, we present an experiment on a hand-curated collection of classical music (Section 4). Since our memory only scales linearly with a small factor (Section 4.3), we are able to run it on longer pieces, enabling us to evaluate the precision of approximation algorithms at scales not previously possible.

2. BACKGROUND

2.1 The Textbook DTW Algorithm

We now briefly review the standard DTW algorithm for context. Given a (possibly multivariate) time series X with M points and a time series Y with N points, there is a notion of allowable matchings that preserve the time order, known as a time-ordered correspondence, or "warping path." A warping path $\mathcal{W}$, is a correspondence between X and Y [1] with K ordered tuples of indices of X and Y so that (assuming 0-indexing) $\mathcal{W}_1 = (0, 0)$, $\mathcal{W}_K = (M-1, N-1)$, and $\mathcal{W}_i - \mathcal{W}_{i-1} \in \{(0, 1), (1, 0), (1, 1)\}$. In other words, matched points between time series must always stay still or advance by at most one along each, and at least one must move forward.

Given a cost measure between the ith element X_i in the first time series and the jth element Y_j in the second time series, $C_{X,Y}(i, j)$, then an "optimal" or "exact" solution to the *Dynamic Time Warping* problem is a warping path $\mathcal{W}^*$ that minimizes the sum

$$\sum_k C_{X,Y}(\mathcal{W}_k^*(1), \mathcal{W}_k^*(2)) \qquad (1)$$

We'll refer to an optimal path as $\mathcal{W}^*$ and the optimal cost as $D_{X,Y}(M, N)$. It is possible to compute the $\mathcal{W}^*$ and $D_{X,Y}(M, N)$ using a well-established dynamic programming approach, which is also shared among edit distance

---

[1] A *correspondence* $\mathcal{C}$ between two indexing sets I and J is a subset of the cartesian product $I x J$ so that every element of I is contained in at least one element of $\mathcal{C}$ and every element of J is contained in at least one element of $\mathcal{C}$

algorithms such as Smith Waterman [6]. In particular, if $D_{X,Y}(i,j)$ refers to the optimal cost of aligning the first i points of X to the first j points of Y, then the following recurrence holds for $i, j \geq 2$

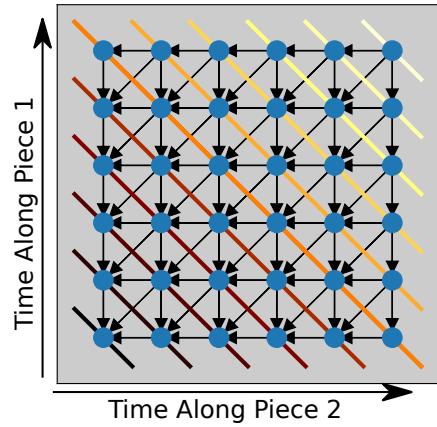
$$D_{X,Y}(i,j) = \min \left\{ \begin{array}{ll} D_{X,Y}(i,j-1) & \text{LEFT} \\ D_{X,Y}(i-1,j) & \text{UP} \\ D_{X,Y}(i-1,j-1) & \text{DIAG} \end{array} \right\} + C_{X,Y}(i,j)$$

(2)

the boundary conditions are set as

$$D_{X,Y}(0,j) = \sum_{k=0}^{j} C_{X,Y}(0,k), D_{X,Y}(i,0) = \sum_{k=0}^{i} C_{X,Y}(k,0)$$

(3)

After filling in the first row and column by Equation 3, it is possible to compute all values of $D_{X,Y}(i,j)$ by applying Equation 2 from left to right, row by row. After processing all MN pairs of subsets in this fashion, $D_{X,Y}(M,N)$ contains the optimal cost.


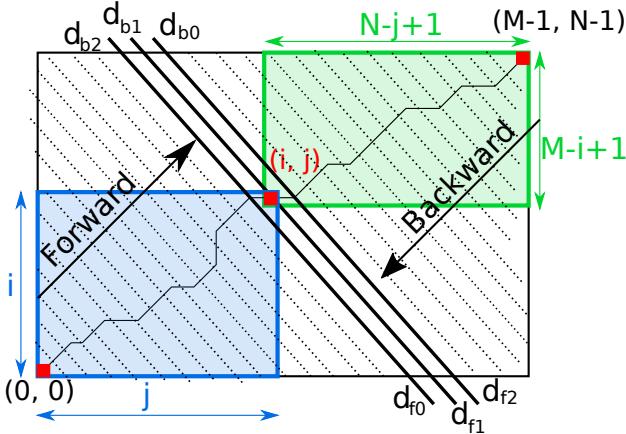
At this point in the algorithm, we merely have a cost, not an optimal warping path that realizes this cost. But if we store a second matrix $P(i,j)$ which remembers one of the three "backpointers" LEFT, RIGHT, and UP that realized the minimum cost at that cell, then we can "backtrace" by following these arrows back from (M,N) to $(1,1)$ to figure out the elements of an optimal $\mathcal{W}$ in between.

2.2 Variants And DTW Algorithms in MIR

There are countless works that incorporate and expand on DTW, so we constrain our focus to approaches and conventions that apply to music processing [3], with a particular focus on techniques that accelerate the algorithm.

There is theory to suggest that in general, $O(N^2)$ computation will always be the worst-case for optimal DTW [7], so many settle for approximate solutions. The so-called "Itakura Parallelogram" [8] and "Sakoe-Chiba Band" [2] were early fixed global alignment restrictions proposed to reduce memory and computation. More adaptive algorithms have also been used to approximate the DTW alignment on audio streams. One popular such example is a recursive multiresolution algorithm known as "FastDTW" [9], which has been used to synchronize orchestral music at large scales [10, 11]. The algorithm computes the warping path of lower resolutions versions of the time series, and then it recursively constrains alignments at finer scales to lie within some band of the lower resolution path. It is guaranteed to have worst case $O(M + N)$ run-time and memory consumption. A similar algorithm, known as "Memory-Restricted MultiScale DTW" (MrMs-DTW) [11] was devised to have constant memory usage, where performance degrades gracefully with a decreasing constant memory, and this technique has proved useful in MIR synchronization applications to pedagogy [12]. We compare to both of these algorithms in Section 4.

Beyond this, researchers have cut down on memory with approximate algorithms that use overlapping blocks [13] and which greedily expand cells to evaluate [14], though, like all of the approximations we've mentioned

Figure 1. A "linear systolic" array for computing the DTW cost. Arrows show dependencies. All elements along a diagonal can be computed in parallel if the diagonals are processed in order from the lower left (dark) to the upper right (light).


so far, they have no worst-case approximation guarantees. The authors of [15] and [16], on the other hand, present some of the only algorithms with worst case guarantees for DTW cost in Euclidean spaces. They achieve linearithmic runtime complexity, with a runtime proportional to the geometric complexity of the time series and inversely proportional to the approximation ratio. There are also several exact algorithms in the literature that use parallel architectures both for DTW [17] and for the related problem Smith-Waterman scoring between gene sequences [18] to speed up computation. We draw on these algorithms in our design in Section 3.1. However, they were designed simply to compute costs/scores, not to extract alignments, so we must build on this work to extract alignments (Section 3.2).

The closest work in spirit to ours is an algorithm for finding the longest common subsequence between strings [19], which also uses a divide and conquer scheme for subproblems that overlap on $O(M)$ cells, yielding an algorithm of $O(MN)$ time complexity and $O(M + N)$ space complexity like ours. However, it does not guarantee a globally optimal solution in the context of DTW [20].

3. OUR ALGORITHM

3.1 Computing the Cost (DiagDTW)

The backbone of our algorithm relies on a different order of filling in sub-problems of the alignment, the hardware implementation of which is an instance of a "linear systolic array" in computer architecture [17, 18]. This part is not yet novel, but it is crucial to our approach, so we review it here. Rather than processing the cells of $D_{X,Y}$ matrix row by row, as in the textbook version, it is also possible to satisfy dependencies needed to complete the recurrences in Equation 2 while filling in $D_{X,Y}$ along diagonals. Figure 1 shows the idea. If the diagonals are processed in order from lower left to upper right, then it follows that all elements on a single diagonal d_k can be computed in parallel from two previous adjacent diagonals d_{k-1} and d_{k-2}. Then, to

Figure 2. Choosing a pivot for the divide and conquer algorithm. At least one element (i, j) on the optimal warping path $\mathcal{W}^*$ resides on one of three central diagonals that overlap from forward and backward computation done halfway, and this element is used to recursively split computation of other warping path points into two halves.

move to the next diagonal, the three diagonal buffers circularly shift; d_k becomes d_{k-1}, d_{k-1} becomes d_{k-2}, and the previous d_{k-2} can be reused as the new as d_k. Since each diagonal has a max length of $\min(M, N)$, this means that one only needs a memory of $3 \min(M, N)$ to maintain such a system of circularly shifting buffers [2]; one never needs to store all of D in memory to compute the optimal cost. Once the algorithm has completed, the optimal cost can be read off as the only element in the last buffer.

Algorithm 1 Diagonal DTW

1: **procedure** DIAGDTW($X, Y, C_{X,Y}$, kstop)   ▷ Time series X and Y with M and N points, a cost $C_{X,Y}$ between them, and the diagonal on which to stop
2:     $d_0 \leftarrow C_{X,Y}(0, 0)$
3:     $d_1[\leftarrow [C_{X,Y}(1, 0) + d_0[0], C_{X,Y}(0, 1) + d_0[0]]$
4:     $d_2 \leftarrow []$
5:     **for** $k = 2$:kstop **do**
6:         Update all elements in d_2 based on d_0 and d_1
7:         $d_0, d_1, d_2 \leftarrow d_1, d_2, d_0$ ▷ Circularly shift
8:     **end for**
9: **return** d_0, d_1, d_2
10: **end procedure**

Algorithm 1 shows a sketch of the process. We refer to this algorithm as *DiagDTW*, and we have implemented it on the GPU using CUDA. For reasons that will become clear in Section 3.2, we take as a parameter $2 \leq$ kstop $\leq M + N - 1$ on which to stop the computation, and we return the states of all three diagonals at that point.

3.2 Extracting Alignment

The linear systolic array provides a way to compute cost, but if we insist on only remembering the most three recent diagonals of backpointers, then there is no obvious way to

---

[2] Ignoring the cost of storing features for the moment

Algorithm 2 Divide And Conquer Linear Memory Dynamic Time Warping (linmdtw)

1: **procedure** LINMDTW($X, Y, C_{X,Y}, m$)   ▷ Time series X and Y with M and N points, cost $C_{X,Y}$ between them, and a minimum dimension m
2:     **if** $M < m$ or $N < m$ **then**
        return DTW($X, Y, C_{X,Y}$)   ▷ Bruteforce path
3:     **end if**
4:     $K \leftarrow M + N - 1$ ▷ Number of diagonals
5:     kstop $\leftarrow \lceil K/2 \rceil$ ▷ Halfway point
6:     $d_{f0}, d_{f1}, d_{f2} \leftarrow$ DiagDTW($X, Y, C_{X,Y}$, kstop)
7:     **if** K is even **then**
8:         kstop $\leftarrow$ kstop $+1$
9:     **end if**
10:     $X_R \leftarrow$ reverse(X), $Y_R \leftarrow$ reverse(Y)
11:     $d_{b0}, d_{b1}, d_{b2} \leftarrow$ DiagDTW($X_R, Y_R, C_{X,Y}$, kstop)
       ▷ $C_{X,Y}(d_{fk})$ is all costs along the kth forward diag
12:     $d_0 \leftarrow d_{f0} +$ reverse(d_{b2}) $- C_{X,Y}(d_{f0})$
13:     $d_1 \leftarrow d_{f1} +$ reverse(d_{b1}) $- C_{X,Y}(d_{f1})$
14:     $d_2 \leftarrow d_{f2} +$ reverse(d_{b0}) $- C_{X,Y}(d_{f2})$
15:     $(i, j) \leftarrow$ argmin index in d_0, d_1, d_2
16:     Now recursively compute other points on $\mathcal{W}^*$
17:     LPath $\leftarrow$ linmdtw($X(1, 2, ..i), Y(1, 2, ..j), C, m$)
18:     RPath $\leftarrow$ linmdtw($X(i, i + 1, ..M), Y(j, j + 1, ..N), C, m$)
19: **return** LPath $+$ RPath($2, 3, ...$) ▷ Don't double count common point on overlapping sub-paths
20: **end procedure**

---

recover all of the backpointers to reconstruct an optimal warping path under $O(M + N)$ memory constraints. Instead, we make the following two observations, which we use to build a different algorithm from standard backtracing which works in a memory-restricted setting:

Lemma 1. *For any warping path $\mathcal{W}$ and any adjacent set of 3 diagonals, at least one element of $\mathcal{W}$ is incident on one of the three diagonals.*

This follows directly from the definition of a warping path in Section 2.1. We also have the following observation

Lemma 2. *Let $\mathcal{W}^*$ be an optimal warping path and $(i, j) \in \mathcal{W}^*$, and let X_R and Y_R be the time series X and Y in reverse order, respectively. Then the cost of the warping path $\mathcal{W}^*$ can be broken into three parts as follows*

$$C_{X,Y}(i, j) + C_{X_R, Y_R}(M - i + 1, N - j + 1) - D_{X,Y}(i, j) \tag{4}$$

This is depicted by the overlapping boxes in Figure 2. In other words, the total cost is the optimal cost of aligning the first half of the path from $(0, 0)$ up to and including (i, j), plus the optimal cost of aligning second half of the path from (i, j) up to and including $(M - 1, N - 1)$, minus the distance from X_i to Y_j (so we don't double count that distance where they overlap). This follows from the fact that warping paths must start and end at the beginning and

end of each time series (so each sub-path is forced to touch (i, j)), and the fact that reversing both time series has no effect on the optimal cost. This is similar to the observation used in MrMsDTW to break up computation into smaller parts [11].

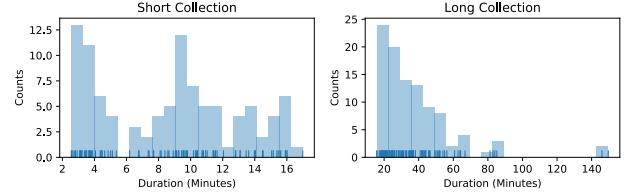
Now we are ready to present the divide and conquer algorithm to compute an optimal warping path $\mathcal{W}^*$. Lemma 1 and Lemma 2 together imply that if we trace the first half of the diagonals in a forward direction and the second half of the diagonals in the reverse direction and add them up pointwise where they meet at the center, subtracting off the distance at those points, then at least one element (i, j) on the three diagonals will contain the optimal cost $C(M, N)$. Furthermore, since this cost occurs on the optimal path, it will by definition be the *minimum cost* over all pointwise sums. Therefore, to find a point towards the center of $\mathcal{W}^*$, we simply do the following

1. Run Algorithm 1 halfway in the forward direction, starting at the beginning

2. Run Algorithm 1 halfway in the reverse direction, starting at the end

3. Perform the sums in Equation 4 where they overlap

4. Take the indices (i, j) of the value that achieves the minimum over all three diagonals (breaking ties arbitrarily, the result of which we explore in Section 4.2)

.


We refer to (i, j) as the "pivot" at this step, and we are guaranteed that (i, j) resides on $\mathcal{W}^*$. At this point, we divide the problem in half at the pivot and find two more points on the warping path to the left and right, which is the recursive step. Algorithm 2 summarizes this process.

Because Algorithm 2 calls DiagDTW as a subroutine and DiagDTW uses $3 \min(M, N)$ memory, Algorithm 2 also uses at most $3 \min(M, N)$ memory. What is slightly less obvious, but still fairly straightforward to show, is that a serial version of the algorithm takes $O(MN)$ time. To see this, parameterize the diagonal by a variable x, where $x = 0$ at the center of the central diagonal, then the total area of the sub-block to the left of the chosen pivot and to the right of the chosen pivot is bounded from above by the following sum of two products

$$A(x) = \left(\frac{M}{2} + x + 1 \right) \left(\frac{N}{2} - x + 1 \right) \quad (5)$$

$$+ \left(\frac{N}{2} + x + 1 \right) \left(\frac{M}{2} - x + 1 \right) \quad (6)$$

Then, $A'(x) = -4x$, and $A''(x) = -4$, so a global maximum occurs at $x = 0$, for an area of $A(0) = M^2 N^2 / 2 + M + N$. In other words, ignoring the edge effects $M + N$ due to the overlap, at most half of the total cells are processed across the two halves of each recursive split. This leads to the recurrence $MN(1 + \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + ...)$, which is bounded from above by $2MN$. To understand the

Figure 3. The distribution of lengths of our orchestral pieces in the short collection and long collection.

edge effects, we note the following: since the number of diagonals, $M + N - 1$, can be subdivided $\log_2(M + N)$ times, this leads to a bound of $(M + N) \log_2(M + N)$, for a total worst-case cost of

$$2MN + (M + N) \log_2(M + N) \quad (7)$$

However, the $2MN$ term will usually swamp the $(M + N) \log_2(M + N)$, unless one of M or N is very small (e.g $M = 1$, in which case it's simply subdividing an interval of length N repeatedly $\log_2(N)$ times). In practice, we parallelize the DiagDTW step on a GPU, so the algorithm runs faster than this. We also keep track of the number of cells processed, and we assume $2MN$ to indicate progress of the the algorithm to the user.

Finally, to save the overhead of initiating too many small GPU alignments, we break off the recursion when the sub-blocks get small enough (Line 2, Algorithm 2). In practice, if either length of of the subdivided time series goes below 500, we use the textbook DTW algorithm to complete the alignment, which uses an insignificant amount of computation and memory at that scale.

4. EXPERIMENTS

Now that the theory for our algorithm has been established, we apply it to align real audio data. We created a dataset with 100 pairs of mostly orchestral pieces, where each pair is performed under different conductors. All of the performances can be found on Youtube, and we provide code to automatically download them for reproducibility [3]. We do not have access to human annotated alignments, but since we can compute exact costs with linear memory, we can use our exact paths to assess the precision of approximate algorithms at very large scales to get an idea of how they perform in that regime. To that end, we split our dataset into two parts. The first 50 pairs are "shorter" pieces that can be handled (albeit sometimes slowly) by the textbook CPU DTW algorithm. The second set are pieces that would quickly use up all memory with the textbook algorithm on a personal computer, including many pieces around an hour or longer. Figure 3 shows the distribution of the lengths of pieces in both sets.

4.1 Features

So far, our discussion has assumed that we had access to some distance function $D_{X,Y}$ between time series X and

---

[3] If any links go down, the code is robust to that and will simply skip those examples

Table 1. Memory requirements of the dynamic programming accumulated cost cells for different algorithms on some of the pieces in our dataset. DTW refers to the naive algorithm, while FastDTW refers to the algorithm in [9] using a band width of $\delta = 30$. The memory requirements for MrMsDTW for 10^5 and 10^7 constant cells is 391KB and 38Mb, respectively

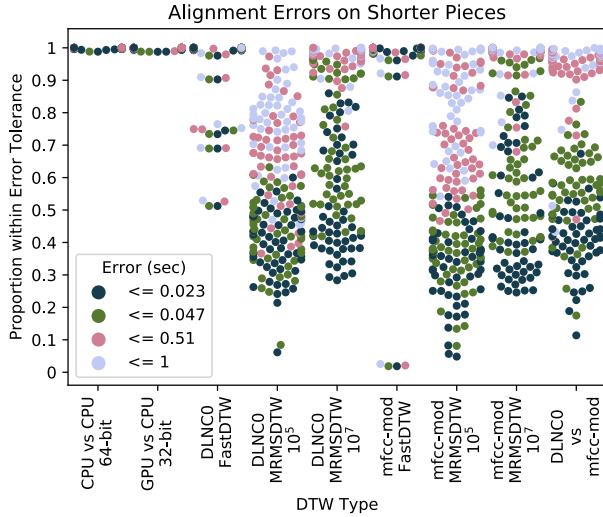
Piece	Version 1	Version 2	DTW	FastDTW	Ours
Vivaldi Spring	Abbado (188 sec)	Gunzenhauser (209 sec)	277 MB	3.86 MB	194 KB
Candide Overture	Bernstein (268 sec)	Dudamel (279 sec)	527 MB	5.5 MB	270 KB
Beethoven. Symph. No.5	Thielemann (445 sec)	Bernstein (514 sec)	1.58 GB	9.12 MB	448 KB
Schumann - Symph. No. 3	Bernstein (2124 sec)	Muti (2199 sec)	23.2 GB	36.9 MB	1.77 MB
Stravinsky The Rite of Spring	Rattle (2053 sec)	Bernstein (2082 sec)	29.4 GB	42.1 MB	2.02 MB
Tchaikovsky Symph. No. 4	Bernstein (2645 sec)	Rozhdestve.. (2530 sec)	46.1 GB	51.9 MB	2.48 MB
Shostakovich: Symph. No. 11	Søndergård (3647 sec)	Nelsons (3765 sec)	94.6 GB	74.8 MB	3.6 MB
Verdi Requiem	Bychkov (4983 sec)	Solti (5042 sec)	173 GB	102 MB	4.9 MB
Wagner - Das Rheingold	Kuhn (8799 sec)	Solti (8759 sec)	542 GB	180 MB	8.6 MB

Y. We now finally describe two different features sets that allow us to compute distances for synchronization, which we use in our experiments. The first set of features are the so-called "decaying locally adaptive normalized C0" (DLNC0) features [21], which are popular for fine scale alignments [4]. The second set of features are referred to as "mfcc-mod" features, which consist of a large number of MFCC coefficients, throwing away the lower order ones to control for loudness. These features were shown to work well at precisely capturing human annotations [22].

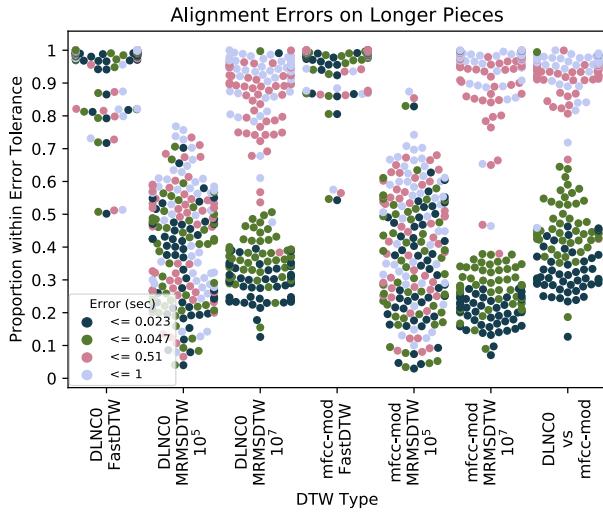
For both feature sets, we sampled audio at 22050hz, and we used a hop size of 512 between feature frames. This corresponds to about 43 frames per second of resolution. For the DLNC0 features, we used librosa's implementation of the CQT with default parameters as a starting point [23]. The DLNC0 features were concatenated to a 0.1 factor of CENS features to improve stability in steady-state regions, as suggested in [21]. For the mfcc-mod coefficients, we used an fft-length of 2048 and computed 120 "HTK" coefficients, leaving the first 20 out. Although [21] recommends using cosine distance for the DNLC0 component, we found lower discrepancies using the Euclidean distances as our measure across the board on all of our features.

4.2 Numerical Precision / Tie Breaking

Since our algorithm is on the GPU, we revert to 32-bit computations, and there is a worry that numerical precision could cause discrepancies, especially since the numbers along warping paths are summed together in a different order in our algorithm, and ties are broken at a different stage. To rule this out as a source of error when comparing approximation precisions, we compare our GPU answer to the brute force 32-bit CPU answer on the textbook algorithm. We also compare two different tie breaking rules on 64-bit CPU brute force implementations; one where diagonal takes precedence over left, and one the other way around. Ultimately, though there are discrepancies, they are negligible compared to errors in approximation, as shown in Figure 4. And the 32-bit versus 64-bit appears to make little difference at these scales.

---


[4] Unlike [10], we do not use a multiscale version of DLNC0, since we are assessing approximations of exact alignments at a single scale

4.3 Memory Requirements


We compare our alignments to both FastDTW [9] with a band $\delta = 30$ and to MrMsDTW using a constant amount of 10^5 and 10^7 cells. To make Equation 4 more convenient to compute in our implementation, we store the distances between corresponding points on the three diagonals in addition to the cumulative sums, so we end up using $6 \min(M, N)$ storage instead of $3 \min(M, N)$ storage. Still, we note that 10^7 cells is an order of magnitude beyond this requirement, while 10^5 cells is on the shorter end of what our algorithm needs on the short dataset, so these are two good reference points for MrMsDTW. To compare memory with FastDTW, we use the equation from [9] which states that the total worst-case space complexity for storing the cells is $N(4\delta + 5)$ values. Hence, though FastDTW also has linear memory requirements, it has a larger constant factor, particularly for reasonable band sizes ($\delta = 30$ is less than a second of wiggle room). Table 1 shows the memory requirements for storing the cells for different algorithms with variable memory, assuming 32-bit precision (4 bytes per cell). This neglects the memory for storing the warping path, which is negligible compared to the cost of storing the accumulated cost cells, and it also neglects the memory requirements of storing features, which is a separate issue mostly independent of the algorithms, since these are all run offline. Still, the memory differences are striking.

4.4 Results

We now examine the results closely. We computed the alignment discrepancies between two warping paths $\mathcal{W}_1$ and $\mathcal{W}_2$ as follows. For every element $(i, j) \in \mathcal{W}_1$, we report the error as $\min |j - k|$ for $(i, k) \in \mathcal{W}_2$. To maintain symmetry, we also add an analogously defined column error to our distributions for every element. Figure 4 shows the approximation error distributions for different algorithms on all of the shorter pieces, including tie breaking discrepancies on the exact algorithm (Section 4.2), while Figure 5 shows approximation errors on all of the longer pieces. In each figure for each pairwise comparison, there are four different color dots per piece that indicate the proportion of correspondences (i, j) that fall below the alignment discrepancies (23 ms, 47 ms, 510ms, and 1 second).

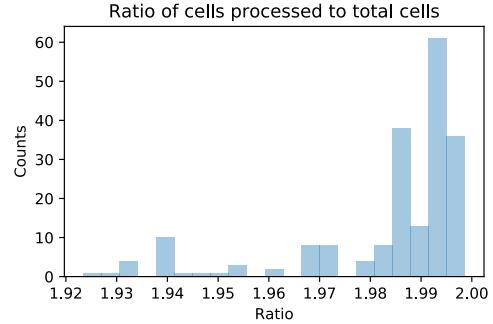
Figure 4. Shorter pieces alignment errors.


Figure 5. Longer pieces alignment errors.

Overall, we find that the approximation algorithms often fail to agree at very fine scales, but they usually agree to within a second of audio, which is particularly impressive on the long pieces. And unsurprisingly, MrMsDTW performs better with more memory.

In addition to approximation errors, we also show the discrepancy between the mfcc-mod and DLNC0 feature sets for reference. Interestingly, their discrepancy is similar to that of approximation with MrMsDTW, suggesting that feature design is at least as important as a good approximation. However, under a good feature choice at a fine scale, it is likely that our exact algorithm will give the most desirable alignment.

Finally, to empirically validate the correctness of our computational complexity bound in Section 3.2, we report the ratio of cells processed to total cells in the full accumulated cost matrix in Figure 6 across all pieces, and we find that the ratio is very close to 2 in all cases, as predicted. Only under very extreme warps away from the center of the matrix would one expect this to be much smaller.

Figure 6. In most cases, our algorithm uses close to the factor of 2 bound we established for computation in Section 3.2

5. SOFTWARE

Since some of the details of linmdtw (Algorithm 2) are tricky to implement correctly, and in the spirit of reproducibility [24], we have provided our CPU and GPU (pycuda) implementations of linmdtw, FastDTW, and MrMsDtw in an open source package at `https://github.com/ctralie/linmdtw`, which can be installed simply with "pip install linmdtw". We have documentation and Jupyter notebooks on the repo for example usage. The software will try run CUDA by default, but if it fails, it will fall back to the CPU implementation. There is also code to replicate the experiments in Section 4 by downloading URLs from Youtube, robustly skipping those no longer available. Finally, we used the Rubberband Library [25] and implemented the refinement technique of Ewert (Section 4 of [26]) to stretch audio to conform to warping paths.

6. DISCUSSION

In this paper, we presented a novel exact memory efficient algorithm for DTW. In addition establishing this new algorithm and proving its correctness, we empirically benchmarked a couple of popular approximation algorithms for DTW alignment in MIR at larger scales than had ever been shown. We found that these algorithms still have fairly good performance with reference to an exact alignment even on longer pieces. MrMsDTW is particularly fast computationally, so this suggests that it's good as a first stop in many cases, though there are outliers, and there are always quality gains to be had for an exact algorithm.

Furthermore, though the focus of this paper was on memory constraints, our vanilla GPU implementation also led to speed increases over the textbook CPU version and had similar but slightly slower runtimes than FastDTW. However, a better GPU implementation would treat global and local memory with more care, along with addressing myriad other issues [27], so we do not believe this algorithm has yet reached its full computational potential.

There are also other computational problems with very similar dynamic programming design DTW, such as edit distance and Smith Waterman [6], which could benefit from the ability to align large sequences under memory restrictions. Even approximate DTW algorithms may benefit from tricks in this paper.

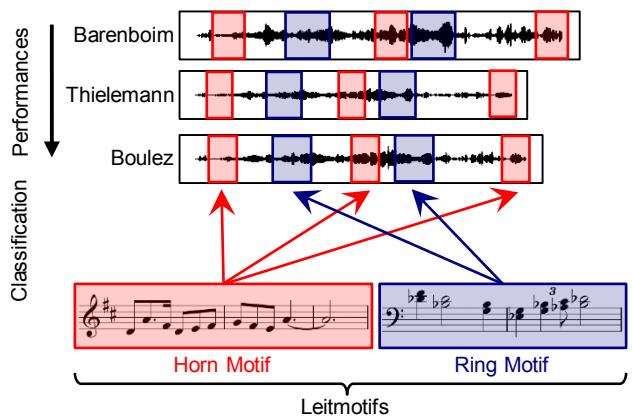
Paper Session 4

CLASSIFYING LEITMOTIFS IN RECORDINGS OF OPERAS BY RICHARD WAGNER

Michael Krause, Frank Zalkow, Julia Zalkow, Christof Weiß, Meinard Müller

International Audio Laboratories Erlangen, Germany

{michael.krause,meinard.mueller}@audiolabs-erlangen.de


ABSTRACT

From the 19th century on, several composers of Western opera made use of *leitmotifs* (short musical ideas referring to semantic entities such as characters, places, items, or feelings) for guiding the audience through the plot and illustrating the events on stage. A prime example of this compositional technique is Richard Wagner's four-opera cycle *Der Ring des Nibelungen*. Across its different occurrences in the score, a leitmotif may undergo considerable musical variations. Additionally, the concrete leitmotif instances in an audio recording are subject to acoustic variability. Our paper approaches the task of classifying such leitmotif instances in audio recordings. As our main contribution, we conduct a case study on a dataset covering 16 recorded performances of the *Ring* with annotations of ten central leitmotifs, leading to 2403 occurrences and 38448 instances in total. We build a neural network classification model and evaluate its ability to generalize across different performances and leitmotif occurrences. Our findings demonstrate the possibilities and limitations of leitmotif classification in audio recordings and pave the way towards the fully automated detection of leitmotifs in music recordings.

1. INTRODUCTION

Music has long been used to accompany storytelling, from Renaissance madrigals to contemporary movie soundtracks. A central compositional method is the association of a certain character, place, item, or feeling with its own musical idea. This technique culminated in 19th century opera where these ideas are denoted as *leitmotifs* [1, 2]. A major example for the use of leitmotifs is Richard Wagner's tetralogy *Der Ring des Nibelungen*, a cycle of four operas [1] with exceptional duration (a performance lasts up to 15 hours) and a continuous plot spanning all four operas. As many characters or concepts recur throughout the

---

[1] While Wagner referred to his works as *music dramas* instead of operas, we choose the more commonly used latter term.

Figure 1. Illustration of example leitmotifs (red for the Horn motif, blue for the Ring motif) occurring several times in the Ring cycle and across different performances.

cycle, so do their corresponding leitmotifs. This allows the audience to identify these concepts not only through text or visuals, but also in a musical way. While all these different *occurrences* of a leitmotif in the score share a characteristic musical idea, they can appear in different musical contexts and may vary substantially in compositional aspects such as melody, harmony, key, tempo, rhythm, or instrumentation. When considering recorded *performances* of the *Ring*, another level of variability is introduced due to acoustic conditions and aspects of interpretation such as tempo, timbre, or intonation. In the following, we denote the concrete realization of a leitmotif in an audio recording as an *instance* of the motif. This paper approaches the problem of classifying such leitmotif instances in audio recordings, as illustrated in Figure 1. In particular, we study generalization across occurrences and performances.

Cross-version studies on multiple performances have been conducted regarding the harmonic analysis of Beethoven sonatas [3] or Schubert songs [4], but also for the *Ring* [5, 6]. Beyond harmonic aspects, the *Ring* scenario was considered for capturing audience experience using body sensors and a live annotation procedure [7] or for studying the reliability of measure annotations [8, 9]. Regarding leitmotifs, several works have focused on the human ability to identify motifs [10–12]. In particular, [13] found that distance of chroma features correlates with difficulty for listeners in identifying leitmotifs. In [6], Zalkow et al. presented a framework for exploring relationships between leitmotif usage and tonal characteristics of the *Ring*.

Name (English translation)	ID	Score	# Occurrences	Length Measures	Seconds
Nibelungen (Nibelungs)	L-Ni		536	0.96 ± 0.23	1.72 ± 0.50
Ring (Ring)	L-Ri		286	1.49 ± 0.65	3.64 ± 2.30
Mime (Mime)	L-Mi		242	0.83 ± 0.25	0.87 ± 0.24
Nibelungenhass (Nibelungs' hate)	L-NH		237	0.96 ± 0.17	3.10 ± 1.11
Ritt (Ride)	L-RT		228	0.66 ± 0.17	1.24 ± 0.37
Waldweben (Forest murmurs)	L-Wa		223	1.10 ± 0.30	2.70 ± 0.76
Waberlohe (Swirling blaze)	L-WL		190	1.21 ± 0.39	4.39 ± 1.60
Horn (Horn)	L-Ho		172	1.38 ± 1.05	2.44 ± 1.57
Geschwisterliebe (Siblings' love)	L-Ge		155	1.31 ± 0.83	3.03 ± 2.55
Schwert (Sword)	L-Sc		134	1.89 ± 0.55	3.68 ± 1.88

Table 1. Overview of the leitmotifs used in this study. Lengths are given as mean and standard deviations over all annotated occurrences (in measures) or instances (in seconds) from all performances given in Table 2.

From a technical perspective, our scenario entails the task of automatically detecting leitmotifs within an audio recording. This paper represents a first step towards this goal by considering a simplified classification scenario with pre-segmented instances (see Figure 1).

Due to the multiple sources of variability described above, we opt for a data-driven approach. Neural networks have emerged as the dominant classification models. In particular, recurrent neural networks (RNNs) are able to handle input sequences of varying length. Our study shows that despite the difficulties of the scenario, an RNN classifier is surprisingly effective in dealing with the variability across occurrences and performances.

The main contributions of our work are as follows: We conduct a case study on classifying leitmotif instances in audio recordings of the *Ring*. For this, we describe the task of leitmotif classification and provide a dataset of more than 38000 annotated instances within 16 performances of the *Ring* (Section 2). We further build an RNN model for classifying leitmotifs in audio recordings (Section 3). We carefully evaluate our model with respect to variabilities across performances and leitmotif occurrences over the course of the *Ring*. Moreover, we investigate the effect of adding temporal context and critically discuss the potential limitations and generalization capabilities of our classifier (Section 4). Finally, we suggest new research directions that may continue our work (Section 5).

2. SCENARIO

We now discuss the dataset and leitmotif classification scenario underlying our experiments.

2.1 Leitmotifs in Wagner's Ring

While Wagner mentioned the importance of motifs for his compositional process [14], he did not explicitly specify the concrete leitmotifs appearing in the *Ring*. Whether a recurring musical idea constitutes a leitmotif—and how to name it—is a topic of debate even among musicologists, see, e. g., [15] where differences in leitmotif reception are discussed. In line with [6], we follow Julius Burghold's specification of more than 130 leitmotifs in the *Ring* [16].

For our experiments, we selected ten central motifs frequently occurring throughout the *Ring* (see Table 1 for an overview including the number of occurrences per motif). These motifs constitute the classes of our classification task. The selection comprises motifs associated with an item such as the sword (L-Sc), with characters such as the dwarf Mime (L-Mi), or with emotions such as love (L-Ge). All occurrences of these motifs were annotated by a musicologist using a vocal score of the *Ring* as a reference, resulting in 2403 occurrences.

As discussed in Section 1, a leitmotif may occur in different shapes over the course of a drama. These musical variations may be necessary to fit the musical context in which the occurrences appear and, thus, be adjusted to the

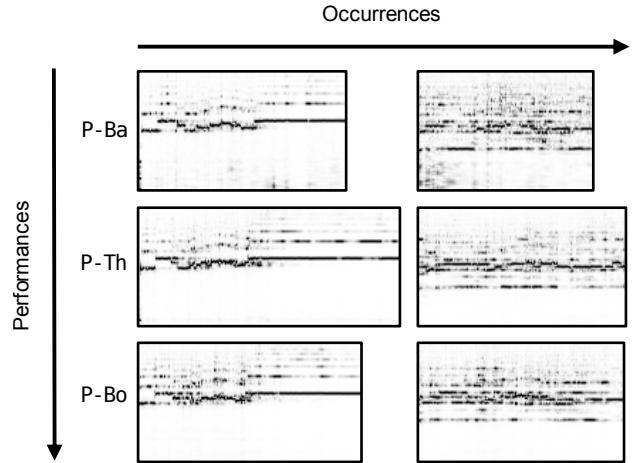
Table 2. Recorded performances of the *Ring* used in this study (see also [6]). Measure positions have been annotated manually for the topmost three performances (P-Ba, P-Ha and P-Ka), which also constitute the test set in our performance split. The three middle performances (P-Sa, P-So and P-We) constitute the validation set.


current key, meter, or tempo. Moreover, occurrences of leitmotifs may appear in different registers, musical voices, or instruments. In addition to this, motifs can also occur in abridged or extended shape, with parts of the motif being repeated, altered, or left out. Despite these diverse musical variations across occurrences, listeners can often identify motifs easily when listening to a performance. This is in line with Wagner's intention of using the motifs as a guideline, thus forming the musical surface of the *Ring* [17].

2.2 Recorded Performances

As mentioned in the introduction, we do not attempt to classify leitmotifs within a score representation but on the basis of a performance given as an audio recording. To be more concrete, our work relies on 16 recorded performances of the *Ring* that have been used before in [6]. For three of these performances, the positions of measures from the score were manually annotated in the audio [8]. For the remaining 13 performances, the measure positions were transferred from the manually annotated performances using automatic audio-to-audio synchronization [9]. Table 2 specifies the performances. We automatically located the 2403 leitmotif occurrence regions from the score in each of the 16 recorded performances using linear interpolation between measure positions. This way, we obtained the 38448 instances used for our experiments. The occurrence and instance positions are made publicly available as a dataset for further research. [2]

2.3 Leitmotif Classification Task

In this paper, we consider the task of leitmotif classification. We define this as the problem of assigning a given audio excerpt to a class according to the occurring leitmotif. Here, we consider ten classes corresponding to the mo-

[2] https://www.audiolabs-erlangen.de/resources/MIR/2020-ISMIR-LeitmotifClassification

Figure 2. Variability of L-Ho across occurrences and performances. Six instances (two occurrences for three performances) are shown in a CQT representation, which is also used as input to our classification model.

tifs in Table 1. We further make the simplifying assumption that only a single leitmotif is played at a time. Thus, we omit excerpts where multiple motifs occur simultaneously. Our classification task therefore becomes a multi-class, single-label problem.

Our dataset allows us to approach the leitmotif classification task from two perspectives, each of which incorporates its own types of variabilities. First, the *performance* perspective concerns variabilities across different performances, resulting from different instrumental timbres, tempi, or other decisions made by the artists. Furthermore, this perspective encompasses technical properties such as acoustic, recording, and mastering conditions, which can lead to the so-called "album effect" [18]. Second, the compositional or *occurrence* perspective concerns diverse musical variabilities of leitmotif occurrences in the score (as discussed in Section 2.1). Figure 2 shows the Horn motif L-Ho for different performances and occurrences. The variability is evident in different durations of the instances as well as different energy distributions due to other musical events sounding simultaneously. These variabilties make our classification task a challenging problem. In our experiments, we investigate the generalization across these two perspectives, similar to the study in [4].

3. RECURRENT NEURAL NETWORK FOR LEITMOTIF CLASSIFICATION

Neural networks have previously proven to be useful for classification tasks in the music domain, see, e. g., [19–21]. As we are dealing with variable length inputs (leitmotif instances may last from less than one to over ten seconds in a performance), recurrent neural networks (RNNs) are a natural choice for our scenario.

As input to our system, we take audio excerpts containing leitmotif instances from our 16 performances of the *Ring*, sampled at 22050 Hz. These excerpts are processed by a constant-Q-transform (CQT) [22, 23] with semitone resolution over six octaves and a hop length of 512 sam-

Layer	Output Shape	Parameters

Mean	0.94	0.94	0.94	0.93	0.91	0.92	0.93	0.92	0.93

Table 4. Main results of our method on the test set of the performance split for different strategies of using temporal context.

ples, where we adjust for tuning deviations (estimated automatically per performance and opera act). These steps are implemented using librosa [24]. Finally, all CQT frames are normalized using the max-norm and the resulting representations serve as inputs to our network.

Table 3 gives an overview of the network structure. We use an RNN-variant, the long short-term memory (LSTM) proposed in [25]. We stack multiple LSTM layers and, after the final LSTM output, append batch normalization [26] as well as a single fully connected classification layer to obtain leitmotif predictions. We set the number of LSTM layers and the size of their internal representation to 3 and 128, respectively. We train this network for 50 epochs by minimizing the cross-entropy loss between predictions and correct classes using the Adam optimizer [27] with a learning rate of 0.001 on mini-batches of 32 excerpts. Since the excerpts in a batch may have different lengths, we need to zero-pad them to the maximum number of frames among excerpts in that batch. During computation, we then use masking to ignore zeros added to shorter inputs. We further avoid overfitting by selecting the weights of the epoch that yields the highest mean F-measure on the validation set (as described in Section 4.2). The network is implemented in Python using Tensorflow.

4. EXPERIMENTS

4.1 Setup and Splits

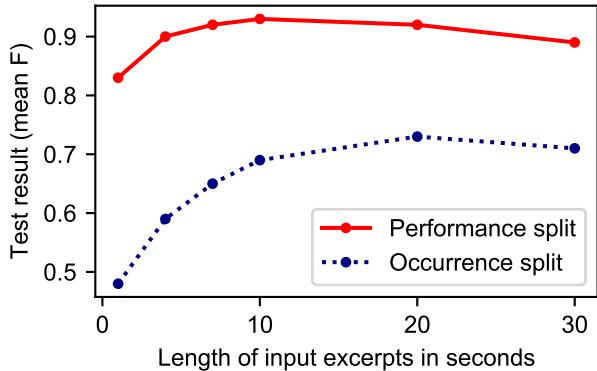
We follow the common machine learning approach of partitioning our dataset into training, validation, and test subsets to train, tune hyperparameters, and estimate the results on unseen samples, respectively. In contrast to standard procedures, we partition the data according to musical aspects as motivated in Section 2.3. We will consider two splits: the performance and occurrence splits.

For the performance split, we select the three recordings with manually annotated measure positions (P-Ba, P-Ha and P-Ka, see Table 2) for the test set and three performances with automatically transferred measure positions for the validation set (P-Sa, P-So and P-We). The remaining ten performances are used for training. In this split, all subsets comprise all occurrences of all motifs. Results on the performance split are given in Section 4.3.

In contrast, for the occurrence split, we randomly choose 80% of the occurrences for training and 10% each

for the validation and test set. [3] We further ensure that the proportions of occurrences for each motif is the same in all subsets. In this split, each subset contains all instances of the occurrences in that subset. Results on the occurrence split are given in Section 4.4.

4.2 Evaluation Measures

We adopt standard measures from information retrieval for evaluating our models. For a given class (i. e., motif), we treat the classification problem as a retrieval problem, yielding class-dependent precision (P), recall (R), and F-measure (F) as usual, see, e. g., [28].


We also report the mean precision, recall, and F-measure over all classes. This gives a general impression of the classification quality. Note that these averages are not affected by class imbalance. Therefore, low results on an infrequent class will influence the mean results as much as low results on a frequent class.

4.3 Results on the Performance Split

Basic Experiment. The left block in Table 4 (*Strict*) summarizes results for our model on the test subset of the performance split. We obtain high classification results with a mean F-measure of 0.94. Results are similar across motifs. Highest precision (P = 0.98) is obtained for L-WL, while highest recall (R = 0.98) is reached for L-Wa. Recall and precision per motif are often similar. We conclude that it is indeed possible to classify leitmotif instances in previously unseen performances, provided that all occurrences were seen before in other performances. In the following, we expand on this result by considering other classification and split scenarios.

Temporal Context. In our basic experiment, we considered isolated leitmotif instances as input to our classification model, i. e., the audio excerpts to be classified start and end strictly at instance boundaries. We therefore call this the *Strict* scenario. Identifying leitmotifs when instance boundaries are not known in advance could pose an additional challenge. However, the temporal context before and

---

[3] The same occurrences are chosen in all experiments for comparability.

Figure 3. Mean F-measures for our model when using different input lengths in the *Fixed* scenario.

Context	*Strict*			*Variable*			*Fixed* (10 sec.)		
	P	R	F	P	R	F	P	R	F
L-Ni	0.67	0.80	0.73	0.67	0.86	0.75	0.80	0.91	0.85
L-Ri	0.36	0.41	0.38	0.44	0.43	0.43	0.49	0.67	0.56
L-Mi	0.79	0.87	0.83	0.82	0.80	0.81	0.97	0.96	0.97
L-NH	0.72	0.20	0.31	0.62	0.25	0.36	0.92	0.32	0.47

L-Ge	0.28	0.30	0.29	0.38	0.43	0.40	0.58	0.68	0.63
L-Sc	0.52	0.50	0.51	0.64	0.53	0.58	0.76	0.58	0.66
Mean	0.55	0.53	0.52	0.57	0.57	0.56	0.73	0.71	0.69

Table 5. Main results of our method on the test set of the occurrence split for different strategies of using temporal context.

after the instance boundaries might also be helpful in identifying the class of an excerpt. Next, we analyze the effect of temporal context on the leitmotif classification results.

To this end, we compare the *Strict* scenario with an alternative, called *Variable*, where we add a randomly chosen amount of temporal context to the input excerpts. Context may be added before and after the motif instance. More specifically, the excerpt length is at most doubled and the instance in question is not constrained to be in the excerpt center. Such use of context also prevents our model from relying on length and boundary properties of the leitmotif instances. The center block in Table 4 gives results for this scenario. Compared to the *Strict* case, the mean F-measure decreases slightly to 0.92.

We also perform experiments on fixed input lengths, which we call the *Fixed* scenario. Here, we randomly take subsections of an instance if it is longer than the fixed input length or add context before and after in case it is shorter. Mean F-measure values for different fixed input lengths are shown in Figure 3 (solid red line). The plot indicates that results decrease for lengths that are shorter than most instances,[4] e. g., one second. When a fixed length of ten seconds is chosen, which encompasses almost all instances in the dataset, results are comparable to the *Strict* case (see also the right block in Table 4). Longer inputs again yield lower results, which may be attributed to the difficulty posed by additional context. However, one should note that for such large durations, input excerpts are no longer guaranteed to contain instances of a single motif only and thus, our initial assumption on a single label per input may be violated.

In Section 5, we discuss how the results for different amounts of temporal context may be interpreted in the context of a leitmotif detection scenario.

Potential for Overfitting. Deep learning models often rely on features of the input that would be deemed task-irrelevant by human experts, see, e. g., [29, 30]. In our case, the correct class for each input may be inferred not only from musically relevant aspects of leitmotifs such as melody or rhythm (as given in Table 1), but also from confounding features of the excerpts such as instrument activ-

ity or volume. This is especially true for the performance split, where a classification model may predict correct outputs on the test set by merely memorizing all occurrences during training instead of distinguishing musically relevant features of the leitmotifs (we will revisit this possibility in Section 4.6). In contrast, for the occurrence split, the model needs to generalize to previously unseen realizations of the leitmotif classes and therefore needs to rely on their common musical characteristics.

4.4 Results on the Occurrence Split

Table 5 presents results for the occurrence split with different strategies for adding temporal context. Overall results are lower than for the performance split. In the *Strict* scenario, the obtained mean F-measure of 0.52 is substantially lower than for the performance split, but still well above chance (which corresponds to 0.1 mean F-measure). Results vary considerably among motifs, with F-measures ranging from 0.23 for L-WL to 0.84 for L-Wa. In addition, the differences between precision and recall per motif can be large as in the case of L-NH (P = 0.72 and R = 0.20). We conclude that classifying leitmotif instances for unknown occurrences is challenging but possible.

We further observe that—in contrast to the performance split—context is beneficial in the occurrence split. Mean F-measures of the *Variable* and *Fixed* scenarios increase to 0.56 and 0.69, respectively. Figure 3 shows F-measures for different amounts of context in the occurrence split (dotted blue line). Results increase for excerpt lengths up to ten seconds and then stabilize. We see two potential reasons for this. Firstly, by training with temporal context, the classifier may learn to identify features that indicate instance starts and ends, which could be helpful for identifying instances in the test set. Secondly, however, longer temporal context also means that instances from the training set may occur in the context added to validation and test instances. Indeed, we observed that for a context length of 10 seconds, 67% of test excerpts overlap with a training instance of the same class, while 8% overlap with a training instance of another class. Predicting the class of known training occurrences would therefore yield good results on

---

[4] Statistics on instance lengths are given in Table 1 (rightmost column).

Split	Performance			Occurrence		
	P	**R**	**F**	**P**	**R**	**F**
Noise	0.90	0.87	0.89	0.32	0.36	0.34
L-Ni	0.90	0.95	0.93	0.63	0.74	0.68
L-Ri	0.89	0.89	0.89	0.28	0.32	0.30
L-Mi	0.94	0.93	0.94	0.78	0.75	0.76
L-NH	0.95	0.88	0.91	0.52	0.28	0.37
L-RT	0.93	0.93	0.93	0.54	0.73	0.63
L-Wa	0.93	0.96	0.94	0.79	0.79	0.79
L-WL	0.94	0.93	0.94	0.17	0.12	0.14
L-Ho	0.89	0.87	0.88	0.40	0.45	0.42
L-Ge	0.91	0.91	0.91	0.20	0.18	0.19
L-Sc	0.90	0.95	0.93	0.68	0.38	0.49
Mean	0.92	0.92	0.92	0.48	0.46	0.46

Table 6. Results of our method when incorporating a noise class in the performance and the occurrence split. No temporal context is added (*Strict* scenario).

the test set. The results for adding temporal context may thus partly be explained by overfitting to the training set.

4.5 Noise Class

So far, we only considered excerpts that contain one of ten leitmotifs. However, the *Ring* also contains regions with other or with no leitmotifs at all. Because of this, we also perform experiments with an additional Noise class, denoting excerpts where none of the leitmotifs in our selection are being played. We evaluate whether our model is able to correctly classify our selection of leitmotifs in the presence of this noise class, both for the performance and the occurrence split. To do so, we randomly select 400 Noise occurrences from the *Ring*, leading to 6400 Noise instances. The model described in Section 3 remains unchanged except for the final classification layer, which now has eleven outputs.

Results are given in Table 6. For the performance split, the additional noise class does not change results by much. Leitmotif classes obtain somewhat lower results (e. g., P = 0.90 for L-Ni compared to P = 0.94 in Table 4) while the noise class yields an F-measure lower than most leitmotif classes (F = 0.89). For the occurrence split, results for the leitmotif classes again decrease slightly (e. g. P = 0.63 for L-Ni compared to P = 0.67 in Table 5), while the noise class itself is especially hard to distinguish (F = 0.34). In both splits, the noise class does not lead to a complete deterioration of results. Section 5 discusses the implications of this for the task of leitmotif detection.

4.6 Random Labels

In all experiments, our model has consistently obtained higher results on the performance than on the occurrence split. As discussed at the end of Section 4.3, the latter split requires generalizing to new musical realizations of a motif. In contrast, the performance split could be tackled by memorizing all leitmotif occurrences, which is not possible on the occurrence split.

To further investigate the gap in results between performance and occurrence split, we now evaluate our model's capability to memorize input features on the performance

split. To do so, we create a variant of the performance split where we assign a random class label from one to ten to each occurrence. Thus, while occurrences are labeled consistently across performances, their classes no longer correspond to leitmotifs. In this variant of the performance split, the class of a test excerpt can only be obtained by memorizing classes for occurrences during training and not by learning common properties of all occurrences for a motif. This random-labeling experiment is inspired by [31].

When training our model on this variant, we obtain a mean F-measure of 0.54 on the test set after 50 epochs, which is much lower than the 0.94 obtained for the original labels (see Table 4). We observed that training for this experiment had not converged after 50 epochs and trained for an additional 75 epochs, leading to an F-measure of 0.57. The faster convergence and higher results on the original labels suggest that our model does learn some relevant characteristics of leitmotifs. Our experiment shows, however, that memorizing excerpts may also contribute to the results.

5. SUMMARY AND FUTURE WORK

In this work, we evaluated the capability of a neural network classification model for identifying leitmotifs in audio excerpts. Despite the complex musical variabilities in this scenario, our RNN-based classification model is able to differentiate between a fixed set of motifs and to distinguish them from non-motif excerpts. Generalization is strong across performances and—to a lesser extent—across occurrences. Using temporal context is helpful in the latter case, although the improvement may partly be the result of overfitting.

Our results encourage the development of a system for automated detection of motif instances in full performances. Unlike the classification task, no pre-segmented instance boundaries would be available for detection. We therefore expect this to be a more challenging scenario.

In our experiments, we have already explored the use of fixed input lengths. Using these, our model may be applied to all positions in an audio recording in a sliding window fashion [32]. This way, we can obtain leitmotif predictions for an entire performance of the *Ring* and not just individual excerpts. Additionally, a model used for automated leitmotif detection from audio would also need to deal with input excerpts that do not contain any leitmotifs at all. Our experiments with a noise class suggest that this may lead to somewhat lower but still useful results.

Furthermore, a detection system would need to handle a much larger number of motifs (around 130 for the complete *Ring*) as well as excerpts containing multiple motifs played simultaneously. Multi-label extensions of our model on fixed input lengths may be suitable for this.

As an even more advanced scenario, one may imagine an informed detection setting in which instances of a previously unseen motif must be identified given only a few exemplary instances of that motif.

ABSTRACT

This paper presents a method for large-scale retrieval of piano sheet music images. Our work differs from previous studies on sheet music retrieval in two ways. First, we investigate the problem at a much larger scale than previous studies, using all solo piano sheet music images in the entire IMSLP dataset as a searchable database. Second, we use cell phone images of sheet music as our input queries, which lends itself to a practical, user-facing application. We show that a previously proposed fingerprinting method for sheet music retrieval is far too slow for a real-time application, and we diagnose its shortcomings. We propose a novel hashing scheme called dynamic n-gram fingerprinting that significantly reduces runtime while simultaneously boosting retrieval accuracy. In experiments on IMSLP data, our proposed method achieves a mean reciprocal rank of 0.85 and an average runtime of 0.98 seconds per query.

1. INTRODUCTION

Imagine the following scenario. A musician is sitting down in front of a piano learning a new piece of music. She pulls out her cell phone, takes a picture of the physical page of sheet music sitting in front of her, and is immediately able to access Youtube videos of performances of that piece and alternate editions of the sheet music. In this paper, we present a method to solve the main technical challenge of identifying the page of music. This is the camera-based piano sheet music identification task.

Most previous works on sheet music retrieval come from the literature on finding correspondences between audio and sheet music. There are three general approaches to the cross-modal retrieval problem. The first approach is to convert the sheet music into MIDI using optical music recognition (OMR), to compute chroma-like features on the MIDI, and then to compare the result to chroma features extracted from audio. This approach has been applied to audio–sheet music synchronization [1] [2] [3] [4], and it translates very naturally to retrieval applications like using a segment of sheet music to identify its corresponding audio recording [5] or to retrieve the corresponding temporal

passage from a specific audio recording [6]. The second approach is similar to the first, except that it replaces the full OMR with a mid-level feature representation based on the location of noteheads relative to the staff lines [7] [8]. The third approach is to train a multimodal convolutional neural network to learn a latent feature space that directly encodes similarity between chunks of audio and sheet music snippets. This approach has been applied to audio–sheet music alignment [9] [10] and retrieval applications like using a snippet of audio to retrieve its corresponding sheet music snippet and vice versa [10] [11] [12] [13]. See [14] for an overview of work on cross-modal retrieval of music data. Also, we note that a recent work [15] has proposed a neural network-based approach for finding corresponding measures between two different sheet music versions of a piece.

This current study differs from previous work in two ways. First, we study the sheet music retrieval problem at a much larger scale. Previous works have studied sheet music retrieval using searchable databases containing hundreds of sheet music scores or a few thousand short snippets of sheet music. In contrast, we perform experiments using all solo piano sheet music scores in the entire International Library Music Score Project (IMSLP) [1] as a searchable database. We believe that this is several orders of magnitude larger than any previous study on sheet music retrieval. Second, we focus on queries that are cell phone images of sheet music. Previous works have primarily focused on synthetic sheet music, scanned sheet music, and audio recordings as input queries. While there have been a handful of works that study OMR on cell phone pictures of sheet music [16] [17] [18] [19] [20], this area of study is still in its infancy. Even though using cell phone pictures arguably makes the task much more challenging due to the additional sources of noise and distortion, we believe that this change leads to a much more practical, user-facing application.

Our approach to the piano sheet music identification task is to combine a recently proposed bootleg score feature representation with a novel hashing scheme. The bootleg score feature was originally proposed for a MIDI–sheet music alignment task [8]. A recent work has explored using the bootleg score features in a hashing framework for de-anonymizing files in the Lakh MIDI dataset by finding matches in sheet music data [21]. We will show that this previously proposed fingerprinting approach is far too slow for our current scenario. Because our task is a real-

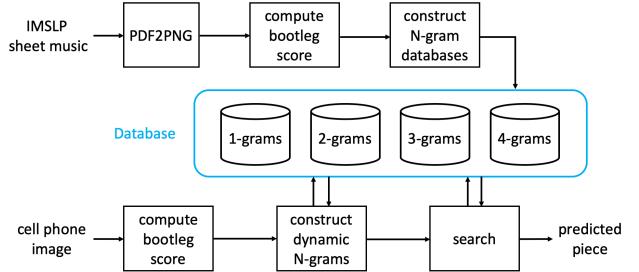
---

[1] https://imslp.org

time application, latency is an extremely important factor (unlike [21], which is an offline task). In this work, we impose a hard constraint that our system must have an average runtime of 1 second or less. We diagnose the reason why this previously proposed fingerprinting scheme is slow, and we develop a novel fingerprinting scheme that is able to achieve our stringent runtime constraint.

This paper has three main contributions. First, we propose a novel hashing scheme called dynamic n-gram fingerprinting. This approach dynamically constructs n-gram fingerprints of variable length in order to ensure that each fingerprint is discriminative enough to warrant a table lookup. Second, we present empirical validation of our proposed method on a very large-scale retrieval task. We perform experiments using all solo piano scores in IMSLP as a searchable database. We show that dynamic n-gram fingerprinting achieves both higher retrieval accuracy and significantly lower runtimes than a previously proposed approach. Our best system achieves a mean reciprocal rank of 0.85 and has an average runtime of 0.98 seconds per query. Third, as a byproduct of this project, we release the precomputed bootleg score features on all piano scores in IMSLP. [2] Because this task required a tremendous amount of time and computation involving the use of a supercomputing infrastructure, we release the features as a standalone repository in the hopes that it will be useful in a variety of other MIR-related tasks.

2. SYSTEM DESCRIPTION

Figure 1 shows the architecture of our proposed system. We will describe the system in two parts: constructing the database and performing a search at runtime.


2.1 Database Construction

Our first goal is to construct a database which will enable us to perform searches very efficiently. The process of constructing this database consists of three steps, as shown in the upper half of Figure 1. These three steps will be described in the next three paragraphs.

The first step is to convert each sheet music PDF into a sequence of PNG images. We decode the PDF into PNG images at 300 dpi, and then resize each image to have a width of 2550 pixels while preserving the aspect ratio. Because there is an extremely large range of image sizes in the IMSLP dataset, we resize the images to ensure that they are within a range that the bootleg score feature computation was designed for.

The second step is to compute a bootleg score for each page. The bootleg score is a recently proposed feature representation of piano sheet music that encodes the position of filled noteheads relative to staff lines [8]. The bootleg score representation itself is a $62 \times N$ binary matrix, where 62 indicates the total number of possible staff line positions in both the left and right hands, and where

Figure 1. Overview of proposed system.

N indicates the total estimated number of simultaneous note events. Figure 2 shows a short section of sheet music and its corresponding bootleg score representation. Note that this representation discards a significant amount of information like duration, key signature, accidentals, octave markings, and clef changes, and it simply ignores non-filled noteheads (e.g. half or whole notes). Nonetheless, it has been shown to be effective in aligning sheet music and MIDI, and we hypothesize that it may also be used effectively for large-scale retrieval. The main benefit of using the bootleg score representation over a full OMR pipeline is processing time. Because OMR is typically cast as an offline task, the best-performing systems require a significant amount of computation. [3] In contrast, the bootleg score can be computed on a high-resolution image in less than 1 second using a CPU. By focusing exclusively on simple geometrical shapes like circles (filled noteheads) and lines (staff lines and bar lines), it can detect objects robustly and efficiently using classical computer vision techniques.

The third step is to construct the n-gram databases. The concept of an n-gram is adopted from the language modeling literature, where the likelihood of a sequence of N consecutive words is estimated based on the frequency of its occurrence in a large set of data. Here, we treat each bootleg score column as a word and consider N consecutive words as a single fingerprint. We generate four separate n-gram databases for $N = 1, 2, 3, 4$. Each n-gram database is constructed in the following manner. First, we concatenate the bootleg score features from all pages into a single, global bootleg score for each PDF. Second, we represent each bootleg score column as a single 64-bit integer. This allows us to represent the bootleg score very compactly as a sequence of integers. Third, we consider every n-gram in the sequence as a fingerprint. For example, if a bootleg score is given by a sequence of 64-bit integers $x_1, x_2, x_3, \cdots$, then the set of 3-gram fingerprints for this bootleg score is given by $(x_1, x_2, x_3), (x_2, x_3, x_4), (x_3, x_4, x_5), \cdots$. Fourth, we store the location information for each fingerprint in a reverse index. For each n-gram database, the hash key is a $(64 \cdot N)$-bit fingerprint, and the reverse index stores a list of $(id, offset)$ tuples for all occurrences of that fingerprint in the database, where id is a unique identifier for the PDF

---

[3] For example, in a recent survey on state-of-the-art music object detectors [22], the best performing system required 40-80 seconds to process each image using a GPU.

Figure 2. A short section of sheet music and its corresponding bootleg score.

and *offset* specifies the offset in the bootleg score.

2.2 Search

At runtime, our goal is to identify the piece of music showing in a cell phone image query. This process consists of three steps, as shown in the bottom half of Figure 1.

The first step is to compute a bootleg score on the cell phone image. This is done using the same feature extraction as in the database construction phase. Note that the inputs in the offline and online phases are very different: whereas the IMSLP data is primarily digital scans of physical sheet music, the queries are cell phone images of physical sheet music. This introduces a lot of noise due to variable lighting conditions, zoom, camera angle, cropping, blur, unwanted objects outside the boundaries of the page, etc. The only reason we can get away with using the same feature extractor in these two very different scenarios is that the bootleg score feature extraction has no trainable weights and only a small set of hyperparameters. This makes it less likely to highly overfit to a set of data. It is also worth pointing out that the bootleg score feature extraction was originally designed to handle the challenging case of cell phone images of sheet music, so we surmise that it will handle the easier case of scanned sheet music reasonably well.

The second step is to construct a sequence of dynamic n-gram fingerprints. We will explain and motivate the use of dynamic n-grams by describing our initial attempts to solve the problem, the issues with these earlier approaches, and how the dynamic n-gram addresses these issues.

Our initial attempt was to consider each column of the bootleg score as a fingerprint. This is equivalent to a 1-gram in the terminology used in this paper. This approach was proposed in a recent work that attempts to de-anonymize files in the Lakh MIDI dataset by finding matches in a set of known sheet music data [21]. When we implemented this approach, we found that the retrieval accuracy was good, but that the system was far too slow. This is an acceptable solution in [21] because the task is offline, but it is an unacceptable solution in our current application because we have a very stringent runtime constraint. Upon further analysis, we found that the frequency distribution of fingerprints was highly peaked and thus ill-suited for hashing. In other words, there was a small set of finger-

prints that occurred very frequently in the database. These fingerprints tended to be bootleg score columns containing a single note event. Because this occurs so frequently in piano sheet music, it forces the system to process an extremely large number of spurious fingerprints at runtime, which significantly slows down the system.

Our second attempt was to use an n-gram fingerprint to address this issue. This introduces a tradeoff. On the one hand, as we increase N the fingerprint becomes more discriminative, which leads to fewer matches in the database and faster runtime. On the other hand, increasing N increases the likelihood that the fingerprint is erroneous, since the entire fingerprint is wrong if even one of its elements has an error. If we roughly model each n-gram as N, independent Bernoulli random variables, then the probability that the entire n-gram is correct decreases exponentially in N. Given this tradeoff, one very reasonable approach is to try different values of N and to select the value that yields the best performance.

The dynamic n-gram gets the best of both worlds. If a single bootleg word x_i (i.e. a bootleg score column converted to a 64-bit integer) is very distinctive, then we simply do a table lookup in the 1-gram database. In this case, it would not benefit us to do a 5-gram lookup if the first element only occurs a few times in the whole database. If, however, the bootleg word is very common, then we prefer not to do a table lookup on the 1-gram database because this would require us to process a large number of spurious fingerprints. In this case, we bump the 1-gram up to a 2-gram and repeat the process. If the 2-gram fingerprint (x_i, x_{i+1}) is distinctive, then we do a table lookup on the 2-gram database. If (x_i, x_{i+1}) is not distinctive, then we bump the 2-gram up to a 3-gram (x_i, x_{i+1}, x_{i+2}). We repeat this process until the fingerprint is distinctive enough to warrant doing a table lookup (up to $N = 4$). As an example, given a sequence of bootleg words $x_1, x_2, x_3, \cdots$, one possible dynamic n-gram sequence would be $(x_1), (x_2, x_3), (x_3), (x_4, x_5, x_6), \cdots$. Note that there is only one hyperparameter γ that specifies the maximum number of fingerprint matches we are willing to process for every table lookup.

The third step is to search the database using the histogram of offsets method. The histogram of offsets was proposed in [23] as a way to efficiently search a very large database. It is based on the observation that the true match in the database will yield a sequence of matching fingerprints at an approximately constant relative offset. For example, if a query bootleg word sequence $x_1, x_2, x_3, \cdots$ matches a reference sequence $\tilde{x}_i, \tilde{x}_{i+1}, \tilde{x}_{i+2}, \cdots$, then the matching fingerprints would all have a relative offset of $i - 1$. If we compute a histogram of relative offsets for all matching fingerprints with that item in the database, we would see a large spike in the histogram at the bin corresponding to an offset of $i - 1$. We can therefore compute a similarity score by constructing a histogram of offsets for matching fingerprints, and then calculate the maximum bin count in the histogram. Once we have calculated a match score for every PDF in the database in this way, we group

the PDFs by piece. The *piece* match score is calculated as the maximum score of any of its constituent PDFs. Finally, we sort the pieces in the database by their match scores. This yields our final predicted ranked list of pieces.

3. EXPERIMENTAL SETUP

In this section, we describe the data and metrics used to evaluate our proposed system.

The cell phone image queries were taken from the Sheet MIDI Retrieval dataset [24]. We include a description of the dataset here for completeness. This data was originally created to study the task of aligning a cell phone picture of piano sheet music and its corresponding MIDI file. It contains 2000 cell phone images of 200 different piano pieces across 25 well-known composers. For each of the 200 pieces, a PDF from IMSLP was downloaded and printed onto physical paper. Ten cell phone pictures were taken across the length of each piece in a variety of locations, lighting conditions, perspectives, and levels of zoom. The pictures contain between 1 and 5 lines of music and were all taken in landscape orientation. We use the same train-test split as the original paper: 400 cell phone images (corresponding to 40 pieces) were used for training, and 1600 cell phone images (corresponding to 160 pieces) were used for testing. By using the same train-test split as the original paper, we ensure that the bootleg score feature extraction has not been tuned to the test data.

The database comes from IMSLP. We first scraped the website and downloaded all PDF scores and associated metadata.[4] We then filtered the data by instrumentation tag label in order to identify a list of solo piano pieces. The resulting dataset contains 29,310 pieces and 31,384 PDFs and 374,758 individual images. This is the dataset that we used to construct the database described in Section 2.1.

We release the precomputed bootleg score features for all piano scores in the IMSLP dataset in a separate standalone repository.[5] We believe this is in itself a significant contribution to the MIR research community, given the amount of time, memory, and computation required to generate it. For example, it took us over a month to scrape the IMSLP website and download all the scores in PDF format. This set of PDFs was approximately 1.2 terabytes in size. If the PDFs had been decoded into high-resolution images, the dataset would be in the tens of terabytes. Because this was too large to store on disk, we decompressed each PDF to a set of high-resolution images, computed the bootleg score features, and then deleted the high-resolution images to conserve disk space. We performed all feature computation on the NSF XSEDE supercomputing infrastructure [25].

We evaluate our system along two dimensions: retrieval accuracy and runtime. Because our goal is to identify the matching *piece* rather than just the exact same PDF,[6] there

is always exactly one correct item in the database. Accordingly, we use mean reciprocal rank (MRR) as our measure of retrieval accuracy. The MRR is calculated as

$$MRR = \frac{1}{N} \sum_{i=1}^{N} \frac{1}{R_i} \qquad (1)$$

where $N = 1600$ indicates the number of test queries and R_i indicates the rank of the true matching item for the ith query. In our task, R_i can range between 1 and 29310, the total number of pieces in the database. MRR ranges between 0 and 1, where 1 indicates perfect performance. We also measure the runtime required to process each test query. The runtime includes all data pre-processing such as converting the JPG image to PNG format. Note, however, that the runtimes do *not* include the network latency that would be present in a real cell phone application. All experiments are done on a single core of a 2.1 GHz Intel Xeon CPU.

4. RESULTS

In this section, we present our experimental results on the piano sheet music identification task.

We are not aware of previous work that directly studies sheet music identification based on cell phone images. As mentioned in Section 1, there are works in the audio–sheet music alignment literature that have studied cross-modal sheet music retrieval. These works could in principle serve as baseline comparisons. However, all of the works we are aware of would not have been practical to evaluate on our task for one of two reasons. First, some approaches do not scale to a large database. For example, approaches that use subsequence DTW [5] [6] [2] [8] would have exorbitantly high runtimes on the IMSLP database. Second, some approaches might have acceptable runtimes at test time, but would have required too much computation to construct the database. For example, the sheet–audio alignment system in [11] is 20 times slower than our proposed system and would have exceeded our computational budget on the XSEDE supercomputing infrastructure. Any approaches that use OMR to convert the sheet music into MIDI format would likewise be too computationally expensive.

Nonetheless, we compare our proposed approach to nine other baseline systems. The first four baselines are representative of the state-of-the-art in image retrieval in the computer vision community. These systems were developed for the Oxford 5k [26] and Paris 6k [27] benchmarks, where the goal is to identify a famous landmark in a query image given a database of known images. All four systems are built on top of pretrained ImageNet classifiers like VGG [28] and ResNet [29], but they differ in the method by which they convert model activations into a final feature representation. The first baseline (MAC [30]) takes the $K \times W \times H$ tensor of activations at the last convolutional layer and computes the maximum activation within each feature map. This yields a fixed-size K-dimensional feature representation regardless of the image size. The second baseline (SPoC [31]) adopts a sim-

[4] We downloaded the data over the span of several weeks in May 2018.
[5] https://github.com/HMC-MIR/piano_bootleg_scores
[6] In Section 5.2, we will test how well our system can identify a piece when only an alternate edition of the sheet music exists in the database.

System	MRR		Runtime	
	cond 1	cond 2	avg	std
MAC [30]	.037	.043	1.17s	.12s
SPoC [31]	.003	.004	1.14s	.10s
GeM [32]	.025	.029	1.18s	.11s
R-MAC [33]	.036	.039	.96s	.11s
1-gram [21]	.709	.659	21.5s	12.5s
2-gram	.845	.784	2.76s	1.11s
3-gram	.808	.767	1.99s	.36s
4-gram	.755	.722	1.12s	.25s
5-gram	.688	.668	1.07s	.13s
dynamic n-gram	.853	.812	.98s	.12s

Table 1. System performance on the piano sheet music identification task. Condition 1 is when the exact same PDF exists in the database. Condition 2 is when only an alternate version of the sheet music is in the database.

ilar approach, but uses average pooling rather than max pooling. The third baseline (GeM [32]) uses generalized mean pooling, which is a generalization of both average and max pooling where the type of pooling is specified by a single, trainable parameter. The fourth baseline (R-MAC [33]) applies max pooling over different regions of the image at various scales and combines the results through another pooling stage. All four baselines also apply various forms of post-processing, such as dimensionality reduction through principal component analysis, whitening, and L2 normalization. Given a query feature representation, similarity with database images is computed with a simple inner product. In our experiments, we compute piece similarity as the maximum similarity with any page in any of the piece's constituent PDFs. We evaluate the baseline systems with their provided pretrained models.[7] The last five baselines are equivalent to our proposed system but using a fixed n-gram fingerprint for $N = 1, 2, 3, 4, 5$. The 1-gram system corresponds to the approach proposed in [21].

Table 1 compares the performance of all models. The systems are presented in three groups: the image retrieval baselines (top), the fixed n-gram systems (middle), and the proposed dynamic n-gram system (bottom). The second column (labeled "cond 1") indicates the MRR on the test set, and the last two columns indicate the average runtime per query and corresponding standard deviation. The column labeled "cond 2" will be discussed in Section 5.2.

There are three things to notice about these results. First, the image retrieval baselines all perform very poorly. The best-performing image retrieval system is MAC, which achieves an MRR of .037. This is not a surprise, since these systems were not designed for working with sheet music images, but it does confirm that existing image retrieval systems do not work out-of-the-box on the sheet music identification task. We do observe, however, that the

systems achieve results significantly better than random guessing (approximately .001 MRR). Second, the fixed n-gram systems show a tradeoff between retrieval accuracy and runtime. As N increases from 1 to 5, we see the average runtime decrease from 21.5 seconds to 1.07 seconds. This reflects the fact that the fingerprint is becoming more and more discriminative, which leads to fewer and fewer matches in the database. At the same time, we observe that the retrieval accuracy decreases from .845 to .688 as N increases from 2 to 5. This reflects the fact that more and more fingerprints are erroneous as fingerprint size increases. The increase in MRR from $N = 1$ to $N = 2$ indicates that the 1-gram fingerprints are not sufficiently distinctive. Third, the dynamic n-gram system achieves both the highest retrieval accuracy (.853) and the lowest average runtime (0.98 seconds). This indicates that the design has achieved its intended goal: to avoid the tradeoff between retrieval accuracy and runtime, and to instead get the best of both worlds.

5. ANALYSIS

In this section, we conduct four different analyses to answer key questions of interest.

5.1 Failure Modes

The first question of interest is, "What are the failure modes of the system?" To answer this question, we identified the queries with poor reciprocal rank values and investigated the reasons for failure. By far the biggest reason for poor performance was failure in the bootleg score feature computation. Common mistakes included missed detection of non-filled noteheads or noteheads occurring in block chords, notehead detection false alarms arising from text and other musical symbols on the page, and staff line estimation errors. Fixing these issues would require re-designing the bootleg feature computation. Another (minor) reason for poor performance came from non-distinctive sections of music. For example, when there are repetitive octaves or long sequences of alternating between two notes in only one hand, this can have a strong match with unrelated pieces of music.

5.2 Effect of Sheet Music Version

The second question of interest is, "How well does the system handle different sheet music versions?" To answer this question, we ran a separate set of experiments in which we remove the exact same PDF from the database. This means that the system can only match against alternate versions of the sheet music. Because some queries only had 1 sheet music version in IMSLP, this additional benchmark was run on a reduced subset of 930 test queries.

The results of this alternate benchmark are indicated in Table 1 as "Condition 2." We see that the MRR of the fixed n-gram systems has been reduced somewhere between .02 and .06, and the MRR of the dynamic n-gram system is reduced by .04. This performance gap between condition

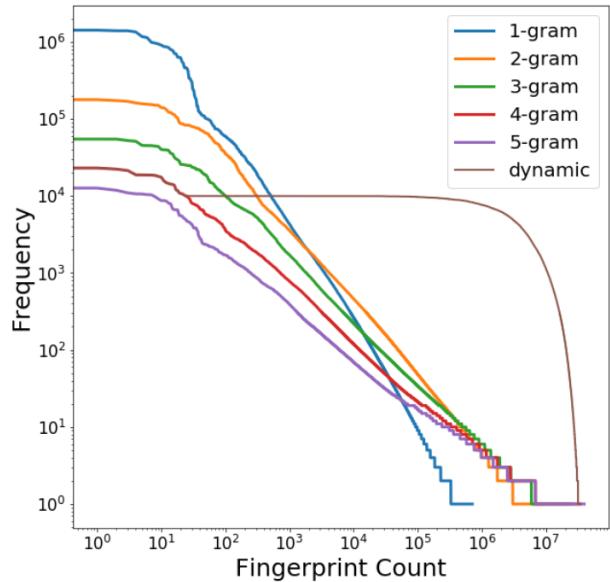
---

[7] Training the baseline systems from scratch would require a large amount of labeled data (to retrain the ImageNet classifier) and would constitute a significant research project on its own. In this work, we simply evaluate the baseline systems out-of-the-box using the provided pretrained models.

System	MRR		Runtime	
	cond 1	cond 2	avg	std
dyn n-gram (20k)	.864	.802	1.67s	.18s
dyn n-gram (10k)	.865	.802	1.53s	.16s
dyn n-gram (5k)	.860	.803	1.21s	.15s
dyn n-gram (1k)	.853	.812	.98s	.12s

Table 2. Comparison of dynamic n-gram systems with various values of γ, which specifies the maximum number of fingerprint matches the system will process on a table lookup before bumping an N-gram to an $(N+1)$-gram.

1 and condition 2 can be interpreted as the additional performance loss that is caused by variations in different sheet music editions. While this is a nontrivial decrease in performance, the proposed system still has a robust overall retrieval accuracy (.812 MRR) when the exact same version is not in the database.

5.3 Effect of γ


The third question of interest is, "How does system performance vary with γ?" Recall that the dynamic n-gram approach has one hyperparameter γ that specifies the maximum number of fingerprints we are willing to process for each table lookup. We ran experiments with several values of γ to determine its effect on system performance.

Table 2 shows system performance for γ ranging from 1000 to $20,000$. As γ decreases, we see a very slight decrease in retrieval accuracy (.864 to .853) and significant improvement in average runtime (1.67s to .98s). In this case, we have a very nice tradeoff: for only a small sacrifice in retrieval accuracy, we can significantly speed up the system. The dynamic n-gram results in Table 1 correspond to $\gamma = 1000$, which is the best system that meets our constraint of 1 second average runtime per query.

5.4 Fingerprint Distribution

The fourth question of interest is, "How well suited for hashing is the dynamic n-gram fingerprint distribution?" As described in Section 2.2, we found that the 1-gram fingerprint proposed in [21] had a frequency distribution that was very peaked and thus ill-suited for hashing. [8] To see how well the dynamic n-gram approach addresses this issue, we compared its frequency distribution to the fixed n-gram approaches.

Figure 3 shows this comparison. Each curve shows the frequency of different fingerprint values, where the fingerprints have been sorted from most frequent (left) to least frequent (right). Both axes are shown on a log scale in order to better visualize the wide dynamic range. Note that all of the fixed n-gram distributions have approximately the same total number of fingerprints in the database, so their only difference is how many unique fingerprint values there are and how the fingerprints are distributed across

Figure 3. Comparing the fingerprint frequency distributions of the fixed n-gram systems and dynamic n-gram with $\gamma = 10,000$. For each curve, the fingerprints have been ordered from most frequent (left) to least frequent (right).

these different values. The curve for the dynamic n-gram system corresponds to $\gamma = 10,000$.

Figure 3 shows the same trends that we see in Table 1. The difference, however, is that Figure 3 explains *why* the results in Table 1 are the way they are. For example, we observed earlier that the fixed n-gram systems exhibit a tradeoff between retrieval accuracy and runtime. Figure 3 explains this tradeoff from a hashing perspective. As N increases, the fixed n-gram distributions become less and less peaked, which translates to fewer fingerprint matches in the database and smaller runtimes. At the same time, this manner of reducing the peak comes with an exponential explosion in the number of unique fingerprint values. This means that the fingerprints will be less generalizable and more error-prone. We also notice that the only fixed n-gram curves that intersect early on are the 1-gram and 2-gram curves. This explains why the 2-gram system is unilaterally better than the 1-gram system: it has a less peaked distribution (smaller runtime) and it has a higher frequency of fingerprints than the 1-gram system for a large fraction of fingerprint values (better retrieval accuracy). Finally, we observe that the dynamic n-gram system has a flatter distribution than any of the fixed n-gram systems across a wide range of its distribution. This confirms that the dynamic n-gram approach is able to transform the distribution into one that is more well-suited for hashing. [9]

---

[8] Note that the ideal distribution for hashing is a uniform distribution.

[9] Note that the curve for the dynamic n-gram system has about 30 fingerprints that occur more than $\gamma = 10,000$ times. This is because we do not include n-grams higher than $N = 4$ in our database.

ABSTRACT

While prior studies investigating the social aspects of music provide a landscape of users' various social behaviors around commercial music services (CMS), there remains a lack in understanding of users' perceptions and value judgments underlying these behaviors. Specifically, there is more to learn about what influences and behaviors individual music users perceive as meaningful in social contexts. We used the Q methodology to explore which behaviors and influences are important to CMS users and why. We extracted two factors that explain the two different viewpoints shared by groups of music users, focusing on how they perceive the meaning and value of different social music behavior and interactions. From these findings, we then revised an existing social music coding dictionary and interaction model and offer new CMS design insights.

1. INTRODUCTION

Music is both personal [1], [2] and part of our social experience [1], [2], [3], [4]. Technologies in use affect what activities occur around music [5, 6] as does the physical and social context of how and where people interact with technology [7]. Furthermore, information technologies have become entangled with individuals' sense of self and social experiences [8]. Commercial music services (CMS), a type of information technology, are part of this ecosystem where individual and social experiences come together with current technologies.

Since music and technology are both so personal, improving our understanding of why CMS users find certain interactions with music and technology to be personally meaningful can help derive design decisions for new CMS technology to better meet these specific needs. Furthermore, in recognizing the influence of technology on music-related activities and the pace of CMS technology change [6], understanding what is meaningful to individuals within socially complex ecosystems can support forward-looking and contextually relevant design decisions.

Although there has been periodic research on music-related social behaviors and technology [4], [6], [9], [10], [11], [12], [13], [14], [15], [16], these studies focused on describing the different behaviors surrounding CMS and less on understanding how and why some behaviors and behavioral influences may be more significant to certain users than to others in social contexts. Previous research methods used include surveys [11], [12], [13], [15], [16],

interviews [4], [12], [14], [15], contextual inquiry [10], ethnographic inquiry [9], ethnographic observation of prototypes [15], field trial of prototype technologies [15], and focus groups [6]. While these methods were appropriate for their studies' goals, we still have a limited understanding of the personal significance of social behaviors surrounding music and the significance of influences on those social behaviors. In other words, we have a better understanding of how users behave in certain ways when it comes to using various music services, but less on what they perceive as meaningful or valuable from their own individual perspectives.

To address this gap, we conducted a study using the Q methodology, a method that better captures the personal significance of social behaviors. First developed in psychology in 1935 [17], [18], the Q methodology has since entered the Human-Computer Interaction (HCI) community [19], [20]. The Q methodology "asks its participants to decide what is 'meaningful' and hence what does (and what does not) have value and significance from their perspective" [18]. Furthermore, it is "used to explore (and to make sense of) highly complex and socially contested concepts and subject matters from the point of view of the group of participants involved" [18].

Using the Q methodology, we identified two distinct segments of CMS users within our participant group. Within each segment, users share similar perspectives about social behaviors surrounding CMS and associated influences on those behaviors. Additional contributions of this research include revisions for an existing coding dictionary and interaction model, and new design insights. Furthermore, the user segmentation could potentially contribute to existing personas identified in previous Music Information Retrieval (MIR) user studies [14], [21].

2. RELATED WORK

2.1 Social Practices Related to Music

Prior research laid the foundation for understanding social practices—and the influences on those social practices—where music intersects with technology. O'Hara and Brown's work captured social practices surrounding music and technology such as sharing, exploring, and peeping at a time when MP3 sharing platforms like Gnutella, Kazzaa, and Soulseek were still in use [15]. The social contexts for these practices included cars, public locations, workspaces, and dance clubs [15].

In 2013, as more users started to stream music and use the Bluetooth features on their mobile phones, Leong and Wright [4] observed the following social practices in

shared settings: exploration, discovery, selection, listening, and sharing. In the same year, Belcher and Haridakis [22] identified social motivators as influences to music listening and selection behaviors. In 2015, Yang et al. [23] identified peers as an influence on the practices of unauthorized music downloading and sharing. Later in 2017, Hagen and Lüders [1] studied how users listen, discover, share, and follow given social features on music streaming services. More recently, Spinelli et al. [6] identified nine social practices and twenty-four influences on these practices at the intersection of music and technology. Park et al. [16] also derived a collaborative playlist framework identifying sharing, recommending, and bonding as social purposes for how collaborative playlists served study participants. Lee et al. [24] explored music recommendations and also identified possible "disparities in how people wish to receive music recommendations and what will influence them to listen to recommendations, versus how they would like to offer recommendations to others."

This body of work builds a compelling story around the social practices surrounding CMS. Our work specifically aims to build upon the comprehensive model of practices and influences identified in prior research [6] and provide insight into how individual CMS users or segments of users perceive the different practices and influences around CMS. The Q methodology was selected to provide a holistic understanding [18] of how these practices and influences were perceived by a group of CMS users.

2.2 Methodology

Meloche introduced an established form of the Q methodology to the field of HCI in 1999 [19]. He believed the field would benefit from the method's ability to reveal the subjective views of individuals [19]. While the Q methodology has not previously been used to study CMS, forms of the method have been used to study other information technologies such as: studying a communication system for children [20], exploring user segmentation of technology services by information seeking preferences [25], and studying the health and technology attitudes of patients to inform the design of self-management interventions [26].

The Q methodology has also been used to study subjective views around music. Wacholtz [27] applied the method to investigate musical preferences and identify different listener types for country music. McKenzie and Brown [28] also studied the musical preferences of students and teachers related to popular music, identifying and describing three factors. While not directly focused on music and CMS, Davis and Michelle conducted research using the Q methodology focused on relevant media audiences and included a comprehensive bibliography of Q methodology research that studied media audiences and media users [29].

Both critiques and criticisms of the Q methodology and its implementation have been made and addressed over the years [30], [31]. A commonly noted challenge of the Q methodology is the potentially ambiguous nature and process of building the Q set [18], [32], [33]. To address this, our application of the Q methodology incorporated results from focus groups where constant comparative analysis was used to develop a Q set after the initial phase of a multi-method study design. Although interviews are often included as a possible method to support the development of a Q set [33], focus groups can enable richer open-ended discussion and interaction between participants which then can help form a meaningful Q set [25], [34]. Researchers also take mixed method approaches incorporating Q methodology—for instance, combining the Q methodology with R-method surveys, a quantitative method [35], [36].

3. STUDY DESIGN AND METHOD

We employed a multi-method approach that harnesses the strengths of both focus groups and the Q methodology. In Phase I, we selected exploratory focus groups to capture a wide breadth of statements from participants that described their social practices and associated influences they have experienced surrounding CMS. In total, the focus group study identified twenty-four possible influences on nine different social practices (both social practices and their influences are subsequently referred to as "themes"). The findings are reported in the Codebook of Social Practices and Influences [6]. In Phase II, the Q methodology was used to study the personal significance of the themes that were uncovered in the focus groups. Focus group statements from Phase I formed the basis for a set of items (the Q set) used in the Q methodology. This paper reports our findings from Phase II.

Twenty-four participants took part in the Q methodology component of this study, of which seventeen participated in Phase I. Each participant completed an in-person sorting activity, followed by brief interviews at the University of Washington, Seattle. These sorting activities and interviews, followed by a factor analysis method and factor interpretation to uncover participant viewpoints, comprise the Q methodology. Each of the 24 individual sorting activities and their follow-up interviews took between 30 minutes and an hour. A facilitator and a note-taker were present at each session. Sessions were also recorded and transcribed to ensure accurate analysis.

3.1 Selection of Participants

Recruitment activities for study participation consisted of displaying flyers, posting to listservs, and posting on social media as well as physical flyers placed on boards around the university campus and in nearby businesses. Participants were compensated with $15 Amazon gift cards for being part of this study. All recruiting avenues directed potential participants to a screener survey.

A screener survey was used to ensure all participants were between the ages of 18 and 34, currently lived with at least one other person, and used at least one CMS. The same screening criteria was used for identifying focus group participants. In total, 24 participants from the screener took part in an individual, in-person card sorting activity and subsequent interview. Of the 23 participants who chose to report a gender identity, 15 were female and 8 were male. Twenty-one participants were between the ages 18 to 24, and 3 were ages 25 to 34. Participants used a diverse array of CMS currently on the market including Spotify, Pandora, Google Play Music, YouTube, Soundcloud, etc.

A Level of Group Intimacy Researchers believed, a priori, that items of this theme pertained to the level of familiarity between group members in a social situation.

A.1 I am comfortable recommending or picking songs to listen to when hanging out with close friends.

A.2 I am comfortable picking music that my close friends will like in social gatherings.

A.3 I am comfortable with my roommates hearing everything I play.

A.4 I would not hesitate to tell my friends to change the music that is playing.

A.5 I would put my headphones on if I did not want to listen to the music that is playing in a shared space.

A.6 I do not feel comfortable making music recommendations in a large group setting.

A.7 I feel comfortable asking to connect my phone/laptop to a speaker at someone's house that I do not know well.

A.8 I do not mind sharing my music taste with people I do not know well at social gatherings.

A.9 I change the music in a large group setting if I do not like it.

A.10 I trust people to use my phone or laptop to play music at a large gathering (e.g., party).

B Effort/Engagement Researchers believed, a priori, that items of this theme pertained to the level of effort or engagement an individual is willing to put forth or the responsibility an individual is willing to take on when engaging with music in a social situation.

B.1 I like being the DJ if others give recommendations.

B.2 I like being the DJ and playing only my music at social gatherings.

B.3 I match the music playing to the mood of the group.

B.4 I would like for everyone to take turns adding music to a playlist.

B.5 I am comfortable forcing my friends to listen to my music recommendations in a social gathering.

B.6 I do not mind being the DJ if I can easily pick a playlist for the mood or activity.

B.7 I like not having to think about what music to play in social gatherings.

B.8 I do not mind changing the song if others do not like the music that is playing.

B.9 I like letting other people choose the music in social gatherings.

B.10 I like being able to add music to a queue in social gatherings.

C Privacy and Security Considerations Researchers believed, a priori, that items of this theme pertained to considerations relating to privacy and/or security that influence an individual's actions in a social music practice.

C.1 I would not let other people use my phone/laptop to listen to music.

C.2 I trust people to not snoop around on my phone/laptop if they are using it to pick music to play.

C.3 There are certain types of music I only listen to when I am alone.

C.4 I chaperone my phone/laptop if it is being used by others to play music in social gatherings.

C.5 I do not mind others playing music from my music accounts if I am already logged in and we are listening to music.

C.6 I am not concerned about other people knowing what I listen to.

C.7 I do not mind sharing my login for a service with my roommates.

C.8 I keep an eye on my phone/laptop if it is being used to play music at a party at my house.

Table 1. The Q set consists of items that represent themes of intimacy, effort, and privacy and security. Analysis and interpretation of study results are based on the participant's interpretations of items as expressed in post-sort interviews, not necessarily the themes they were intended to represent (shown here).

3.2 Q Set Generation from Focus Group Data

A Q set is a diverse collection of items curated to broadly represent the subject matter at hand, with each item "making a different (but nonetheless recognizable) assertion" [18]. For this study, the themes and items were elicited from focus groups where social practices and their related influences were discussed [6]. Researchers chose the themes to investigate using two criteria. First, the personal significance of each theme had to appear to vary within the participant group. Second, the themes had to appear interrelated. Both the themes and relationships between themes were identified on an affinity diagram created using a process of constant comparative analysis. Three influences on social music behaviors met these criteria and were selected as themes of focus for this study: 1) level of group intimacy, 2) level of effort and engagement, and 3) privacy and security considerations.

Researchers reviewed the focus group transcripts that had previously been coded with at least one of the three themes to gather items for the Q set. Statements were selected as items for the Q set based on three criteria: focus, coverage, and balance [33]. Focus refers to including items that can be sorted by a "single, face-valid assumption" [33]. Coverage refers to the set being "broadly representative" of the domain at hand [33]. Balance refers to including all the opinions and perspectives in the Q set [33]. After items were selected, the Q set was piloted to ensure participants understood both the items and sorting activities for the study.

3.3 Q Sorting Activity and Interviews

During a Q sort, individual participants organize items (Table 1) into a forced distribution known as a Q pyramid (Figure 1) and place items they agree with most to the right (+3) and most disagree with to the left (-3). During the Q

sort and subsequent interviews, participants express their interpretations of items along with their reasoning for placement into the Q pyramid.

We laid out three pieces of paper for Agree, Disagree, and Neutral along with the Q set items printed out on cards. We asked participants to sort the Q set cards into the three groups and afterwards, arrange the cards in accordance with a provided image of a Q pyramid. After participants had finished sorting the cards, we asked them to tell us about the items they felt most and least strongly about as well as the items in the center of their distribution (See supplemental material for the complete protocol). Individual Q sorting activities with post-sort interviews were held privately for confidentiality.

Figure 1. Factor exemplifying sorts for Factor 1 and 2 displayed in the Q pyramid used in this study. Consensus items that do not distinguish one factor from another are flagged (*).

3.4 Analysis

Analysis of the Q sorts is completed using "a by-person factor analysis in order to identify groups of participants who make sense of (and who hence Q 'sort') a pool of items in comparable ways" [18]. We took an inductive approach using a process in line with exploratory factor analysis [33] as we observed that individuals in the population valued the three themes in the Q set differently, but we did not have a hypothesis about the differences. Factor arrays—representative viewpoints of the perspectives expressed by participants in their Q sorts—were extracted from a correlation matrix, built from the intercorrelation of all the Q sorts [33]. Factor extraction was done at the same time as the coding of post-sort interview transcripts.

Factor extraction was conducted using PQMethod; a free software dedicated to the Q methodology [33]. To determine the appropriate number of factors to extract, we first used the Kaiser-Gutman Criterion followed by a Scree Test. We then performed a varimax rotation on the factors and extracted our final factors. We determined PQMethod's pre-flagging was both appropriate and more than sufficient for our exploratory purposes. Including every sort in the creation of factor estimates increased the reliability of our factor estimates and arrays while reducing error [33]. Thirteen Q sorts were flagged for Factor 1 and eleven Q sorts for Factor 2. To enable cross-comparison between factors, total factor estimate scores are converted to Z scores [33]. Exemplary factor arrays for Factor 1 and Factor 2 were then created from Z scores (Figure 1).

In preparation of Factor interpretation, post-sort interview transcripts were coded. The transcripts were coded with the relevant Q sort item being discussed, the exemplary Factor number that represents the participant making the statement, and the applicable themes from the Codebook of Social Practices and Influences [6]. By coding transcripts with the Q sort item and Factor number representative of the participant, we were able to quickly filter relevant statements to interpret each factor array. Themes from the Codebook of Social Practices and Influences captured the meaning of the Q set item as expressed by each participant in post-sort interviews rather than by the researchers' a priori beliefs. The two exemplary factor arrays identified during factor extraction are representative viewpoints of the perspectives expressed by participants in their Q sorts [33].

Factor extraction and coding of transcripts provided the foundation for factor interpretation, which was conducted applying Stenner and Watts' Crib Sheet method to each factor array [33]. Items were separated into four categories: items ranked at +3, items that ranked higher than other arrays, items that ranked lower than other arrays, and items that ranked -3 (Figure 1). Following an abductive process, each item was interpreted individually and then in the context of the entire viewpoint. Item by item, the viewpoint grew into the holistic viewpoint for the factor array. During this process, participant statements and themes from the prior work provided insight into how participants interpreted each item in context of the larger Q set. Our interpretation at this stage reflected this understanding of items, not our a priori understanding of each item. Using this lens, we found all items supported a holistic viewpoint

for each factor, including consensus items that did not rank differently across factors.

4. RESULTS

For this study, we reached a two factor outcome that explains 45% of the total study variance in the correlation matrix. Common factor solutions that capture 35-40% or more of the total study variance are considered sound [33], [37]. Eigenvalues (EV) provide another way to compare factors within a study, and a higher EV is viewed as positive [33].

A cross-factor analysis identifies 23 items as being ranked significantly differently at the p < 0.01 level. Five consensus items were identified as non-significant at p > 0.01. This means the two identified factors (participant groups) had statistically significantly different views about 23 items but generally agreed on 5 items. Factor 1 is factor-exemplifying for 13 Q sorts, or put another way, Factor 1 is representative of the Q sorts of 13 participants. Factor 2 is factor-exemplifying for 11 Q sorts.

In the following subsections, we provide the viewpoints developed from interpreting the factors in the context of post-sort interviews. The supporting Q sort item identifier and item rank used for factor interpretation are included for each statement in the viewpoints (i.e. identifier: rank).

4.1 Factor 1 Interpretation: Viewpoint 1

Users with Impression Management and Security Concerns, but also Confident Music Selectors

Factor 1 explains 23% of the total study variance and has an EV of 7.26. Thirteen participants are significantly associated with this factor.

These users did not want others to know the type of music they were listening to due to impression management concerns or appropriateness for the social situation. They had impression management concerns; they did not want their roommates to know what they listen to (C.3: +3; A.3: -1) and considered some of the music they listen to as guilty pleasures (C.3: +3; A.3: -1; C.6: -1). Another reason they listen to music alone is they believed some music types are not appropriate for social situations (C.3: +3).

In social situations, these CMS users are confident in their ability to pick music that their social group will enjoy (A.1: +3; A.2: +2)**.** They believe they can match music selections with the mood of a gathering, and this becomes easier when the gathering is intimate (B.3: +2). They are so confident in their understanding of their close friends' music tastes that they may force them to listen to a song they know their friend will like; this would not be the case for friends they know less intimately (B.5: 0). Similarly, in large group settings they recommend generic, safe choices —they choose popular songs due to impression management concerns that an untested song will not be appreciated by the group (A.6: 0; A.8: -1).

Although they would not hesitate to tell a close friend to change the music currently playing, they feel it is often unnecessary or inappropriate (A.4: 0). **They believe they can tolerate any music in a social situation** (A.5: -1) **and think it is especially rude to change other people's music**

in large groups (A.9: -2). In fact, they do not expect to be able to provide input in many situations—like at someone else's wedding (B.10: 1). When they are playing music, they do not mind changing the song if there is group consensus that it should be changed (B.8: 1). They also do not mind situations where everyone takes turns adding songs to a playlist as long as the flow is consistent (B.4: 0).

When they are with their friends, these CMS users prefer to focus on interacting with them, and not on choosing the music (B.7: 0; B.6: +1). It is a lot of effort to pick all the music for an event, and it is not considerate to ask guests to pick songs (B.2: -2). *Anything that reduces the amount of effort needed is seen as beneficial, like selecting a playlist* (B.6: +1). They want to reduce their impression management concerns and their effort in selecting music for social situations (A.9:0). When others give recommendations, it ensures these users do not have to take responsibility for what they play—something they really like (B.1: +2; B.9: +1). An added benefit is that letting others choose the music reduces the effort they need to put into the activity (B.1: +2).

These CMS users generally do not trust that others will not snoop on their phone or laptop (C.2: -2). This is especially true in large groups where they would never share their phone (A.10: -3). In more intimate settings, they will likely let friends use their account to play music if they are already logged into an account (C.5: 0). Regardless of how intimate the situation is, they will monitor their device to make sure snooping does not occur and device use is limited to the music app (C.8: +2; C.4: +1).

4.2 Factor 2 Interpretation: Viewpoint 2

Very Considerate CMS Users with Almost No Impression Management or Security Concerns

Factor 2 explains 22% of the total study variance and has an EV of 3.44. Eleven participants are significantly associated with this factor.

These CMS users are not concerned about other people knowing what they listen to at all (C.6: +2). *They do not have any privacy concerns about their music tastes and do not mind if that information becomes known to the group* (A.3: +2). They would share their tastes if people at a gathering were interested but are also okay if people are not interested (A.8: 0). They listen to certain types of music alone if it is not popular with their friends or if the music does not fit with the social event (C.3: +1).

They are comfortable making individual song recommendations to friends because they are familiar with their tastes (A.1: +2; A.2: +1). It would be very unlikely for them to force a friend to listen to a music recommendation (B.5: -1).

When confronted with music they do not like, they want to be considerate, likely tolerating a song they do not like or leaving the physical space (A.9: -3; A.5: -1). Some in this group worry that putting on headphones to block out music is antisocial (A.5: -1). They really want to be considerate of others and not critical (A.9: -3). Rather than putting on headphones they might instead comment that they liked music that was played earlier, and in that way, gently nudge music selection back in that direction

(A.9: -3). Unless they are in an intimate situation, like a small group in a car, they probably would not tell a friend to change the music (A.4: -1).

These CMS users are very considerate of others' experience with music and will participate in music activities that support everyone's enjoyment (B.8: +3). However, they do not want to make the decisions and do not want to be super engaged (B.9: +3). They prefer not to think about what to play at a social gathering (B.7: +1). They would hate being the DJ and sole decision maker at a social gathering because of how much effort it would involve (B.2: -3). To reduce the effort of selecting music, they might select a playlist, but they would still rather not have to select anything at all (B.6: 0). When selecting music they would try to match the mood of the group, but they are not confident they would be able to (B.3: 0) and are unsure that they could select the best music for the group and situation (B.2: -3). They also do not believe it would be considerate to others if they were the only ones selecting music (B.2: -3). Thus, if needed, they would take recommendations to ensure everyone is happy (B.1: -1). They like the idea of everyone being able to give input even in a large group setting, but they do not think it is always necessary or that people should feel compelled to do so (A.6: -1; B.4: 0; B.10: +1). They definitely want to make sure everybody is happy (B.3: 0).

Although they would prefer to use someone else's device, they would let others use their phone/laptop to listen to music (C.1: -2; C.4: -2). While they would not want people to snoop, they trust that people will not do so (C.2: +1). They also do not think they have anything embarrassing on their phones and laptops (C.2: +1). They envision that they might be concerned about leaving their phone or laptop out to play music in situations with a lot of strangers, such as a large party, but they have done so in the past without issues (C.8: 0; A.10: 0). However, when they are at someone else's house they do not know well, they would not feel comfortable asking to connect their phone/laptop to a speaker (A.7: -2). They would prefer others to share their logins, but situations have come up where they would share their own logins (C.7: -1); e.g., they do not mind sharing an account if they are already logged in (C.5: +2).

5. DISCUSSION

This study provided two clear viewpoints in the form of exemplifying Q sorts for two different segments of participants. The viewpoints captured the inter-relatedness of themes pertaining to social music behaviors and associated influences surrounding CMS. We confirmed that the viewpoints are an excellent way to evaluate design insights especially with a deeper understanding of influences that could drive or inhibit the adoption of a new design [25]. While a focus group study inspired many ideas, the Q methodology left us with a clearer vision of what some segments of participants would love, hate, or not care about. Based on the results of this study, researchers will also be able to investigate how viewpoints identified here can contribute to personas already existing in the field [21].

5.1 Updating an Existing Model

The Q methodology uncovered shortcomings in our interpretation and understanding of participants' statements made in focus groups. For example, Q set item A.5 *I would put my headphones on if I did not want to listen to the music that's playing in a shared space* was interpreted by researchers as it relates to intimacy. This was our a priori belief when building the Q set. After interpreting the post-sort interviews however, it became clear many participants interpreted item A.5 as it relates to considerateness and social norms rather than intimacy. Thus, analyzing participants' post-sort interview statements not only gave insight into why they sorted items the way they did, but also into how they interpreted those items.

Insight gleaned from post-sort interviews led to a better understanding of participants' viewpoints and to the identification of issues with the coding dictionary and the model from the focus group study [6]. For example, *Privacy and Security Considerations* is a theme that emerged from focus groups describing an internal influence on social practices surrounding music. Items capturing the breadth of *Privacy and Security Considerations* discussed by participants in focus groups were selected for the Q set. This Q methodology study uncovers that privacy was an inclination, almost a behavior, driven by impression management, security, or both. An updated codebook and model reflects this finding by keeping Impression Management as a theme and separating Privacy from Security considerations.

5.2 Applied Design Insights for CMS

5.2.1 Social Playlist for Gatherings

As participants in both viewpoints appreciate any features that reduce the effort needed to select songs or playlists for a group due to impression management concerns, we suggest CMS to include auto-suggested playlists that are based on the listening history of group members who have opted into this function. At a group gathering, hosts can invite their guests to add their listening history and music preferences into the mix so that the CMS can add or suggest songs for the queue. The host's invitation to guests validates and follows a previous recommendation to maintain social norms [6], such as the host having ultimate say in who chooses music for a co-located gathering. After group members have opted in, the CMS would (1) automatically queue up "safe" songs that have been previously played by a majority of individuals in the group and (2) suggest additional songs for each user to add to the queue. Suggested songs would either have been played/liked by someone else in the group or have a strong match for other criteria that the group could also select, such as a mood or social situation. Suggested songs would not be as "safe" as songs that are automatically queued, but would still reflect the interests and character of the group. This feature could alleviate viewpoint 2's lack of confidence in suggesting songs for the group since the CMS would only suggest songs where evidence of it being liked by others exists. For viewpoint 1, this feature would decrease the effort needed to think of songs that the group would like, providing them with more time to connect with others, which they value.

5.2.2 Jukebox Mode: Public-friendly Mode of CMS

For situations where a device, such as a phone or laptop, is passed around in social gatherings for guests to add songs to the queue, we recommend designers include a "Jukebox mode" on the CMS. This would lock away all of the device's other applications and private communications so that they are hidden, and only the owner can unlock the phone again to its full capabilities. Additionally, Jukebox mode would switch the CMS interface to a public-friendly version of the app, hiding the owner's private playlists so that other guests cannot view the owner's music listening history. Essentially the device becomes a jukebox, where guests can only use the device to access the CMS and its library of music. Also, a guest's music selection would not affect future music recommendations for the owner, which was another concern that CMS users expressed with sharing their phones in group settings. While akin to the Guided Access feature currently available on iPhones and Androids [38], [39], where users can lock the device to a single app on the phone through a phone setting, this feature would be part of the CMS. This mode would accommodate viewpoint 1's hesitation to have their device be used for music selection purposes, assuaging their fear of others snooping and mitigating their need to chaperone their phone. While viewpoint 2 was slightly more comfortable with others using their devices than viewpoint 1, they were less comfortable sharing in larger, less intimate groups. The "Jukebox mode" could thus address both of these viewpoints' concerns.

6. CONCLUSIONS AND FUTURE WORK

In this work, we identified two viewpoints shared by different segments of our participant group, updated a codebook and interaction model, and generated design insights. We learned how our participant group perceives social practices and associated influences surrounding CMS.

While this research is a step forward in addressing the gap in understanding social practices and associated influences surrounding CMS, the identified segments are not generalizable to the general population. A survey, informed by the segments identified in this study, would provide insight into the generalizability of these findings. Future research could also explore CMS users' perspectives in relation to culture and geography.

We believe that focus groups and other qualitative methods could support systematic Q set development, but this process has yet to be fully explored. Specifically, from this case study on social music practices, we found that exploratory focus groups and the Q methodology are excellent complementary methods. Analyzing data through constant comparative analysis, affinity diagramming, and coding of transcripts were effective in identifying the scope of the Q methodology research and generating a Q set. In future research, we plan to investigate other elicitation methods and analysis techniques to form Q sets, and explore the use of the Q methodology as a complement to methods such as narrative analysis and ethnographies. Additional research into this multi-method approach is notably important for researchers studying topics that are especially personal and private, where focus groups would not be an appropriate complementary method.

`matevz.pesek@fri.uni-lj.si`

ABSTRACT

We present the development and evaluation of a gamified rhythmic dictation application for music theory learning. The application's focus is on mobile accessibility and user experience, so it includes intuitive controls for input of rhythmic exercises, a responsive user interface, several gamification elements and a flexible exercise generator. We evaluated the rhythmic dictation application with conservatory-level music theory students through A/B testing, to assess their engagement and performance. The results show a significant impact of the application on the students' exam scores.

1. INTRODUCTION

Music theory learning and ear training is not very popular among students in music education and informal music learning, although knowing about music theory stimulates knowledge about music and enhances music appreciation. Considering the expansion of e-learning, an overwhelming part of the music theory learning still takes place in the traditional paper-and-pen form. Opportunities therefore exist for increasing student engagement with appropriate information and communications technology (ICT) tools that would support the learning process while motivating the students to use them through the use of gamification elements.

Games and gamified applications have gained traction in recent years and have become important tools in the ICT and e-learning communities. The evaluation of gamification [1, 2] and student engagement [3] has received significant attention, and the development of specialised platforms and apps for e-learning has flourished [4, 5]. Gamification has often been a medium for information retrieval and collaborative data gathering [6]. In music information retrieval, several approaches for gamification of music annotation and meta-data gathering have been proposed.

Kim et al. [7] proposed the Moodswings game for mood labelling, where the users were asked to plot the mood on the valence-arousal graph. They collected over 50.000 valence-arousal point-labels on more than 1000 songs. The authors identified gamification as the key component of user engagement. In a similar manner, Mandel and Ellis [8] proposed a web-based game for collecting song meta-data, such as genre and instrumentation. Law et al. [9] created the TagATune game for music and sound annotation. The game collects comparative information about sounds and music, where users play the game in pairs. The authors collected responses from 54 test users. They also focused on the user engagement through three aspects: sense of competence for the user, pleasantness and sensory user experience, and the opportunity to connect with a partner. Burgoyne et al. [8] presented a game named Hooked to explore the "catchiness" of songs on the responses provided by 26 users. The dataset consisted of 32 songs. Aljanaki et al. [10] developed a 'game with a purpose' to gather emotion responses to music. They collected more than 15,000 responses from 1,595 participants. Overall, in the MIR community, the developed applications mainly served as a medium to gather data.

On the other side, many web and mobile platforms for music learning exist, that also incorporate gamification elements, from instrument-related applications (e.g. My Piano Assistant [1], Yousician [2]) and music accompaniment software (e.g. iReal Pro [3]) to music-theory platforms (e.g. theoria.com, musictheory.net, Musition [4]). These platforms, however are commercial and closed-source, they are not extensible to new topics (by teachers) or adjustable to individual learning groups and curricula. While there is no doubt that they can help the user to improve their knowledge and performance, the lack of adjustment to in-class use within existing curricula is difficult without code-level access. Access to such commercial platforms may also not be affordable for all parties (e.g. public music schools).

In the paper, we present the Rhythmic dictator: a rhythmic dictation application, which is part of our larger effort to gamify various aspects of music theory learning into a common open-source platform. It is implemented as a

---

[1] Available on Google Play and Apple App store

[2] `https://yousician.com`

[3] `https://irealpro.com/`

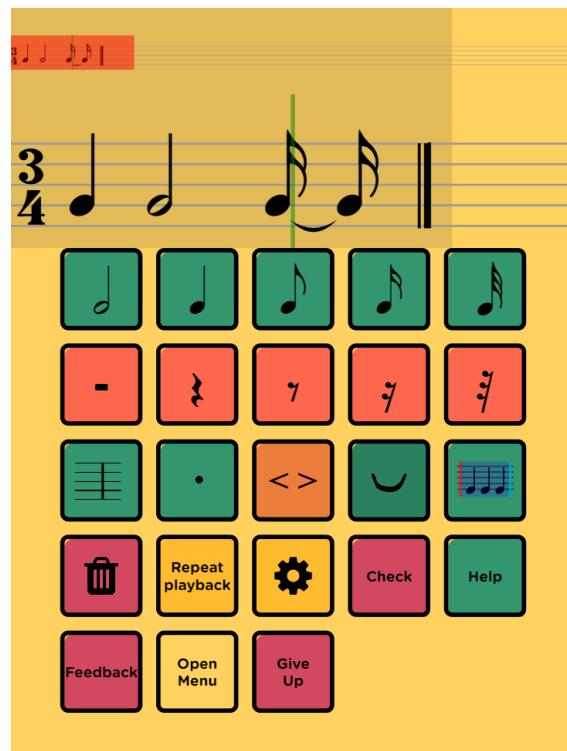
[4] `https://www.risingsoftware.com/musition`

web-based application with a responsive user interface that is specifically designed for mobile devices, since these are the most commonly used by students. The application automatically generates exercises according to the student's level of knowledge and in-app progress. To increase student engagement, gamification elements, including badges and leaderboards are implemented.

We analyse two aspects of the application's in-class use with first and second year conservatory-level students: the students' engagement, and the application's impact on the students' performance.

2. THE RHYTHMIC DICTATOR

Three exercise types are commonly performed by music theory students: melodic (interval) dictation exercises, rhythmic dictation exercises, and harmony exercises. Conventional practice usually consists of listening to a pre-recorded or teacher-performed dictation and solving it on paper. Evaluation and grading is done by the teacher.

Our rhythmic dictation application (the Rhythmic dictator) offers an easy to use and automated way for students to solve rhythmic dictation exercises in-class and out-of-class with immediate feedback on their performance and a customizable exercise generator which adapts the difficulty of generated exercises to the student's level of knowledge. The application was developed as a responsive web application, which adapts well to mobile devices. In this way, the development and maintenance of the platform is simplified, as the platform is browser-accessible on all major platforms—Windows, Linux, OS X for desktop environments, as well as Android and iOS for mobile devices.


The application is incorporated into the Troubadour platform [5], which is a framework for music theory learning with support for gamification elements including badges, points and leaderboards. The application and the platform are easily deployable with the use of package management tools, and the code is available as open source software and publicly accessible on GitHub [6].

2.1 The user interface

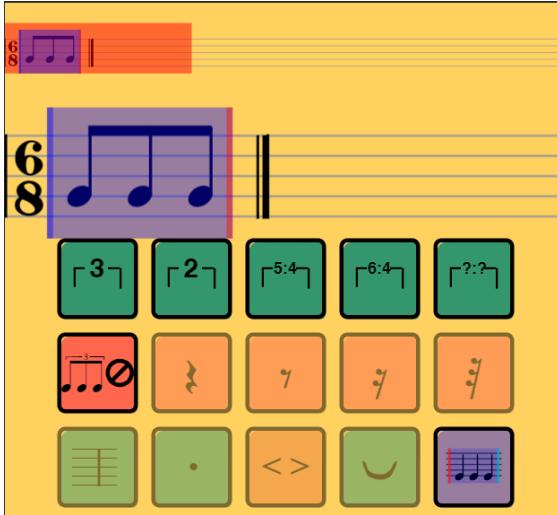
In rhythmic dictation, the students listen to a rhythmic sequence, which they have to write down in music notation. The main part of the Rhythmic dictator's user interface (Figure 1) therefore includes two staves displaying the input rhythmic sequence and a rhythm input interface. The upper (smaller) stave shows the entire sequence with a red rectangle indicating the area shown in the lower larger stave, where the user inputs their response to the dictation. The dictation can be played-back repeatedly and paused while playing.

The rhythm input keyboard supports a variety of rhythmic inputs: note and pause lengths, subdivisions and syncopation. To accommodate for the small screens of mobile

---

[5] https://trubadur.si
[6] https://bitbucket.org/ul-fri-lgm/troubadour_production

devices, the inputs are split into two layouts: on the primary layout, the most common note and pause lengths are displayed. With keys for subdivision and syncopation, the layout changes to show a set of additional input options, as shown in Figure 2.

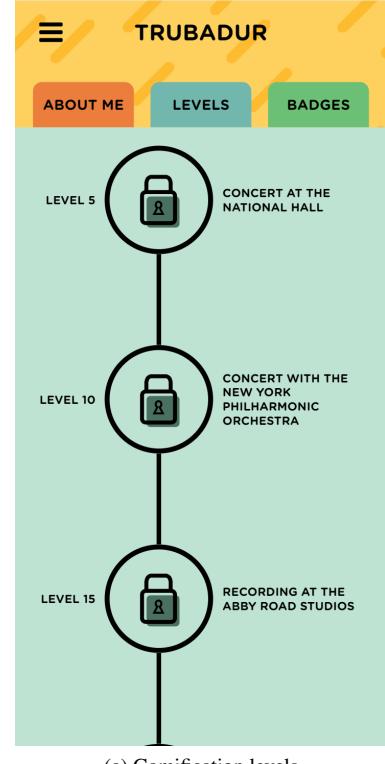
Figure 1: The main screen of the rhythm dictation application on a mobile device. The primary rhythm input interface is shown below the staves.


Each exercise begins with a metronome indicating the meter and is followed by the rhythmic dictation playback. The student can pause and replay the dictation, and adjust the playback speed and volume. The dictation is played using an organ sound. The sound was chosen in discussion with music theory teachers due to its fast onset, steady sustain and a clear offset. While the sound of piano is commonly used for melodic dictation, its unclear offset can cause ambiguities in determining the event length (vs. pause). Our choice of the sound was also evaluated with the users during the evaluation period.

2.2 Automatic generation of exercises

The Rhythmic dictator includes an exercise generator that can generate exercises of different difficulty levels. The difficulty of a rhythmic exercise is governed by several parameters: subdivision complexity (from quarter notes, to 32nd notes), subdivision types (dual vs. ternary), subdivision distributions, and the number of events (length of the sequence). Randomly generating the exercises with uniform distributions of these parameters yields meaningless and unrealistic sequences that are non-intuitive and difficult to solve and which lower the student's motivation. We therefore analyzed the existing materials that teachers used

Figure 2: The secondary keyboard layout with options for adding and modifying subdivisions.

in their classes and created parameter distributions for various difficulty levels. The distributions take into account the frequency of event occurrences, as well as their in-bar position, to reflect the rhythmic patterns, which are common in music. In this way, the randomly generated sequences become more musically meaningful and engage the student individually with sufficient difficulty, while not overwhelming them with either too difficult or meaningless examples.


We arranged the distributions into 16 difficulty levels, ranging from elementary music school to academia. The levels are split into four major levels, and each major level is split into additional four minor levels. We marked the levels with numbers {11-14, 21-24, 31-34 and 41-44}, with the first digit corresponding to the major and the second to the minor difficulty level. The parameter distributions for each level were set as the default values for exercise generation in the rhythmic dictation application, however teachers are able to modify the distributions according to their didactic expertise and needs.

2.3 Gamification elements

To increase the motivation for using the application among the students, we enriched it with elements of gamification. We use three gamified elements related to students' performance: progression between multiple levels of proficiency, a leaderboard and achievement badges. The gamification elements are visible on the home screen, where students can browse through their achievements, as seen in Figures 3a and 3b.

While using the application, students earn points by solving the exercises, which directly affects their achievements. Each exercise consists of two sequences that can be answered multiple times. After each completed exercise, the student's points are calculated, measured as a function of several factors: exercise difficulty (across the 16 difficulty levels), time taken (in minutes), number of corrections (additions and deletions of notes), the use of the

metronome (yes/no), the number of submission attempts (checks for correctness), and whether the final sequence was correct. The sum of points can be either positive or negative.

(a) Gamification levels

(b) Achieved badges

Figure 3: Gamification elements. The left screen shows progression between multiple badge levels of proficiency, while the right screen shows the badges obtained during the practice.

By solving more excercises and progressing through levels of difficulty, students increase their level of proficiency (Figure 3a). The levels were defined by the teachers, and vary from local orchestra, to different competitions and international institutions.

The badges, shown in Figure 3b, reflect three different aspects of student progress. The first aspect is accuracy: completing an exercise with(out) a certain amount of mistakes (from 50% up to 100% correct answers). The second aspect is the continuity of the student's engagement with the platform: playing an exercise for a certain amount of days in a row—3 days, 5 days, a week, two weeks, a month. The third aspect is the student's speed: the amount of time needed to complete an exercise in 5 minute intervals, ranging from 25 minutes to 5 minutes.

As an additional element of gamification, we implemented a leaderboard. The leaderboard shows the cumulative points collected by an individual. More points can be achieved by both the number of solved exercises and the exercise difficulty. The students can observe their performance and compare it to the other players. By clicking on one of the platform's users the selected user's profile page is displayed, with their achieved levels and badges.

3. EXPERIMENT

The primary goal of the developed application was to provide an open platform, which would engage students and increase their performance in rhythmic dictation tasks. The application was tailored to increase student engagement through gamification elements and an intuitive interface on mobile devices. In our experiment, we wanted to assess whether these goals were achieved.

We evaluated several hypotheses. First, we assumed the mobile-friendly interface will enable the students to engage with the application. While the students might spend more time with an individual exercise at the beginning to get used to the interface, the time spent for solving an exercise should in time decrease due to familiarity with the interface and the student's increased proficiency. Second we hypothesized that student engagement will have an impact on their exam performance.

During the experiment, we collaborated with first and second year students at the Conservatory of Music and Ballet Ljubljana, Slovenia. First, we developed the application through continuous evaluation with four conservatory students (two first and two second year), who represented a sample of our target audience. We continually evaluated the students' interaction with the application: whether they understood the user interface, whether the exercises were appropriately demanding and whether the exercises were sufficiently interesting and engaging.

We then evaluated the application with the first and second year students at the conservatory. The students were randomly divided into one test and one control group in each year. The evaluation lasted for five weeks, during which we held four in-class meetings with the students of the test groups. Students were asked to use the application during the meetings through a group student challenge, during which the students competed to achieve points in the application.

After the five week period, students of both test and control groups participated in a standard curriculum exam. We compared the exam results and observed the application's impact on exam performance. The test groups consisted of 11 first and 12 second year students, while the control groups consisted of 11 first and 13 second year students.

In this section, we first describe the evaluation, followed by an analysis of the collected data.

3.1 Application evaluation - student challenge

During the five-week application evaluation period, four meetings with the test group students were organised. The meetings were held during the music theory classes. Our goal was to observe the student engagement with the application. To gain the interest of students, we proposed a student challenge, where the students competed to gain points and rank high on the leaderboard.

3.1.1 Initial questionnaire

At the first meeting, the students of both control and test groups were given a questionnaire that contained general questions about the use of tools for practicing music theory on mobile devices. The first part of the questionnaire involved questions about which applications (including music theory apps) the students use on their mobile devices. The second part of the questionnaire consisted of questions about the students' rhythm practicing at home.The questionnaire was answered by 47 students.

All students were using mobile applications, such as social, messaging and music apps (SnapChat, Instagram, FB Messenger, YouTube). 79% of the students reported on using mobile apps for learning new skills, such as foreign languages and instruments. However, applications for practicing music theory, such as Teoria.com, TonedEar and MyEarTrainer, were rarely mentioned. Only a few students (17%) used various rhythmic dictation exercises. In the second part of the questionnaire, most students reported practicing rhythmic exercises at home (67%), however they showed mixed opinions on whether they wanted additional ways to exercise rhythmic dictation, as 55% of students did not want additional rhythmic dictation exercises. The shift in their opinion therefore posed a key challenge for the success of the proposed application.

3.1.2 Weeks 2 and 3

During weeks 2 and 3, we enabled access to the application to the test groups. We conducted a live challenge during a music theory class. The goal of the challenge was to increase student engagement with the application, by enticing them to gather points and rank high on the leaderboard. During the challenge, we motivated the students further by presenting intermediate results live on a classroom display. Symbolic rewards were given to the first three students.

During the week 3 meeting, we also distributed questionnaires to the test group students. We asked the students about their experience with the application. The results of

the questionnaire were mostly positive. When asked if the application was difficult to use, all students answered no (100%). Most of them answered that the exercises were not difficult (16 students, 69%) and that they got used to the application's use over time (16 students, 69%). The answers were consistent with the goal that the application should be easy to use. Most students responded that the rhythm input keyboard worked as intended (13 students, 72%). The majority did not use additional paper and pencil (17 students, 94%) exercises. However, the sound of the organ used by the application was perceived as disturbing (16 students, 89%). Many answered that they would rather listen to the piano because they are more accustomed to it. Two thirds of the students had enough time to complete the exercises (12 students, 67%), and did not adjust the speed of the dictation playback (67%).

3.1.3 Week 5

Five weeks after the beginning of the application's evaluation period, we organised the fourth meeting. We presented the final results of the participating students and handed out plaques to the winners of the challenge. All students received symbolic rewards in gratitude.

We also asked the test group students to respond again to the questionnaire which was handed out during the third meeting. We investigated the changes in their opinions after one month of application use. Again, we received positive responses. The students replied that the exercises were not difficult (91%). All students got used to the application during this time. To most students, the rhythm input keyboard functionality seemed logical and worked as intended (82%). All students began using the application to practice and stopped using the conventional paper and pencil practice. The students also grew accustomed to to the sound of the organ used for playback (73 percent).

Most students had enough time to complete the exercises (91%), and did not adjust the playback speed (91%). When asked whether they showed the application to their friends, the majority responded positively (73%). In their final remarks, the students highlighted the following features:

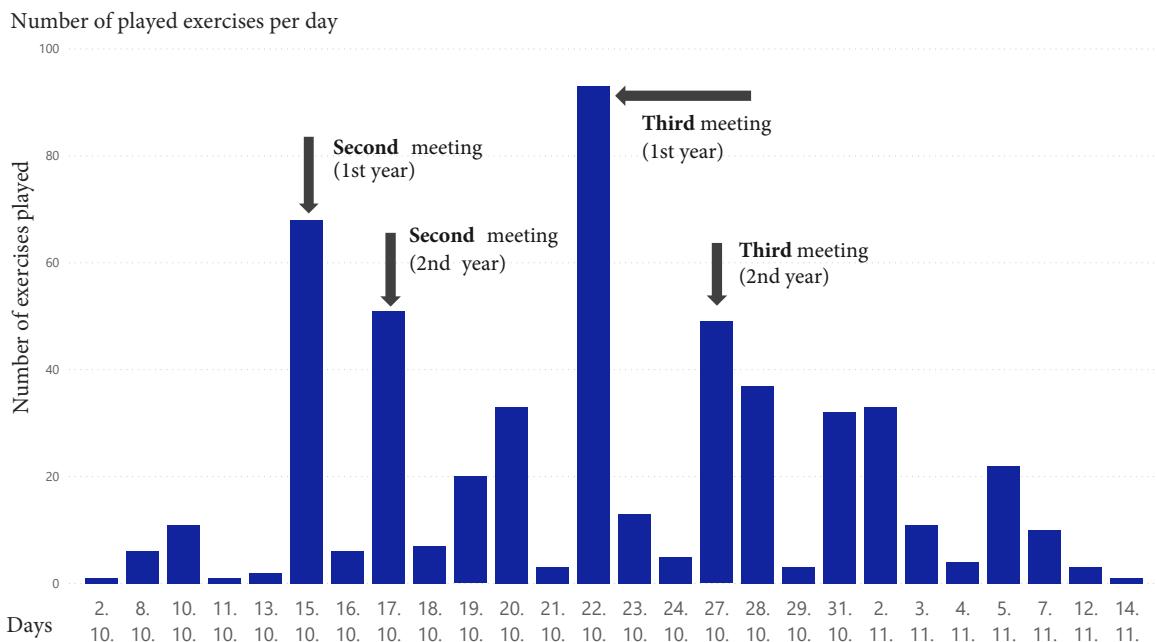
- the students liked the ability of using the application on a personal computer in addition to the mobile device,

- the scoring and achievements (badges) were motivating,

- the ability to pause/stop the playback was helpful.

3.2 Analyzing the application data

Twenty-three students, 11 from the first and 12 from the second year, completed 496 exercises in total. Each exercise consisted of two rhythmic sequences that could be answered multiple times. In total, the students answered 837 sequences correctly. The first-year students averaged 24.5 sequences and the second-year 26 sequences.

The rhythm dictation application is organised into 16 difficulty levels. In order to advance to a higher level, the student had to complete at least 12 exercises at the current level. When starting the application, the student could choose which level to start at from the subset of levels they already achieved. 39% of the students remained at the first level (level 11), because they did not complete enough exercises to pass on to the next level, while others moved to higher levels. During the evaluation, only one student reached all the rhythmic levels available. We also observed the time needed to complete the individual exercises. In their first exercises, the students needed more time than in later repetitions - the average time gradually decreased with the number of exercises played. With increasing difficulty levels, we noticed that the number of event deletions increased. The number of dictation plays remained steady across all levels of difficulty. The number of attempts to solve also remained steady with the exception of level 11 (1/16 difficulty level), where sequences were trivial for the conservatory-level students to solve.


The gathered data confirmed our assumption that some of the observed values, such as time spent, decreased over time, while others remained steady due to the increasing difficulty of exercises. Student engagement in out-of-class use gradually increased, which we consider a success in terms of user experience - student liked the interface and found it easy to use - as well as gamification elements, which, through the student challenge, brought competitiveness into interaction between students.

3.3 Exam performance

At the end of the evaluation period, the students completed an exam as part of their standard curriculum. The exam was taken in the traditional form, with the teacher dictating the rhythmic sequences and students writing their responses on paper. We analyzed the exam results and compared the grades within and between the groups. The exam was evaluated with grades 1 (worst grade) to 5 (best grade). The first-year control group students achieved an average grade of 4.3, while the test group students achieved an average of 4.5 (4% increase). The results were statistically tested using the MannWhitney U-test and the difference was not statistically significant (U=16, p >0.05). A larger difference was observed for second-year students, where the control group achieved an average score of 3.58 and the test group 4.44 (19% better, significant difference, U=24, p<0.001). As better results were achieved by students using the rhythmic dictation application, we can conclude that the use of the application had a positive effect on their performance in the exam. As both groups were relatively small, we also used a resampling method to compare the group averages. At 1000 replicates, the method estimated a 69.2% probability that the average test group score was greater than the average control group score for the first-year student groups. For second-year results, the algorithm estimated this probability at 99.6% at 1,000 iterations. These estimates confirmed the Mann-Whitney U test, therefore showing that students who used the application performed better in the exam.

The difference between the first (no significant impact)

Number of played exercises per day

Figure 4: Graph of the application's usage frequency per day. The second and third meetings are marked individually for each test group. The engagement (# of exercises) was initially higher for the first year students, however, it decreased over time, while the engagement for the second year student group remained steady.

and second year (significant impact) students could be attributed to the fact that the second year students were on average more steadily engaged during the application's evaluation period (Figure 4). The students who ranked highest in the competition rankings were from the second year test group. However, both groups were small and a larger longitudinal study is needed to further confirm the results of this evaluation, and to fully evaluate the application's impact on the learning process and performance.

4. CONCLUSION AND FUTURE WORK

In this paper, we presented the Rhythmic dictator—a rhythmic dictation application. The application features a mobile-friendly user interface supported by gamification elements for attaining student engagement, while offering a flexible environment for the teachers. We investigated two aspects of the application—student engagement and exam performance. To engage students, we created a five week challenge during which the students were asked to use the application through a gamified experience of collecting points and badges, which were visible to other students. Their performance was later tested in a conventional exam, where we compared the results of the students who used and who did not use the application.

The evaluation showed that students support the use of a gamified application. Overall, the students reported a very positive user experience, which was further substantiated by the claim that they would recommend the application to their friends.

The comparison of exam results between the control and the test groups showed a positive impact of the application's use on exam results, which was statistically sig-

nificant for second year students. Although the test and control groups were small and the results should not be too quickly generalised, the study was carried out at the Conservatory of music and ballet, Ljubljana, Slovenia, which represents roughly 50% of the state-wide student population enrolled in a music programme at this level. Based on the evaluation presented in this paper, we can corroborate the gamified Rhythmic dictator application aids the students' performance, which we attribute to gamification and automatization of rhythmic dictation exercises.

To further confirm the application's impact on music theory learning, our current work includes a longitudinal study with new exercise types and an evaluation of the use of the multi-player mode for real-time remote interaction. The application is currently also used in class, where we are collecting new student engagement data.

LEARNING TO DENOISE HISTORICAL MUSIC

Yunpeng Li   **Beat Gfeller**   **Marco Tagliasacchi**   **Dominik Roblek**

Google

ABSTRACT

We propose an audio-to-audio neural network model that learns to denoise old music recordings. Our model internally converts its input into a time-frequency representation by means of a short-time Fourier transform (STFT), and processes the resulting complex spectrogram using a convolutional neural network. The network is trained with both reconstruction and adversarial objectives on a synthetic noisy music dataset, which is created by mixing clean music with real noise samples extracted from quiet segments of old recordings. We evaluate our method quantitatively on held-out test examples of the synthetic dataset, and qualitatively by human rating on samples of actual historical recordings. Our results show that the proposed method is effective in removing noise, while preserving the quality and details of the original music.

1. INTRODUCTION

Archives of historical music recordings are an important means for preserving cultural heritage. Most such records, however, were created with outdated equipment, and stored on analog media such as phonograph records and wax cylinders. The technological limitation of the recording process and the subsequent deterioration of the storage media inevitably left their marks, manifested by the characteristic crackling, clicking, and hissing noises that are typical in old records. While "remastering" employed by the recording industry can substantially improve the sound quality, it is a time-consuming process of manual labor. The focus of this paper is an automated method that learns from data to remove noise and restore music.

Audio denoising has a long history in signal processing [1]. Traditional methods typically use a simplified statistical model of the noise, whose parameters are estimated from the noisy audio. Examples of these techniques are spectral noise subtraction [2, 3], spectral masking [4, 5], statistical methods based on Wiener filtering [6] and Bayesian estimators [7, 8]. Many of these approaches, however, focus on speech. Moreover, they often make simplifying assumptions about the structure of the noise, which makes them less effective on non-stationary real-world noise.

Recent advances in deep learning saw the emergence of data-driven methods that do not make such *a priori* assumptions about noise. Instead they learn an implicit noise model from training examples, which typically consist of pairs of clean and noisy versions of the same audio in a supervised setup. Crucial challenges facing the adoption of the deep learning paradigm for our task are: i) can we design a model powerful enough for the complexity of music, yet simple and fast enough to be practical, and ii) how can we train such a model, given that we have no clean ground truth for historical recordings? In this paper, we address these issues and show that it is indeed feasible to build an effective and efficient model for music denoising.

1.1 Related Work

Sparse linear regression with structured priors is used in [9] to denoise music from synthetically added white Gaussian noise, obtaining large SNR improvements on a "glockenspiel" excerpt, and on an Indian polyphonic song. [10] considers the problem of removing artifacts of perceptual coding audio compression with low bit-rates. That work, which uses LSTMs, is the first successful application of deep learning for this type of music audio restoration. Note that in contrast to our work, aligned pairs of original and compressed audio samples are readily available. Statistical methods are applied in [11] to denoise Greek Folk music recorded in outdoor festivities. In [12], the author applies structured sparsity models to two specific audio recordings that were digitized from wax cylinders, and describes the results qualitatively. In [13], the authors describe how to fill in gaps (at known positions) of several seconds in music audio, using self-similar parts from the recording itself.

Our method is also related to audio super-resolution, also known as bandwidth extension. This is the process of extending audio from low to higher sample rates, which requires restoring the high frequency content. In [14, 15] two approaches which work for music are described. On piano music, for example, [15] obtains an SNR of 19.3 when upsampling a low-pass filtered audio from 4kHz to 16kHz.

Many existing denoising approaches focus on speech instead of music [16–19]. Given that these two domains have very different properties, it is not clear a priori how well such methods transfer to the music domain. Nevertheless, our work is inspired by recent approaches that use generative adversarial networks (GANs) to improve the quality of audio [18, 20, 21]. For example, [21] obtains

significant improvements denoising speech and applause sounds that have been decoded at a low bit-rate, using a wave-to-wave convolutional architecture.

In this paper, we present a method to remove noise from historical music recordings, using two sources of audio: i) a collection of historical music recordings to be restored, for which no clean reference is available, and ii) a separate collection of music of the same genre that contains high-quality recordings. We focus on classical music, for which both public domain historical recordings as well as modern digital recordings are available. This paper makes the following contributions:

- We provide a fully automated approach that succeeds in removing noise from historical recordings, while preserving the musical content in high quality. Quality is measured in terms of SNR and subjective scores inspired by MUSHRA [22], and examples on real historical recordings are provided [1].

- Our approach employs a new architecture that transforms audio in the time domain, using a multi-scale approach, combined with STFT and inverse STFT. As this architecture is able to output high-quality music, it may be a useful architecture for other tasks that involve the transformation of music audio.

- We provide an efficient and fully automated method to extract noise segments (without music) from a collection of historical music recordings. This is a key ingredient of our approach, as it allows us to create synthetic pairs of <clean, noisy> audio samples.

The rest of this paper is organized as follows. Our approach is described in detail in Section 2, and experimental results are given in Section 3. We conclude in Section 4.

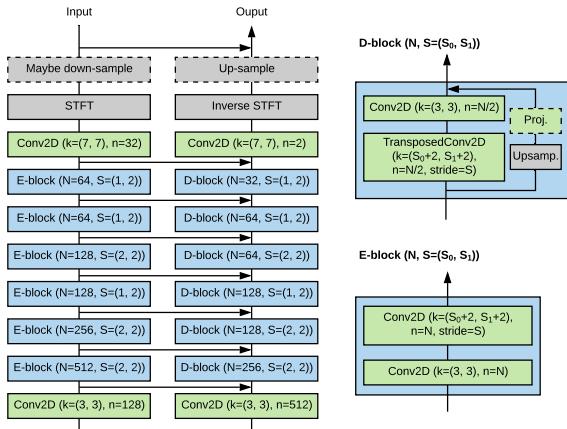
2. METHOD

Our model is an audio-to-audio generator learned from paired examples with both reconstruction and adversarial objectives.

2.1 Creating paired training examples

For training, we use time-aligned pairs of <clean, noisy> examples, where clean music is used as targets, and noisy music as inputs to the generator. We take a data-driven approach to generate noisy audio from clean references. We synthesize noisy samples by simulating the degradation process affecting the historical recordings, namely applying band-pass filtering, followed by additive mixing with noise samples extracted from "quasi-silence" segments of historical recordings.

Specifically, we scan the noisy historical recordings looking for low-energy segments in the time domain, which corresponds to pauses in the musical scores. To this end, we compute the rolling standard deviation from the raw audio samples with a window size equal to 100ms.

Then, we estimate an adaptive threshold τ based on the q-th quantile of the standard deviations and keep the segments that satisfy the following two conditions: i) the local standard deviation is below τ, and ii) the segment has a minimum duration of T. Intuitively, the value of q is selected based on a trade-off between the number of extracted segments and the need of extracting noise-only segments. In our experiments, we set $q = 0.5\%$ and $T = 100$ms. In this way, from 801 different recordings, we are able to extract around 8900 noise samples.


From each of these short noise segments, we need to generate noise samples having the same length as the clean audio references. We do this by replicating the noise segment in time, using overlap-and-add (OLA) with an overlap equal to 20% of the segment length. Given the short duration of most noise segments, this operation alone would lead to periodic noise patterns which differ from the noise characteristics found in historical recordings. Therefore, we alter each noise segment replica before the OLA synthesis step in two ways: i) applying a random perturbation to the phase of the noise segment (adding Gaussian noise $\sim \mathcal{N}(0, 0.1)$ to the phase of the STFT); ii) applying a random shift in time (with wraparound). We found that these simple operations produce longer noise samples with auditory characteristics similar to the ones encountered in the historical recordings, avoiding artificial periodic patterns.

Finally, we create time-aligned pairs of <clean, noise> examples by: i) applying band-pass filtering with cut-off frequencies randomly sampled in [50Hz, 150Hz] and [5kHz, 10kHz], respectively; ii) mixing a randomly selected noise sample with a gain in the range [10dB, 30dB].

2.2 Model architecture

The generator processes the audio in the time-frequency domain. It first computes the STFT of the input, the real and imaginary components of which are then fed as a 2-channel image to a 2D convolutional U-Net [23] followed by an inverse STFT back to the time domain. Finally the output is added back to the input, making the model a residual generator.

The U-Net in our generator is a symmetric encoder-decoder network with skip-connections, where the architecture of the decoder layers mirrors that of the encoder and the skip-connections run between each encoder block and its mirrored decoder block. Each encoder block is a 3×3 convolution followed by either a 3×4 convolution with stride of 1×2 (if down-sampling in the frequency dimension), or a 4×4 convolution with stride of 2×2 (if down-sampling in both time and frequency dimensions). We choose kernel sizes to be multiples of strides to ensure even contribution from all locations of the input feature map, which prevents the formation of checkerboard-like patterns in resampling layers [24]. The decoder blocks mirror the encoder blocks, and each consists of a transposed convolution for up-sampling followed by a 3×3 convolution. Each decoder block additionally includes a shortcut connection between its input and output. The shortcut consists of a nearest-neighbor up-sampling layer, which

---

Figure 1. Generator architecture. Dashed-line components are included on a need-to-have basis: Up/down-sampling of the input/output audio is needed for processing at coarser resolutions in a multi-scale setup; The linear projection (by 1x1 convolution) in the decoder block is present only when the output of the block has a different number of channels from its input.

is followed by a linear projection using 1x1 convolution when the output has a different number of channels from the input. We do not include a shortcut in the encoder block, since it already shares the same input with a U-Net skip connection and therefore only needs to produce the residual complementary to the skip path. The architecture of the generator is shown in Figure 1.

We use two discriminators for the adversarial objective, one in the waveform domain and one in the STFT domain. The STFT discriminator has the same architecture as the encoder module of the generator. For the waveform discriminator, we use the same architecture as MelGAN [25] except that we only double (instead of quadruple) the number of channels in the down-sampling layers. We found this light-weight version to be sufficient in our setup, and that using the full version had no additional benefit. Both discriminators are fully convolutional. Hence the waveform discriminator produces a 1D output spanning the time domain, and the STFT discriminator has a 2D output spanning the time-frequency domain.

We use weight normalization [26] and ELU activation [27] in the generator, while layer normalization [28] and Leaky ReLU activation [29] with $\alpha = 0.3$ are used in the discriminator.

2.2.1 STFT Representation

In the generator, the STFT is represented by a 2-channel image, where the channels are the real and imaginary components. We also explored a polar representation, where the channels are the modulus and the phase; additionally we experimented with processing only the modulus channel and reusing the original phase, as is done in [30]. Nevertheless, we found the real/imaginary representation to perform better in our experiments.

Furthermore, we tried aligning the phase so that the phase in each frame is coherent with a global reference (e.g., the first frame) rather than its local STFT window. Again, we observed no advantage in doing so, which suggests that the neural network is capable of internally handling the phase offsets. Unlike [30], we do not convert STFT to logarithmic scale as we found it be detrimental to performance (even with various smoothing and normalization schemes).

2.2.2 Multi-scale Generator

We can further stack multiple copies of the generator described above, each with its own separate parameters, in a coarse-to-fine fashion: The generators at earlier stages process the audio at reduced temporal resolutions, whereas the later-stage generators focus on restoring finer details. This is equivalent to halving the sampling rate in each scale. This type of multi-scale generation scheme is routinely used in computer vision and graphics to produce high-resolution images (e.g., [31]).

Let K be the total number of scales, then generator G_k at scale k ($k \in \{0, \ldots, K-1\}$) down-samples its input by a factor of 2^k before computing the STFT and up-samples the output residual (after computing the inverse STFT) by the same factor to match the resolution of the input. The overall generator G is the composite of $G_0 \circ \cdots \circ G_{K-1}$.

Compared with simply stacking U-Nets all at the original input resolution, as done in [32], the benefit of the multi-scale approach is two-fold: i) the asymptotic computational complexity is constant with respect to the number of scales, as opposed to linear in [32], due to exponentially decreasing input sizes at coarser levels; ii) the intermediate outputs of the generator correspond to the input audio processed at lower resolutions, which allows us to meaningfully impose multi-scale losses on the intermediate outputs in addition to the final output. We will describe how this can be accomplished in the next section.

2.3 Training

The generator can be trained using the reconstruction loss between the denoised output and the clean target. This can be further complemented with an adversarial loss, given by discriminators trained simultaneously with the generator, a practice often used in audio enhancement (e.g., [18,20,30], among others). In the case of our multi-scale generator, we use the same number of waveform and STFT discriminators as generator scales. This way, there is one discriminator of both types for each of the (down-sampled) intermediate outputs and final output in each domain. For the adversarial loss, we use the hinge loss averaged over multiple scales. Since the discriminators are convolutional, this loss is further averaged over time for the waveform discriminator and over time-frequency bins for the STFT discriminator. Similarly, the reconstruction loss is also imposed on the outputs at each scale.

More formally, let (x, y) denote a training example, where x is the noisy input and y is the clean target, and $k \in \{0, \ldots, K-1\}$ denote the scale index. Hence y_k is the

clean audio down-sampled to scale k, and $\hat{y}_k$ represents the intermediate output of the generator $G_k \circ \cdots \circ G_{K-1}(x)$ down-sampled to the same scale. Note that for the finest scale $k = 0$ at full resolution, $y_0 = y$ is simply the original clean audio and $\hat{y} \triangleq \hat{y}_0 = G(x)$ is the final output of the generator. Thus the L^1 reconstruction loss in the STFT domain can be written as

$$\mathcal{L}_G^{\text{rec}} = \mathbb{E}_{(x,y)} \left[\sum_k \frac{\|\omega_k - \hat{\omega}_k\|_1}{S_k^{\text{STFT}}} \right], \qquad (1)$$

where 2D complex tensors ω_k and $\hat{\omega}_k$ denote the STFT of down-sampled clean audio y_k and generator output $\hat{y}_k$ for scale k, respectively, and S_k^{STFT} is the total number of time-frequency bins in ω_k and $\hat{\omega}_k$. We find this STFT-based reconstruction loss to perform better than either imposing per-sample losses directly in the waveform domain or using losses computed from the internal "feature" layers of discriminators (e.g. [25]).

For the adversarial loss, let t denote the temporal index over all T_k logits of the waveform discriminator at scale k (recalling that the discriminators are fully convolutional) and let s denote the index over all S_k logits of the STFT discriminator. Then discriminator losses in the wave and STFT domains can be written as, respectively,

$$\mathcal{L}_D^{\text{wave}} = \mathbb{E}_y \left[\sum_{k,t} \frac{1}{T_k} \max(0, 1 - D_{k,t}^{\text{wave}}(y_k)) \right] +$$

$$\mathbb{E}_x \left[\sum_{k,t} \frac{1}{T_k} \max(0, 1 + D_{k,t}^{\text{wave}}(\hat{y}_k)) \right] \qquad (2)$$

$$\mathcal{L}_D^{\text{STFT}} = \mathbb{E}_y \left[\sum_{k,s} \frac{1}{S_k} \max(0, 1 - D_{k,s}^{\text{STFT}}(y_k)) \right] +$$

$$\mathbb{E}_x \left[\sum_{k,s} \frac{1}{S_k} \max(0, 1 + D_{k,s}^{\text{STFT}}(\hat{y}_k)) \right], \quad (3)$$

and the corresponding adversarial loss for the generator is given by

$$\mathcal{L}_G^{\text{adv}} = \mathcal{L}_G^{\text{adv, wave}} + \mathcal{L}_G^{\text{adv, STFT}}$$

$$= \mathbb{E}_x \left[\sum_{k,t} \frac{1}{T_k} \max(0, 1 - D_{k,t}^{\text{wave}}(\hat{y}_k)) + \right.$$

$$\left. \sum_{k,s} \frac{1}{S_k} \max(0, 1 - D_{k,s}^{\text{STFT}}(\hat{y}_k)) \right]. \qquad (4)$$

The overall generator loss is a weighted sum of the adversarial loss and the reconstruction loss, i.e.,

$$\mathcal{L}_G = \mathcal{L}_G^{\text{rec}} + \lambda \cdot \mathcal{L}_G^{\text{adv}}. \qquad (5)$$

We set the weight of the adversarial loss λ to 0.01 in all our experiments, except those where we do not use discriminators (which corresponds $\lambda=0$). We train the model with TensorFlow for 400,000 steps using the ADAM [33]

optimizer, with a batch size of 16 and a constant learning rate of 0.0001 with $\beta_1 = 0.5$ and $\beta_2 = 0.9$. For the STFT, we use a window size of 2048 and a hop size of 512 when there is only a single scale. For each added scale we halve the STFT window size and hop size *everywhere*. This way the STFT window at the coarsest scale has a receptive field of 2048 samples at the original resolution, whereas finer levels have smaller receptive fields and hence focus more on higher frequencies.

Our model has around 9 million parameters per scale in the generator. At inference-time, it takes less than half a second for every second of input audio on a modern CPU and more than an order of magnitude faster on GPUs.

3. EXPERIMENTS

We evaluate our model on a dataset of synthetically generated noisy-clean pairs, using both objective and subjective metrics. In addition, we also provide a subjective evaluation on samples from real historical recordings, for which the clean references are not available.

3.1 Datasets

Our data is derived from two sources: i) digitized historical music recordings from the Public Domain Project [34], and ii) a collection of classical music recordings of CD-quality. The historical recordings are used in two ways: i) to extract realistic noise from relatively silent portions of the audio, as described in Section 2.1; and ii) to evaluate different methods based on the human-perceived subjective quality of their outputs. The modern recordings are used for mixing with the extracted noise samples to create synthetic noisy music, as well as serving as the clean ground truth. We additionally filter our data to retain only classical music, as it is by far the most represented genre in historical recordings. The resulting dataset consists of pairs of clean and noisy audio clips, both monophonic and 5 seconds long, sampled at 44.1kHz. The total duration of the clean clips is 460h.

3.2 Quantitative Evaluation

We quantitatively evaluate the performance of different methods on a held-out test set of 1296 examples from the synthetic noisy music dataset. For the neural network models, whose training is stochastic, we repeat the training process 10 times for each model and report the mean for each metric and its standard error.

Evaluation metrics: Objective metrics such as the signal-to-noise ratio (SNR) faithfully measure the difference between two waveforms on a per-sample basis, but they often do not correlate well with human-perceived reconstruction quality. Therefore, we additionally measure the *VGG distance* between the ground truth and the denoised output, which is defined as the L^2 distance between their respective embeddings computed by a VGGish network [35]. The embedding network is pre-trained for multi-label classification tasks on the YouTube-100M dataset, in which labels are assigned automatically based

	ΔSNR (dB)	-ΔVGG
1 scale	**3.4±0.0**	0.68±0.01
2 scales	**3.4±0.0**	**0.78±0.01**
3 scales	3.2±0.0	0.73±0.01

Table 1. Performance of our model with different numbers of scales K in terms of SNR gain (ΔSNR) and VGG distance reduction (-ΔVGG). Higher is better.

on a combination of metadata (title, description, comments, etc.), context, and image content for each video. Hence we expect the VGG distance to focus more on higher-level features of the audio and less on per-sample alignment. Note that the same embedding used by Frechét audio distance (FAD) [36], which measures the distance between two *distributions*. However, FAD does not compare the content of individual audio samples, and is hence not applicable to denoising.

We report the SNR gain (ΔSNR) and VGG distance reduction (-ΔVGG) of the denoised output relative to the noisy input, averaged over the test set. For reference, the noisy input has an average SNR of 14.4dB and VGG distance of 2.09. Table 1 shows the performance of our model with different numbers of scales. We use $K = 2$ scales for the rest of our experiments. We evaluate variants of our proposed model in an ablation study and compare with alternative approaches and well-established signal processing baselines:

- **Ours, λ=0**: Our model trained with only reconstruction loss.

- **Ours, λ=0.01**: Our model trained with both adversarial and reconstruction losses.

- **Ours, bypass phase**: Same as above, except that the phase of the noisy input is reused and only the modulus of the STFT is processed by the U-Net (as a single-channel image). This is similar to the approach of [30], but trained and evaluated for music denoising instead of speech.

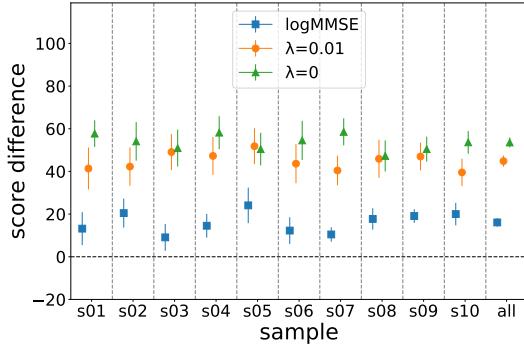
- **MelGAN-UNet**: A 1D-convolutional waveform-domain generator inspired by MelGAN [25], where the decoder is the same as the generator of MelGAN and the encoder mirrors the decoder.

- **DeepFeature generator**: The 1D-convolutional waveform-domain generator of [17], which does not use U-Net but rather a series of 1D convolutions with exponentially increasing dilation sizes. Unlike U-Net, the temporal resolution and number of channels remain unchanged in all layers of this network.

- **log-MMSE**: A short-time spectral amplitude estimator for speech signals which minimizes the mean-square error of the log-spectra [37]. In our implementation, the estimation of the noise spectrum is based on low-energy frames across the whole clip, rather than considering the frames at the start of the audio clip. We use this deviation from the standard implementation as it gives better SNR results.

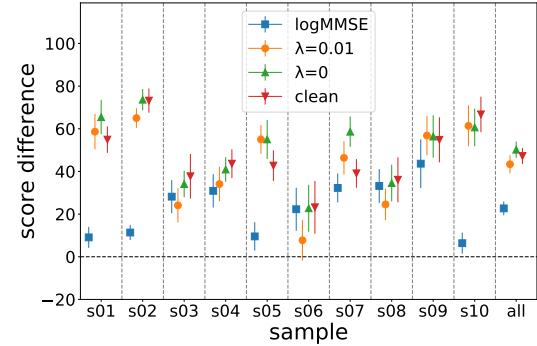
- **Wiener**: A linear time-invariant filter that minimizes the mean-square error. We adopted the SciPy [38] implementation and used default parameters, as different parameter settings did not improve the results.

For waveform-domain generators, we tried waveform-domain losses – including reconstruction losses in the "feature space" of discriminator internal layers [17, 25] – as well as STFT-domain losses, and found the former to work better with the DeepFeature generator while the latter gave better results for the MelGAN-UNet generator. The results shown for these generators are those obtained with the better loss variant. We also divide the test set into three subsets, each containing the same number of examples, with low noise (avg. 19.8dB SNR), medium noise (avg. 14.2dB SNR), and high noise (avg. 9.4dB SNR), and compute the same metrics on each subset as well as on the full test set.

The results in Table 2 show that, for all noise levels, our model consistently outperforms the signal processing baselines and the waveform-domain neural network models, which have proven highly successful in speech enhancement but are not adequate for the complexity of music signals. The signal-processing baselines (log-MMSE and Wiener filtering) are hardly able to improve upon the noisy input at all. This is not too surprising given the non-Gaussian, non-white nature of the real-world noise in the evaluation data. Comparing the results among the variants of our model, we further make the following observations:


- Using adversarial losses does not help in terms of SNR, as is evident from the top two rows of Table 2. The SNR decrease is small but significant. The adversarially trained variant, however, scores better on the high-level feature oriented VGG distance metric, which is in line with past observations [18, 25]

- It is advantageous to take both the modulus and the phase into account when processing the STFT spectrogram, as the "bypass-phase" variant which reuses the input phase produces consistently worse results across all noise levels. This shows that the proposed model is able to reconstruct the fine-grained phase component of the original clean music.

3.3 Subjective Evaluation


In the previous section we compared results by means of objective quality metrics, which can be quantitatively computed from pairs of noisy-clean examples. These metrics can be conveniently used to systematically run an evaluation over a large number of samples. However, it is difficult to come up with an objective metric that correlates with quality as perceived by human listeners. Indeed, the SNR and VGG distance metrics do not agree in our quantitative evaluation – the proposed model is better in terms of VGG distance, but worse in terms of SNR compared to its counterpart without discriminator. We now describe our

	ΔSNR (dB)				-ΔVGG

Figure 3. Average score differences for the synthetic dataset, relative to the noisy sample.

subjective evaluation which we ran in order to identify the method that performs best when judged by humans.

Following recent work on low-bitrate audio improvement [21], we use a score inspired by MUSHRA [22] for our subjective evaluation. Each rater assigned a score between 0 and 100 to each sample. The main difference to actual MUSHRA scores is that since no clean reference exists for historical recordings, we do not include an explicit reference in the rated samples (although we do include the clean sample in the synthetic dataset evaluation).

We perform our evaluation on 10 samples of historical recordings, and separately on 10 samples from the synthetic dataset, using 11 human raters. As in the objective evaluation, each sample is 5 seconds long. We evaluate the following four versions for each sample: (i) Original historic audio example, (ii) denoised example using our model with λ=0.01, (iii) denoised example using our model with λ=0, (iv) denoised example using log-MMSE.

For the synthetic dataset, we use the four versions above, but instead of the historic audio we use the synthetically noisified one. We do not include Wiener filtering as a competing baseline here since we noticed that it produces outputs that are consistently near-identical to the noisy input, and hence including it in the subjective evaluation would provide little value. We use the original noisy audio as the reference from which to compute score differences for the historical recordings, and the synthet-

ically noisified sample as the reference for the synthetic data. The results are shown in Figure 2 for the historical recordings, and in Figure 3 for the synthetic dataset. Error bars are 95% confidence intervals, assuming a Gaussian distribution of the mean. Both of our methods significantly improve the historical recordings, by around 50 points on average. In comparison, the logMMSE baseline only improves by an average of 16 points. We also performed a Wilcoxon signed-rank test between our λ=0.01 and λ=0 models, to find that the difference is statistically significant (p-value $< 1.19 \times 10^{-11}$). On the synthetic data, again the λ=0 model outperforms the λ=0.01 variant, with a p-value $< 2.13 \times 10^{-8}$. On the other hand, there is no significant difference between the mean score differences of the λ=0 model and the clean sample (p-value = 0.097).

4. CONCLUSION

We presented a learning-based method for automated denoising and applied it to restoration of noisy historical music recordings, matching a high quality bar: Judged by human listeners on actual historical records, our method improves audio quality by a large margin and strongly outperforms existing approaches on a MUSHRA-like quality metric. On artificially noisified music, it even attains a quality level that listeners found to be statistically indistinguishable from the ground truth.

ABSTRACT

Lyrics-to-audio alignment methods have recently reported impressive results, opening the door to practical applications such as karaoke and within song navigation. However, most studies focus on a single language - usually English - for which annotated data are abundant. The question of their ability to generalize to other languages, especially in low (or even zero) training resource scenarios has been so far left unexplored. In this paper, we address the lyrics-to-audio alignment task in a generalized multilingual setup. More precisely, this investigation presents the first (to the best of our knowledge) attempt to create a language-independent lyrics-to-audio alignment system. Building on a *Recurrent Neural Network* (RNN) model trained with a *Connectionist Temporal Classification* (CTC) algorithm, we study the relevance of different intermediate representations, either character or phoneme, along with several strategies to design a training set. The evaluation is conducted on multiple languages with a varying amount of data available, from plenty to zero. Results show that learning from diverse data and using a universal phoneme set as an intermediate representation yield the best generalization performances.

1. INTRODUCTION

Lyrics-to-audio alignment aims at synchronizing lyrics text units such as paragraphs, lines or words to the timed position of their appearance in the audio signal. Tools dedicated to this task have many practical applications: they can be applied to generate new annotated data to train more robust singing voice recognizers [1]; or be used as building blocks in specific applications such as karaoke [2], navigation within songs [3] or explicit lyrics removal [4]. Lyrics alignment methods are typically inspired from text-to-speech methods. Although text-to-speech alignment is a mature [5] and widely studied task [6], lyrics-to-audio alignment remains a challenging problem with specific limitations. First, the musical accompaniment acts as

a loud background "noise", potentially highly correlated with the signal of interest since vocalists usually sing in harmony and rhythm with instruments. A singing voice separation algorithm pre-processing step is often used to partially overcome this problem [7]. Second, singing voice exhibits more variety than speech with potentially large phonemes pronunciation variations between songs and extended tessitura. Recent studies have proposed efficient alignment methods for singing voice [8,9], but only for the English language, for which annotated data is abundant. The question of their ability to generalize to other languages, especially in low (or even zero) training resource scenarios, has not been properly addressed.

Arguably a monolingual evaluation is unrepresentative of the variety of music recordings available in large scale collections. Commercial streaming services commonly serve content in hundreds of languages and a non-negligible number of popular songs even have multilingual lyrics [10]. However, annotated data on this type of content are scarce. A source of inspiration comes from the related field of multilingual speech recognition [11]. Transfer learning methods [12] have been shown to improve performance on language with few to zero training data. However, this improvement on low-resource languages can sometimes be detrimental to performances on languages with more resources [11].

The goal of this paper is to evaluate and extend state of the art lyrics-to-audio alignment methods to a language-independent setup. First, we review the fitness of these systems to the multilingual framework. Then, we focus on one architecture and study two key features likely to allow generalization to several languages: 1) the intermediate representation space (character versus phoneme) and 2) the design of the training dataset. Evaluation is performed on multiple languages with various amounts of data available, from plenty to zero. The paper is organised as follows: related works are presented in Section 2. We then describe the proposed method in Section 3. The experimental setup and results are described respectively in Section 4 and Section 5. Finally, conclusions are drawn in Section 6 and future works are discussed.

2. RELATED WORKS

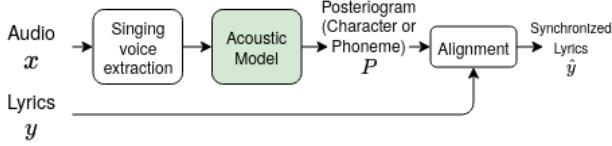
Singing voice alignment methods are typically inspired from text-to-speech alignment systems. Classically, an

acoustic model is trained and used to force text to audio alignment using a Viterbi algorithm [5]. These models are usually trained using alignment annotations, at the frame level, between audio and text. However, the availability of such annotations is very limited for polyphonic music where they are traditionally generated by employing an intermediate model [1], leading to suboptimal performances [8]. More generally, the development of such approaches for singing voice was slowed down by the lack of publicly available annotated dataset at word or even line level. Some models were trained on speech and adapted to singing using speaker adaptation technique and a small singing dataset. For instance, in [13], a monophone *Hidden Markov Model* (HMM) is trained on speech and adapted on a small corpus of manually annotated *a cappella* songs with *Maximum Likelihood Linear Regression* (MLLR). The alignment is then performed on polyphonic songs after extracting the singing voice with a melody transcription and a sinusoidal modeling technique. Other models were trained with "low quality" automatic annotations generated with forced alignment using an *Automatic Speech Recognition* (ASR) system. In [1], a speech recognizer is used to generate a large amount of singing annotations by aligning a large corpus of *a cappella* singing to their corresponding lyrics. Annotations are then used to train a new acoustic model. This new model is used to align 19 vocal tracks from English language pop songs: the phoneme sequence is estimated for each track and its Levenshtein distance to the ground truth sequence from the lyrics is computed to find the alignment path. To help alignment, multiple approaches tried extending speech recognizers with external information such as chords [14], score [15] or note onsets [16].

The recent release of the DALI dataset [17] has led to significant progress in lyrics-to-audio alignment. This dataset is the first publicly annotated singing voice dataset available. It contains 5358 audio tracks with time-aligned lyrics at paragraph, line and word levels. These annotations are created from manual annotations and are considered to be very good. It is composed of varied western genres (*e.g.* rock, rap and electronic) in several languages. Novel singing voice separation algorithms displayed impressive results [18] and were also shown to improve significantly lyrics-to-audio alignment systems performances [7]. State-of-the-art approaches for lyrics alignment were compared in the MIREX 2019 challenge [1] . Two submitted systems showed particularly strong performances. The first one was SDE2, described in [8]. It is based on an end-to-end audio-to-character architecture, more precisely a wave-U-net. A preprocessing step of singing voice separation is performed, during training and inference, using a U-net convolutional network. The acoustic model is trained on a private English dataset of 40000 songs using a CTC algorithm. The second one was GYL1, described in [9], which obtained the best results on the challenge. It is based on a *Time Delay Neural Network* (TDNN) which

is trained on the English subpart of the DALI dataset. It uses an extended lexicon to cope with long vowels duration in singing and genre labelling information (phoneme units are annotated with genres) but does not rely on a preprocessing step of singing voice separation.

Although it achieved the best performances in the MIREX challenge, GYL1 can not be straightforwardly used in a multilingual setup: it is composed of multiple parts, some of them, such as the pronunciation dictionary and the language model, being specific to English. To be able to use it on a new language, it would require to modify, or retrain, these parts. In comparison, SDE2 is based on an end-to-end acoustic model, trained with CTC algorithm, that directly outputs characters. It is more suitable to perform multilingual lyrics-to-audio alignment as it can be theoretically applied to any languages being based on the same script (writing system) as the training language.

Employing characters may not be optimal for multilingual lyrics-to-audio alignment: [8] suggest that using phoneme as an intermediate representation could be more relevant for aligning song in other languages. They argue that, for phoneme based systems, only the pronunciation dictionary has to be replaced for a new language, while a character based system is limited by the set of characters that the acoustic model outputs. For instance, SDE2 can only be used to align songs in Latin script languages. The output of the acoustic model could be extended with characters from scripts of new languages, as in [19], but it would require retraining the acoustic model each time a new script is added in the language pool. Using phoneme as an intermediate representation, any language can be theoretically aligned for any trained model if a pronunciation dictionary is available. In this work, we study a system inspired from [8] using either a character or a phoneme intermediate representation.


3. PROPOSED METHOD

A general overview of the proposed system is described in Figure 1. It is composed of three parts: a singing voice separation model, an acoustic model and a lyrics-to-audio alignment procedure. It takes as input a song x, its corresponding lyrics y and output the synchronized lyrics $\hat{y}$. Vocals are extracted from the song using a singing voice separation module. The acoustic model processes features extracted from the isolated vocal signal. The acoustic model consists in an RNN trained with a CTC algorithm. The set of outputs of the acoustic model is either characters of the Latin alphabet or phonemes of an universal phoneme set. Lyrics-to-audio alignment is performed on outputs of the acoustic model by a CTC-based alignment decoding function.

3.1 Acoustic model

The acoustic model of our system is a RNN trained with a CTC algorithm. CTC-based acoustic models were successfully used for multilingual speech recognition [19,20]. The RNN part is composed of bi-directional *Long Short-*

Figure 1. Overview of the lyrics-to-audio alignment system. Our study focuses on the training of the acoustic model (section 3.1) and the design of intermediate posteriogram representation spaces (section 3.2). The alignment block is described in section 3.3

Term Memory (LSTM) layers. Authors in [21] argue that such models can give reliable alignments given that outputs at each frame depend on the entire input sequence. In contrast, uni-directional CTC acoustic model suffers from alignment delay [22].

CTC makes it possible to directly train RNN models using weakly aligned annotations, e.g. at word or line level. To do that, the CTC algorithm introduces a new symbol called "blank" (noted ϵ) which represent a non-emission token. The total probability of the output label sequence is then marginalized over all possible alignment for a given input. In our case, the output label sequence is a sequence of character or phoneme. Since the objective function is differentiable, the network can be trained with standard back-propagation through time. The CTC algorithm is more extensively described in [23].

3.2 Character vs Phoneme

We consider two different intermediate representations for our architecture. The first one is a character set, here the Latin alphabet. This representation does not need any kind of expert linguistic knowledge as the acoustic model directly outputs characters probability. However, such a representation is not suitable to perform alignments of songs in a language with a different script. To process those, the acoustic model would need to be retrained with new data on the given script. Moreover, even for languages sharing the same script, a character-based representation is suboptimal for transferring knowledge between languages, as characters pronunciation can significantly differ from one language to another. Our approach relies on the following remarks: all languages share some common phonemes and phonemes are considered to be language independent [24], i.e. to be pronounced the same way across languages. Therefore, using a universal phoneme set as an intermediate representation makes it possible to leverage similarity between sounds across languages. The idea is to use consistent phonemes across languages used for training and that most phonemes from an unseen language appear in the languages used for training.

It can be achieved using *international phonetic alphabet* (IPA) symbols. The IPA is a set of phonetic notations which is a standardized representation of sounds of all spoken language. IPA Pronunciations of words from all languages can be obtained using *Grapheme-To-Phoneme* (GTP) tools. Such tools are available for most common

languages. The universal phoneme set is created by concatenating and merging the union of phoneme sets of all languages based on their IPA symbols.

3.3 Lyrics to audio alignment

In order to align a song to its corresponding lyrics y, the audio is sliced into segments of 5 seconds with a step size of 2.5 seconds. A posteriogram is generated by the trained acoustic model for each segment. To obtain the final posteriogram, all segments posteriograms are concatenated, cropped to half of their duration centered in their middle. We obtain a posteriogram $P \in [0,1]^{|C| \times T}$, C being the set of symbols supported by our acoustic model, either characters of phonemes, and T the number of temporal frames of the song. This matrix provides an estimation of the posterior probabilities of each symbol through time. Alignment annotations are then predicted, using the generated posteriogram P and lyrics y, with a CTC-based alignment function inspired from the CTC-based decoding function presented in [25] and is akin to a Viterbi forced alignment [26]. Viterbi forced alignment is a simpler version of Viterbi decoding where the possible paths are limited to the lyrics symbol sequence. To allow the use of ϵ during decoding, y is extended to z by adding a ϵ at the beginning, end, and between every unit. A decoding network of size $|z| \times T$ is then constructed from z. The goal of the decoding function is to find the path in the network that give the most probable alignment $\hat{y}$ of y given the posteriogram P. More precisely:

$$\hat{y} = \underset{B(\hat{y})=y}{\arg\max} \prod_{j=1}^{T} P(\hat{y}_j, j) \qquad (1)$$

where B is an operator that removes blanks and repetitions from a sequence $\hat{y}$. To do that, network's node $\alpha_{s,j}$ is defined as the probability of the best alignment of the subsequence $z_{1:s}$ after j frames. $\alpha_{s,j}$ scores can be calculated efficiently using a forward-backward algorithm, by merging together paths that reach the same node. $\alpha_{s,j}$ is then computed recursively from the values of α in the previous frame. Only transitions between blank and non-blank characters, and between pairs of distinct non-blank characters are allowed. ϵ at the beginning and end of the sequence being optional, there are two valid starting nodes and two final nodes. The coefficients α are initialized such as:

$$\alpha_{s,1} = P(z_s, 1) \text{ for } s \in \{1,2\} \text{ and } \alpha_{s,1} = 0, \forall s > 2 \quad (2)$$

Recursion is given by:

$$\alpha_{s,j} = \max_{\tau \in \{0,1\}} (\alpha_{s-\tau,j-1}) P(z_s, j), \text{if } z_s \in \{\epsilon, z_{s-2}\}$$

$$\zeta_{s,j} = \underset{\tau \in \{0,1\}}{\arg\max}(\alpha_{s-\tau,j-1})$$

$$\alpha_{s,j} = \max_{\tau \in \{0,1,2\}} (\alpha_{s-\tau,j-1}) P(z_s, j), \quad \text{otherwise}$$

$$\zeta_{s,j} = \underset{\tau \in \{0,1,2\}}{\arg\max}(\alpha_{s-\tau,j-1})$$

$$(3)$$

Then, the probability of the best alignment is given by:

$$P(\hat{y}) = \max_{\tau \in \{0,1\}} (\alpha_{|z|-\tau,T}) \qquad (4)$$

Alignment $\hat{y}$ can finally be computed with an inverse recursion. The initial unit is initialized such as:

$$\hat{y}_T = |z| - \arg\max_{\tau \in \{0,1\}} (\alpha_{|z|-\tau,T}) \qquad (5)$$

Inverse recursion is given by:

$$\hat{y}_{j-1} = \hat{y}_j - \zeta_{\hat{y}_j,j} \qquad (6)$$

Calculations are performed in log-space using the log-sum-exp trick [27] to avoid numerical instabilities. As some phonemes from target languages can be unseen in the training languages, the acoustic model will be unable to predict them, resulting in all alignment having a probability of zero. To get rid of this problem, a small amount of uniformly distributed noise is added to all entries of the posteriogram, as suggested in [8].

4. EXPERIMENTAL SETUP

4.1 Dataset

For this study, we consider several language subsets of the DALI dataset. They are described in Table 1. Experiments are conducted using 5 source languages for the initial multilingual system development. These source languages are: English, German, French, Spanish and Italian. English is considered as a high-resource language. The 4 others languages are considered as low-resource languages in this study. The split between train, validation and test datasets for the first five languages is an artist aware split [28]. We also consider 4 additional target zero-resource languages: Portuguese, Polish, Finnish and Dutch. Data from these languages are only used for evaluation. The split of the different language data, i.e. dali ids belonging to each dataset, are made publicly available at https://github.com/deezer/MultilingualLyricsToAudioAlignment. One dataset, that we named *5lang*, is created for multilingual training. The training and validation sets of this dataset are generated by simply concatenating respectively the training and validation sets of the 5 source languages. This dataset is largely unbalanced, English data dominating the corpus. Balancing the dataset with oversampling was tested without modification on performances of the multilingual model on low-resource and zero-resource languages. Similar results were also found for speech [29]. Worse, it significantly degrades results for the English language. These results were expected as the quantity of English data being far superior in comparison to other languages in the multilingual dataset, diminishing their importance could only degrade results for the multilingual model when tested on English dataset. Results of multilingual models trained with balanced dataset are displayed in supplementary materials.

Language	# Phonemes	Train (h)	Test (h)
English (en)	44 (5)	192.7	31.5
German (de)	44 (1)	17.4	2.3
French (fr)	42 (0)	8.9	0.9
Spanish (es)	35 (3)	8.4	1.1
Italian (it)	33 (0)	8.5	1.2
Portuguese (pt)	37 (0)	X	1.8
Polish (pl)	31 (2)	X	4.2
Finnish (fi)	25 (0)	X	3.1
Dutch (nl)	41 (2)	X	3.1

Table 1. Description of DALI language subset datasets and corresponding phoneme dictionary sizes. In parenthesis are displayed the number of phonemes only occurring in the given language and its equivalent ISO 639.1 code

The procedure to generate training samples and corresponding labels for the acoustic model is similar to the one described in [25]. To recall, Spleeter [18] is used to isolate vocals from each song. Training samples are then computed by segmenting extracted vocals. The character sequence associated with a segment is created from word level annotations of DALI by concatenating all words whose start position is within the segment. An instrumental token is generated if no words are present in the segment. For phoneme models, the phoneme sequence associated with a segment is generated from his corresponding character sequence using Phonemizer[2]. Phonemizer includes GPT tools for most common languages. It decomposes each word into a sequence of IPA symbol. To create the phoneme dictionary of one given language, we collect all IPA phonemes present in the corresponding dataset. For simplicity, we did not consider IPA symbols others than vowels and consonants. Sizes of dictionaries of phoneme of each language are given in Table 1. After concatenating and merging all dictionaries, we obtain a universal phoneme set of 62 phonemes. The language sharing factor [24] for the nine languages we used in this study is 5.35. It means that, on average, one unit of the universal phoneme set is shared by 5 to 6 languages of the language pool which supports the fact that IPA phonemes are rather consistent across languages that we consider in this study.

4.2 Parameters of acoustic models

We use the same architecture for all acoustic models. Several sets of regularisation and architecture's size parameters were tested without a clear impact on performances. Parameters of architecture are similar to those used in [25]. The model has 3 layers of bidirectional LSTM and a dense layer. It takes as input mel-scale log filterbanks coefficients and energy plus deltas and double-deltas. The acoustic model output is the probabilities of characters or IPA phonemes. In the first case, the set of outputs is the concatenation of the Latin alphabet, the apostrophe, the instrumental token, the space token and the CTC blank symbol

---

[2] https://github.com/bootphon/phonemizer

ϵ. A set of size 30 is obtained. In the second case, it is constituted of the universal phoneme set, plus the instrumental token, the space token and the CTC blank symbol ϵ. A set of size 65 is obtained. Parameters of training are the same as those used in [25].

4.3 Evaluation

To evaluate our system, we use the *Average Absolute Error* (AAE) [13]. For its calculation, the absolute difference between the actual start of the word timestamp and its estimation for each word is calculated. The final error score for a song is obtained by averaging over all word-level errors. A known issue of this metric is its perceptive dependence on tempo. In fact, one absolute error will not be perceived the same if the tempo is fast or slow. The *Percentage of correct onsets* (PCO) [14] was proposed to mitigate this effect. It is computed as the percentage of start of the word timestamps whose estimation are below a certain distance from the ground truth. This metric considers that errors bellow a certain threshold fall within human listeners perceptive tolerance. We use 0.3 seconds as the tolerance window. Both metrics are classic metrics of MIREX lyrics-to-audio alignment challenge. They are computed using the same evaluation script as the one used for the challenge [30] [3].

5. RESULTS AND DISCUSSION

5.1 State of the art comparison

To validate our implementation, We first compare our system with two state-of-the-art ones. Results are collected from the 2019 MIREX lyrics-to-audio alignment challenge. For this comparison, we use characters as intermediate representation space and only English for training. We use three standard evaluation datasets for lyrics-to-audio task. Hansen [31] and Mauch [14] are constituted of respectively 9 and 20 English pop music songs. Jamendo [8] is made of 20 English music songs of several western genres. All three datasets are annotated with start-of-word timestamps. Results are summarized in Table 2.

Our system performances are close to those of GYL1, with no significant differences for PCO metric on the three evaluation datasets. Although we use an architecture somewhat similar to SDE2 (i.e. a CTC based approach with a pre-step of singing voice separation), we report significantly better performances. It is worth noting that GYL1 and our system both use the English part of DALI as training dataset, while SDE2 uses a private dataset of unknown quality. We can postulate that the DALI dataset annotation quality is higher, which would explain the better performances reached by our implementation despite using a much smaller train set than SDE2.

[3] https://github.com/georgid/AlignmentEvaluation

Dataset	System	Mean AAE (s)	Mean PCO (%)
Hansen	SDE2 [8]	0.39 (0.12)	88 (3)
	GYL1 [9]	**0.10 (0.03)**	**97 (1)**
	Ours	0.18 (0.05)	95 (2)
Mauch	SDE2 [8]	0.26 (0.04)	87 (2)

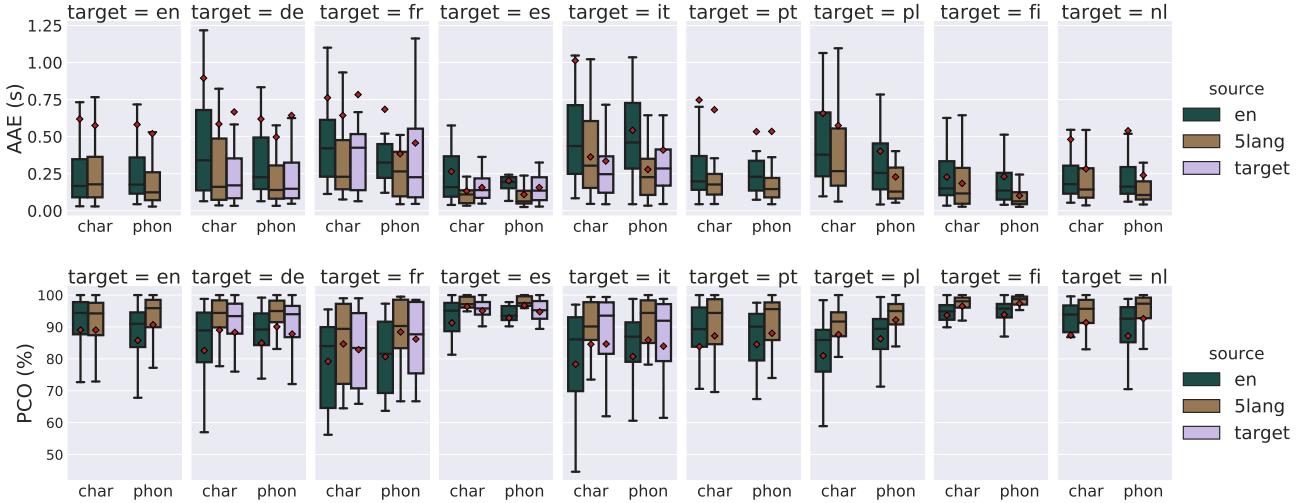
Table 2. Comparison between our character based architecture trained with the English part of DALI and state-of-the-art systems on standard lyrics-to-audio alignment evaluation datasets. Mean AAE is better if smaller, mean PCO is better if larger. Standard errors over tested songs are given in parenthesis


5.2 Multilingual generalization

Results of multilingual generalization experiments are displayed in Figure 2. Precise numerical values are reported in supplementary materials. Several conclusions can be drawn:

- Using a multilingual training set helps For both character and phoneme based architectures, the model exhibiting the best multilingual generalization is trained with multilingual dataset. In fact, this model significantly outperforms the ones trained on English on low-resource and zero-resource languages without degrading performances on English. With phoneme as intermediate representation, it even improves results on English. On low-resource languages, multilingual trained model obtains results on par with models trained only on the target language (e.g. French trained model on French dataset). It is worth noticing that the multilingual training dataset is only marginally larger than the English one. Performances differences are to be attributed to the additional information the model was able to extract from the diversity of languages seen during training.

- Use phonemes over characters as an intermediate representation has better performances Performances of phoneme based architectures are almost always better than those of their character based counterparts in all our experimental setups. The gap is bigger for models trained on the multilingual dataset than for those trained on monolingual ones. The only models that are not improved are the ones trained and tested on the same languages. Such results show that the use of phoneme as an intermediate representation enables transfer knowledge between language better than character representation.

- Training on multilingual data and a phoneme internal representation yields the best results in all considered cases Training the acoustic model on multilingual data and use a universal phoneme set is a relevant way for improving the generalization capacity of the considered lyrics-to-audio alignment architecture even to zero-

Figure 2. Lyrics-to-audio evaluation on DALI language subset datasets for phoneme and character based architectures. Several training set design strategies are considered. Languages are given by their ISO 639.1 code. Here "source" refers to data language used to train the given model and "target" refers to data language used to evaluate the trained model. When source is equal to target, architectures are trained and tested on the same language. Mean AAE is better if smaller, mean PCO is better if larger. Mean values are displayed using squares

resource scenarios.

6. CONCLUSION

In this paper, we investigated extending state-of-the-art methods in the multilingual context. Focusing on one architecture that seemed fit for generalization, we demonstrated that design choices regarding the training dataset and the acoustic representation space are salient factors. We have shown that using many languages to train the acoustic model and a universal phoneme set improves the multilingual generalization of such architecture. In this work, we have built a dataset using the language distribution found in DALI, which resulted in a largely unbalanced dataset. For comparison, we also conducted experiments with a balanced dataset, in which all 5 languages were equally present. The performance was similar, except for English, when it was significantly degraded. This raises the issue of how to design training sets in a setting where several high-resource languages are available. Although there are no publicly available datasets exhibiting such characteristics, future work should investigate this case. Existing works on multilingual speech processing [11] point towards increasing model complexity to circumvent this. Also, only a small set of languages were considered in this study. Additional experiments on a wider, more diverse set of songs remain to be conducted. Finally, future works should consider the specific case of songs with multilingual lyrics. This problem, known as code-switching, has been studied for speech [21] but never for music. Such a phenomenon is however not uncommon in popular music [10], thus it should be addressed too.

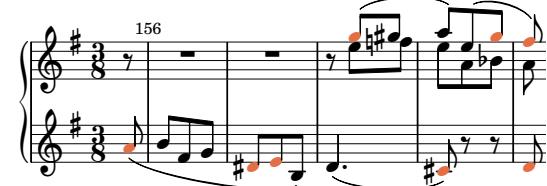
ABSTRACT

Musical schemata constitute important structural building blocks used across historical styles and periods. They consist of two or more melodic lines that are combined to form specific successions of intervals. This paper tackles the problem of recognizing voice-leading schemata in polyphonic music. Since schema types and subtypes can be realized in a wide variety of ways on the musical surface, finding schemata in an automated fashion is a challenging task. To perform schema inference we employ a skipgram model that computes schema candidates, which are then classified using a binary classifier on musical features related to pitch and rhythm. This model is evaluated on a novel dataset of schema annotations in Mozart's piano sonatas produced by expert annotators, which is published alongside this paper. The features are chosen to encode music-theoretically predicted properties of schema instances. We assess the relevance of each feature for the classification task, thus contributing to the theoretical understanding of complex musical objects.


1. INTRODUCTION

Voice-leading schemata are frequently used patterns that can be found across historical periods, ranging from Renaissance, Baroque, and Classical to modern tonal music; examples include such well-known schemata as the Lamento, the Pachelbel, the descending-fifths sequence, and cadences [8, 10, 4, 11]. A schema serves as a template for contrapuntal structure that can be elaborated in multiple ways.

At present, there is only scant quantitative evidence about the frequency and diachronic distribution of schemata across history (e.g., [10, 2]); large-scale, machine-readable datasets on schemata are not yet available. For assessing the prevalence of schemata in a corpus of music, automated recognition of schema instances

(a) A (true) Fonte at the beginning of K281-iii.

(b) A possible candidate for a Fonte in K283-iii.

Figure 1: An example of a Fonte (a) with structural notes highlighted. The task is to decide whether proposed instances such as (b) are true instances or not.

can be a time- and cost-efficient alternative to manually labelled data. However, there are two key challenges for computational approaches when seeking to uncover note patterns in music: (1) the multidimensional (polyphonic) structure of music as opposed to, for example, the sequential structure of written text [17]; (2) the highly flexible nature of these patterns, given that the structural notes in the individual voices can be elaborated in a wide variety of ways.

Voice-leading schemata can be defined as configurations of two or more voices that move together through a sequence of stages, forming particular patterns of successive vertical intervals that occur within a specific tonal context. Consider the example of the Fonte (e.g., [10]): The Fonte is a four-stage pattern involving at least two voices. The bass moves through the scale degrees $\sharp\hat{1} \rightarrow \hat{2} \rightarrow \hat{7} \rightarrow \hat{1}$ of a major scale, while the soprano follows the pattern $\hat{5} \rightarrow \hat{4} \rightarrow \hat{4} \rightarrow \hat{3}$, thus producing the following sequence of vertical intervals: tritone $\rightarrow$ minor third $\rightarrow$ tritone $\rightarrow$ major third. The schema prototype can be elaborated in actual compositions in many different ways. For instance, the notes belonging to one stage can be displaced in time; any number of elaboration notes can be inserted between the structural notes of one stage and between stages... An example illustrating the surface realization of a Fonte is

shown in Figure 1a. While containing the correct interval pattern is a central property of any schema instance, it is not sufficient: the selected notes must also provide the contrapuntal template for its context, so that the notes contained in the time-span covered by the schema candidate can be meaningfully interpreted as ornamentations of the selected notes. Figure 1b shows a candidate for a Fonte instance. The task at hand is to decide whether or not such a candidate is a true schema instance.

To tackle the problem of schema detection, this paper provides two contributions. First, we propose a novel dataset with hand-annotated schemata found in Mozart's piano sonatas (Section 3). Second, we present a binary classifier that recognizes true schema instances among a set of proposed schema candidates based on rhythm and pitch features related to regularity, complexity, salience, and harmonic context (Section 4). We evaluate the impact of these features on the classification task using a logistic regression (Section 5).

2. RELATED WORK

Automated discovery and recognition of musical patterns is a topic of ongoing interest in the MIR community [15, 5, 17, 3, 9, 12, 16]. Voice-leading schemata as a specific class of patterns have so far received only little attention; they have been approached with computational methods only very recently. For instance, Symons [23] has developed an algorithm that recognizes schemata in a small corpus, pointing out the importance of rhythmic regularity. Finkensiep et al. [7] tackle the problem of temporal displacement and free polyphonic textures using a two-dimensional extension of skipgrams, which have previously been proposed by Sears et al. [21, 22]. Recently, Katsiavalos et al. [13] have presented a system that uses heuristics-based time-span reduction to discover and recognize schemata.

Several studies aimed at finding cadences, which can be viewed as a subcategory of voice-leading schemata, and evaluated the features relevant for the classification task. Bigo et al. [1] evaluated a set of 44 features linked with the moment of cadential arrival, which are integrated using a support-vector machine for classifying beats as belonging to a cadence or not. Sears et al. [21] use skipgrams on vertical slices to find cadences using a figured bass-like representation of the notes in each slice. Duane [6] approaches cadences directly as voice-leading patterns by trying to recognize and learn them from melodic motion.

3. DATASET

Our dataset is based on the full set of Mozart's piano sonatas encoded in MusicXML format. These 18 sonatas with 3 movements each (thus 54 movements in total) have been composed between 1774 and 1789 and constitute a prominent sample of the classical style. The pieces in the dataset contain 103,829 notes in total distributed over 7,500 measures, with 244 hand-annotated true instances (0.13%) and 190,994 automatically generated false

Table 1: List of schemata with their variants and number of occurrences in the Mozart's Piano Sonata dataset.

instances (99.87%) for the selected schema types and subtypes (see Table 1).

3.1 Schema Formalization and Lexicon

For the present study, we selected 10 schema types and 20 subtypes (listed in Table 1) which have been suggested in the literature [10, 4, 20, 19]. The approach presented here assumes that a schema type consists of (1) a fixed number of voices; (2) a fixed number of stages, whereby each stage contains one note per voice; and (3) a characteristic interval pattern between these notes. The prototype for each schema variant (or subtype) is specified using a formal notation. For instance, the prototype of the two-voice Fonte is encoded as:

```
"fonte.2": [["a1", "P5"],
            ["M2", "P4"],
            ["M7", "P4"],
            ["P1", "M3"]]
```

where ".2" indicates the two-voice variant of the Fonte. Each note is given as an interval to some arbitrary reference point. Since all possible transpositions of the schema are considered by the matcher, it is not necessary to know the reference key.

Schema instances are encoded as nested arrays of notes in the same form as the corresponding prototypes. Instances may deviate from the shape of the prototype if (a) a note that would repeat its predecessor (e.g. the second $\hat{4}$ in the Fonte) is held over or missing, or (b) two adjacent voices merge and are represented by a single note on the surface.

3.2 Data Production

The dataset consists of two parts: manual annotations by experts and automatically retrieved candidates for schema instances, i.e. sets of notes with an interval pattern conforming to a schema variant. Both the annotations and the computed candidates share the same encoding format, namely a nested lists of note IDs (one sublist per stage, one note per voice) that corresponds to note elements in a MusicXML representation of the scores. While the manual annotations provide the true instances of the dataset, the false instances consist of all skipgram candidates that do not appear in the annotations. [1] The complete dataset is available on github. [2]

3.2.1 Expert Annotations

Two annotators (the third author and Adrian Nagel) provided their analyses by using a web-based annotation app that was specifically developed for the annotation process. The app displays a score using the Verovio toolkit [18], and allows the user to select individual notes from the musical score to mark schema instances. Instances are automatically checked for conformance with the schema prototype in the lexicon, while permitting the deviations described in Section 3.1. The annotators also considered additional criteria such as harmonic signature, phrase structure, pattern repetition, and form-functional context. [3]

3.2.2 Computing Candidates with Skipgrams

In order to compute all candidates of schemata for the classifier, we base our work on the generalized skipgram model proposed in [7], which enumerates two-dimensional note configurations that occur within certain temporal bounds. We use this algorithm to find configurations with a maximal note displacement of 1 bar per stage and a maximal distance of 1 bar between the onsets of two adjacent stages. The configurations are filtered for a specific interval pattern during enumeration regardless of the local keys. This method provides us with all candidates for a schema instance within a reasonable window. However, due to the exhaustive search and a high number of possible note combinations, our resulting dataset is extremely unbalanced. Because of the high combinatoric complexity, we restrict this study to two-voiced schema variants. Furthermore, we reduced the number of candidates to at most 25 per group of temporally overlapping candidates using a previous version of the model presented here.

4. FEATURES AND SCHEMA CLASSIFICATION

4.1 Musical Features

By using precomputed schema candidates that are known to have the correct interval structure (which is all infor-

mation that we consider for a specific schema type), the problem is narrowed down to deciding whether or not the candidate consists of the structurally important notes. To this end, we have defined a set of features with regard to rhythmic, pitch, and metric information, inspired in part by previous work [10] and that we wish to evaluate with the classifier. These features attempt to measure the *recognizability* of the candidate as a structural pattern, assessing, for example, its complexity, salience, or regularity in various musical dimensions. For a schema candidate C that consists of a number of stages n_s and a number of voices n_v, let $C_{s,v}$ denote the note from stage s and voice v. Each note is represented by an onset, an offset, and a pitch. Whenever pairs of notes are compared, K denotes the numbers of compared note pairs (excluding pairs with missing notes).

The first feature can be considered a rough estimate of the *harmonic or modal signature* of the schema candidate. We define the *harmonic profile* of a candidate as the distribution of pitch-classes (relative to the transposition of the match) of notes that overlap with the time span of the candidate (excluding the matched notes themselves). The `profiledist` is defined as the euclidean distance between a match's pitch profile and the average pitch profile of all true instances of the same schema. Thus, this feature uses training data to derive the prototype profiles instead of defining a harmonic signature a priori.

Three features address the *regularity* of pitch and rhythm between pairs of stages. `rreg` measures the average rhythmic dissimilarity between each pair of stages. For a pair of stages, the rhythmic dissimilarity is defined as the sum of the temporal distance of the notes of the same voice, given the best alignment possible when projecting one stage unto the other. `mreg` is defined very similarly, but here the alignment offset is fixed to whole beats to preserve metric position. Finally, `preg` measures the average pitch dissimilarity between each pair of stages. Similar to rhythmic dissimilarity of a pair of stages, pitch dissimilarity is defined as the sum of the pitch distances of the notes of the same voice, given the best pitch alignment possible when projecting one stage unto the other. These features are defined as

$$\star\texttt{reg} = \frac{1}{K} \sum_{\substack{(s,s') \in stage \\ s \neq s'}} \min_{\delta} \left(\sum_{v=1}^{n_v} |\mu(C_{s,v}) - \mu(C_{s',v}) - \delta| \right),$$

(1)

where μ corresponds to onset for `rreg` and `mreg`, and to pitch for `preg`. For `mreg`, δ is restricted to integer multiples of a beat.

We then define features corresponding to the *complexity* of the candidates in terms of displacement between pairs of notes. `rdsums` and `pdsums` respectively correspond to the average temporal and pitch distance between each note of the same stage. They are defined as

$$\star\texttt{dsums} = \frac{1}{K} \sum_{s=1}^{n_s} \sum_{\substack{(v,v') \in voice \\ v \neq v'}} |\mu(C_{s,v}) - \mu(C_{s,v'})|, \quad (2)$$

---

[1] This includes alternative versions of true instances with several possible note selections.

[2] https://github.com/DCMLab/schema_annotation_data

[3] As detailed in the schema-annotation guidelines (https://github.com/DCMLab/schema_annotation_data/blob/master/manual/manual.pdf).

where μ corresponds to onset for `rdsums` and to pitch for `pdsums`. Similarly, `rdsumv` and `pdsumv` respectively correspond to the average rhythmic and pitch distance between each note of the same voice. They are defined as

$$\star\texttt{dsumv} = \frac{1}{K}\sum_{v=1}^{n_v}\sum_{\substack{(s,s')\in stage \\ s\neq s'}}|\mu(C_{s,v})-\mu(C_{s',v})|, \quad (3)$$

where μ correspond respectively to onset and pitch for `rdsumv` and `pdsumv`.

Another perspective at pitch displacement is provided by `vdist`, which measures the average amount of octave jumps within a voice from one stage to the next, and is defined as

$$\texttt{vdist} = \frac{1}{K}\sum_{v=1}^{n_v}\sum_{s=1}^{n_s-1}\left\lfloor\frac{\text{pitch}(C_{s+1,v})-\text{pitch}(C_{s,v})}{\text{octave}}\right\rfloor. \quad (4)$$

While a certain complexity may be necessary to make a regular pattern recognizable in the first place, a more complex pattern can be more difficult to detect in the presence of other notes. For this reason, `onsets` counts the average number of distinct note onsets in the context of each stage. A low number of onsets allows the stages to be rhythmically displaced while still being recognizable as a unit. Given the number of distinct note onsets D_s for each state s, we have

$$\texttt{onsets} = \frac{1}{n_s}\sum_{s=1}^{n_s}D_s. \quad (5)$$

Finally, we define two features representing the *salience* of the candidate. First, we consider `dur`, which corresponds to the sum of all note durations in the candidate,

$$\texttt{dur} = \sum_{s,v}\text{offset}(C_{s,v})-\text{onset}(C_{s,v}). \quad (6)$$

Then we consider `mweight`, a feature based on metric weight. We define our metric weight function as follows:

$$\text{mw}(C_{s,v}) = \begin{cases} 2 & \text{if } \text{onset}(C_{s,v}) \text{ is on a strong beat.} \\ 1 & \text{if } \text{onset}(C_{s,v}) \text{ is on a weak beat.} \\ \frac{1}{2^p} & \text{if } \text{onset}(C_{s,v}) \text{ is on a subbeat,} \end{cases}$$

where p is the number of prime factors needed to express the subbeat. Given that function, `mweight` corresponds to the average metric weight of each note of the candidate:

$$\texttt{mweight} = \frac{1}{K}\sum_{s=1}^{n_s}\sum_{v=1}^{n_v}\text{mw}(C_{s,v}). \quad (7)$$

4.2 Classification and Evaluation Method

The features described above are used as an input to a logistic regression model, a simple binary classifier model that uses a linear combination of the input features and applies a sigmoid to that score, yielding a value between 0 and 1 that indicates the probability of the input to be a true instance. Since a logistic regression is a special case of a neural network without hidden layers, this approach can be naturally extended to include more layers, allowing for more complex, non-linear feature combinations. However, preliminary experiments have shown that non-linear models (such as simple neural networks and support-vector machines) do not increase model performance and instead lead to overfitting, so we exclude them here.

The input data consists of expert annotations and skip-gram candidates, produced as described in Section 3.2. To get consistent temporal information about the notes, we unfold all repetitions and jumps notated in the scores. Repeated occurrences of notes are disambiguated by selecting for every schema candidate those note occurrences that have a consistent temporal order and cover a minimal time span. Finally, matches that have incomplete stages (due to implicit notes, as described above) are converted into complete instances with missing notes marked explicitly.

To evaluate the model's performance, we use 5-fold cross validation.[4] The pitch histograms used for `profiledist` are computed on the respective training set of each run. In order to get an unbiased model, we follow the advice given in [14] and balance our dataset by upsampling the true instances to match the number of false instances. The model is trained on the balanced training data using the Julia package `GLM.jl`[5] and applied to both balanced and unbalanced test data. In addition, a prior-corrected version of the model (see [14]) is applied to the unbalanced data.

The code for the whole evaluation pipeline is provided online[6], including a notebook[7] that was used to generate all results and figures in this paper.

5. RESULTS AND DISCUSSION

5.1 Classification Performance

The overall performance of the model is shown in Table 2, aggregating over the predictions on all test sets. When applied to data balanced by upsampling, the model achieves a high classification performance with an F-score of 0.894 and a Matthews correlation coefficient (MCC) of 0.787. Since the model is trained on balanced data, applying it to unbalanced data simply scales the number of true positives and false negatives, resulting in a drastically reduced precision. Using the prior correction of the unbalanced dataset results in a very high accuracy; however, it introduces a bias to label matches as non-instances, which results in the false negatives dominating the false positives.

Figure 2 shows how the predicted probability of being a true instance is distributed for instances and non-instances (upper-left corner). Non-instances overwhelm-

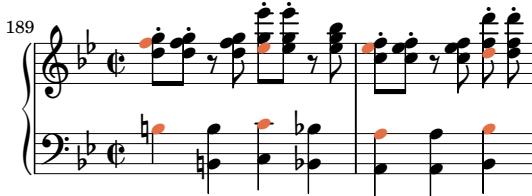
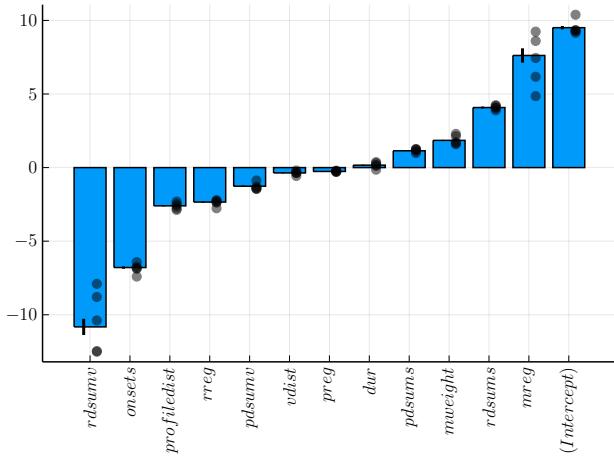
Figure 2: Distribution of model prediction (a) and feature values (b) over instances and non-instances as a kernel density estimate. The more the curves tend in opposite directions, the better the two classes are separated.


ingly receive low probabilities and instances are typically rated very high. This is in line with the model's good performance on raw data, but it also reveals why imbalance poses a serious problem: while the majority of non-instances are correctly discarded by the model, a minority remains indistinguishable from true instances under the model. When the skipgrams propose many more non-instances than instances, the small part of indistinguishable non-instances becomes huge in relation to the true instances. Note that simply reducing the number of matches does not necessarily improve the situation: taking away the matches with a rating < 0.5 still leaves us with the problematic cases.

A lot of non-instances are proposed as combinatoric variations around true instances. To test whether the problematic cases are variations of true instances or genuine non-instances, we group all matches according to temporal overlap (prior correction is based on the imbalance of the groups here). The results (Table 2) show that grouping drastically increases the performance compared to the ungrouped condition but does not get close to the performance on balanced data, indicating that there is still a significant number of indistinguishable true non-instances.


This effect of indistinguishability may be seen as an indicator that our list of features lacks those features that would help resolve the remaining cases and clearly separate the classes. However, it is not clear that finding such features is easily attainable. First, consider that while the existing features are already very informative, the information needed to distinguish the problematic cases would have to be much more precise. Even when the probability of getting a positive result for a non-instance is only 10^{-3}, a true instance proportion of 10^{-3} still leaves a 50% chance that a positive result is a false positive. Second, our annotators conformed to very strict standards in order to discard non-instances, restricting true instances to cases where the schema is a highly plausible template for the musical surface. Such judgments rely on implicit music-theoretical knowledge and intuition, which are difficult to model.

Finally, a look at some highly confident false positives suggests that if schema classification is defined as a binary task (a surface pattern is a schema instance or not), then the performance of this task can hardly been improved.

For example, the excerpt in Figure 1b may not look like a very plausible Fonte at first sight (and was not classified as such by the annotators). However, the last two bars clearly contain the correct contrapuntal pattern for

Figure 3: An ambiguous Fonte match (K333-iii). While intrinsically this is a highly plausible instance (interval pattern, tonal context, melodic parallelism), the context discards it, as the pattern is in fact part of a larger descending-fifths sequence.

Figure 4: The parameters $\vec{\beta}$ of the model trained on the full upsampled dataset (bars) and normalized by multiplication with the average value of the respective feature. Error bars indicate the 95% confidence interval of the fit. Black points indicate the normalized parameters for each model trained during cross validation.

the stages 3 and 4. The beginning can be interpreted as a melodic unfolding of an Em chord that is ornamented by the notes of a B^7 chord, most clearly in the neighbor note d♯ to e (i.e., the bass for the stages 1 and 2 of a Fonte). Therefore, it can be argued that this section shares its contrapuntal structure with the Fonte, even though the typical parallelism is missing. Another, converse, example can be seen in Figure 3: in isolation, the pattern is a clear instance of a Fonte, but it is continued in the manner of a larger descending-fifths sequence, which, depending on the definition used, may discard it as a Fonte. A negative definition like this is very difficult to check under the current paradigm.

5.2 Feature Evaluation

Figure 4 shows the influence of each feature in a model trained on the full balanced dataset. Overall, schemata seem to expose a high regularity and low complexity compared to non-instance candidates. The strong negative factors `rdsumv` and `onsets` disregard candidates with a large temporal extension and a high degree of non-simultaneity. Metric regularity (i.e. rhythmic regularity aligned to the metrical grid) has a strong positive influence,

indicating a preference for a regular temporal organization.

The preference for simultaneity of the notes in the same stage is somewhat contradicted by the moderately positive influence of the `rdsums`, the average note displacement within stages. This is particularly surprising when looking at the distribution of this feature over instances and non-instances (Figure 2b), which shows that instances generally show less displacement than non-instances. One possible explanation of this phenomenon is that the combination of both features (`onsets` and `rdsums`) expresses a general preferences for little displacement, but when the notes are non-simultaneous, then a higher distance is preferred, which may make the structural notes more recognizable.

Less important are features based on pitch (`profiledist`, `pdsum*`, `preg`, and `vdist`) as well as features that indicate basic salience (`dur` and `mweight`). Pitch features are likely of moderate to little importance because most of the relevant pitch-related information is already implied by the schema's interval structure. Interestingly, duration and metric weight (both properties that are taken from each note in isolation) play little to no role, which is confirmed in Figure 2b. This indicates that local properties do not mark notes as structural, this role seems to depend *only* on how the note is used in relation to other notes.

6. CONCLUSION

As the results presented above show, distinguishing between incidental and structural note configurations based on a small number of musically and cognitively motivated heuristics works well in the vast majority of cases. Even if a number of misclassifications remain, a closer look at these cases provides valuable insights into the problem at hand. First, the main limitation of our approach is that the model assesses suggested schema instances individually, without considering, or comparing it to, alternative interpretations. In many cases, the main reason for human experts to reject a candidate does not seem to be a lack of plausibility of the match itself, but rather the availability of a "better explanation", i.e. an alternative analysis of the match's context that identifies a more plausible contrapuntal scaffold. This result is in line with the reduction-based approach of Katsiavalos et al. [13]. Since the features used in this study already proved useful for independent classification, they likely benefit from a general structural-analysis approach, in which schema instances are recognized in reductions of the musical surface.

A second insight concerns the idea of schema itself and its relation to a classification task. From a cognitive perspective, a schema does not need to be instantiated unambiguously or even completely. It is sufficient if listeners recognize the schema as the template for the surface events, or if they understand the composer's intention to evoke the schema. In this regard, *discrete* binary classification into instances and non-instances may be as unattainable as it is undesirable, falling short of the complexity the relationship between schema and realization can exhibit.

SEMANTICALLY MEANINGFUL ATTRIBUTES FROM CO-LISTEN EMBEDDINGS FOR PLAYLIST EXPLORATION AND EXPANSION

ABSTRACT

Audio embeddings of musical similarity are often used for music recommendations and autoplay discovery. These embeddings are typically learned using co-listen data to train a deep neural network, to provide consistent triplet-loss distances. Instead of directly using these co-listen–based embeddings, we explore making recommendations based on a second, smaller embedding space of human-intelligible musical attributes. To do this, we use the co-listen–based audio embeddings as inputs to small attribute classifiers, trained on a small hand-labeled dataset. These classifiers map from the original embedding space to a new interpretable attribute coordinate system that provides a more useful distance measure for downstream applications. The attributes and attribute embeddings allow us to provide a search interface and more intelligible recommendations for music curators. We examine the relative performance of these two embedding spaces (the co-listen–audio embedding and the attribute embedding) for the mathematical separation of thematic playlists. We also report on the usefulness of recommendations from the attribute-embedding space to human curators for automatically extending thematic playlists.

1. INTRODUCTION

Automatically annotating music with semantically meaningful and musically relevant attributes is an important effort with a long history [1–5]. It has become especially important as music-streaming services have made large catalogs of recorded music available to people worldwide and as the user interface to these services continues to shift towards voice activation rather than text search or graphical browsing. Describing music using such musical attributes has many applications such as:

- allowing consumers to search for music that satisfies musical, emotional or psychological constraints, using text or voice queries;

- browsing for such music using common usage patterns reflecting activities (*e.g.,* "running") or moods (*e.g.,* "chill");

- sequencing playlists for users that allows them to choose which aspect of musical similarity to maintain, rather than simply following general co-listen patterns;

- providing power users and curators the ability to program specific experiences using higher-order operators.

In this paper, we describe a system for understanding and describing music content. The paper is divided into two main parts. The first part (Section 2) describes how we extract semantically meaningful attributes from features primarily based on audio-spectrogram embeddings trained on co-listen user behavior. The second part (Section 3) explores using these semantic-attribute embeddings both to characterize and to extend professionally curated playlists.

2. EXTRACTING SEMANTICALLY MEANINGFUL ATTRIBUTES FROM CO-LISTEN EMBEDDINGS

We collaborated with the YouTube Music curation team to establish a prioritized list of semantically meaningful audio attributes. Several attributes are subjective, making it difficult to get enough ground truth data to support training. Typical deep networks require many labeled examples, due to the millions of trainable parameters in modern deep networks: for example, ResNet-18 (used by [6]) has around 11 million trainable parameters. We could use existing meta-data for some attributes, such as genre, but other important attributes, such as vocalness (presence of vocals) and energy, are not as prevalent. Even with genres, there is not a consistent set of labels available across different music distributors.

We first review the work of [6]: building on this work allows us to have shallow yet powerful attribute embeddings. In Subsection 2.2, we describe our approach to extracting full-track–level attributes from those co-listen–based audio embeddings. We then discuss our work in measuring attribute *consistency* across the duration of the track (Subsection 2.3). Finally, in Subsection 2.4, we report our accuracy.

2.1 Co-listen–based Audio Embeddings

To allow us to train only comparatively shallow networks, we build on the audio-embedding work done by [6]. In this subsection, we review the approach taken in that previous work.

In [6], an initial audio embedding was obtained using triplet loss from aggregated listening sessions. With the triplet loss, tracks that were (in aggregate) listened to together were trained to be closer in the embedding space than those that were not. The unaveraged embedding is generated using a modified version of Resnet-18, operating on overlapping 3-second audio-spectrogram windows (with a 1-second overlap). For training, [6] used random 3-second samples from the anchor, positive-example, and negative-example tracks. They evaluated by holding back 10% of the 10.5-million audio tracks in their co-listen dataset. When testing on this hold-out set, they achieve over 50% improvement in performance as [2] under the same training regime (0.079 average precision vs. 0.055 for [2]).

In this paper, we use averages of the [6] embeddings as our audio embeddings, with averaging either over the full song duration (Subsection 2.2) or over 10-second tiles (Subsection 2.3).

2.2 Co-Listen Embeddings to Full-Track Attributes

In this paper, we consider the following attributes:

- Genre: A subset of the full international set of genres, including only those deemed important for the US market [1], specifically: Hip-Hop/Rap, R&B/Soul, Blues, Country, Jazz, Rock, Metal, Pop, Dance/Electronic, Alternative/Indie, Latin Urbano, Regional Mexican, Reggae, K-Pop, Korean Ballads, and Classical;

- Valence (or hedonic tone): a measure of the emotional positivity or negativity of the music;

- Vocalness: a measure of the prominence of speaking and singing (or even wordless screaming or humming);

- Energy: a qualitative measure of the intensity (or autonomic arousal) of the music;

- Temporal consistency of energy across a track (Subsection 2.3).

The primary source of ground-truth labels for our attribute-classification models is the team of music experts at YouTube Music. This source means that were are limited to between and 10,000 and 20,000 training examples for the energy, valence, and vocalness classifiers and around 1,000 manual labels per genre for the multi-label genre classifiers.[2]

To allow robust training, even from this small amount of data, we train comparatively small, separate, fully-connected neural nets on top of the (frozen) audio embeddings given by [6]. This is a version of transfer learning but we do not attempt to fine-tune the underlying audio embeddings for our semantic-attribute task, due to the comparatively small amount of training data we have available in our attribute space.

We then create an attribute embedding space using the continuous-valued outputs of the final logits of each of these classifiers, followed by pooled-variance normalization, as will be described in Subsection 3.2.

Details about the classifier network architectures and the training data are given next.

2.2.1 Genre

The genre model is a multi-label classifier (outputting 0 or more labels per video) from a vocabulary of 54 genres. It is trained on a mix of 50,000 manually labeled videos and 6,500,000 labels inferred from the DDEX feed delivered by music labels.[3] The genre-classification network is fully connected with 8 512-wide hidden layers. The input features are:

- Average audio embeddings [6] (across the full track)

- Average video embeddings [7] (across the full track)

- Image embedding of the video thumbnail [8]

- Word embeddings derived from a CBOW model [9] trained on 10B search queries. They are applied to the tokenized title, free-text DDEX genre, and free-text music label name of the video.

- Inferred language of the title [10, 11]

- Video type (Art Track [12], official music video, user-generated content)

While we might have been able to achieve higher music-genre accuracy by learning cross-modal co-embeddings [13–15], we instead use video, image, and word embeddings trained for general video retrieval, without restriction to music-related content. This allows us to re-purpose more general embeddings, again avoiding the overhead of large-network training, just as we have with re-purposing the audio–co-listen embeddings [6].

We trained a genre-classifier network for 2 million steps using Adagrad with a learning rate of 0.05 and a mini-batch size of 64. We did not use regularization. We selected per-class thresholds by choosing the point that maximizes F1 on a separate test set.

---

[1] We restricted our genre set since our evaluation was focused on playlists generated primarily for the US market and since the definition/assignment of genre is not uniform across the globe.

[2] For genres, we also have other sources of label data, as described in Subsection 2.2.1 but that secondary source is significantly less reliable.

[3] The DDEX feed labels must be mapped from the often idiosyncratic genre tags provided by each music label to the 54 genre label set that forms our vocabulary. That mapping is difficult to correctly determine, resulting in noisy training data. We do not use this secondary source of label data at all in evaluation.

Figure 1. Temporal Computed Energy for *Stairway to Heaven*.

2.2.2 Energy

Energy is computed using the output of a regression model using full-track-average audio embeddings [6] as its only input. It was trained on around 20,000 human-labeled examples with ratings in one of 3 buckets (i.e., low, medium, high). These ratings are then converted to scores of 0, $\frac{1}{2}$, and 1. The network is fully connected with 2 hidden layers: the first layer is 128 units wide and the second, 64 units wide. It used Adam optimizer with a decay rate of 0.98 and was trained for 10,000 steps.

2.2.3 Valence

Valence is computed using the output of a regression model, again using full-track-average audio embeddings as its only input. The network is fully connected with 3 hidden layers: the first and third layers are 256 units wide and the second, 512 units wide. It was trained on 10,500 human-labeled examples. As with energy, the training data was human bucketed ratings with 3 distinct levels, from negative (sad or angry), neutral, to positive (happy or content) and the buckets were assigned to 0, $\frac{1}{2}$, and 1. It used Adam optimizer with a decay rate of 0.96 and was trained for 10,000 steps.

2.2.4 Vocalness

Vocalness is computed using the output of a binary classification model, using full-track-average audio embeddings as its only input. It was trained on 18,000 human-labeled examples. The raters were asked to indicate if there were significant lyrics or other vocal elements in the track. Like valence, the network is fully connected with 3 hidden layers: the first and third layers are 256 units wide and the second, 512 units wide. It used Adam optimizer with a decay rate of 0.96 and was trained for 10,000 steps.

2.3 Temporal Inference

While the attributes listed above are often used to describe the entirety of a music track, there can be significant variations in some attributes over the temporal extent of a song. As an example, Figure 1 shows computed energy for the song *Stairway to Heaven*. Generating a single audio embedding representing the whole track via the mean of window samples results in a loss of information on this aspect.

For attributes like this, we shift to performing inference on 10-second segments of audio, using the time-localized audio embeddings. We do this in two steps. As a first step, we train a full-track model of the desired attribute, with the *track-level average* of the local audio embeddings as its

input. With that trained model in hand, we reuse it, running a separate inference on each 10-second audio embedding, to generate time-localized attribute estimates. From this sequence of localized estimates, we compute a track-level estimate using an aggregate heuristic. For example, for the track-level energy, we take the maximum over the moving average of this temporal estimate as follows:

$$\mathrm{E} = \max_{0 \le i < N-W} \frac{1}{W} \sum_{j=i}^{i+W-1} e_j \qquad (1)$$

where N is the the number of 10-second segments in a track, e_j is the raw energy estimate for the jth segment, and W is the window size which also a function of N according to $W = \max\{3, \frac{N}{6}\}$.

In the future, we could train a time-localized regression using explicit labels on the 10-second segments or using the temporal estimates provided by the full-track model as weak labels. However, for the purpose of this paper we restrict ourselves to the method described above.

Separately, using the sequence of local estimates, we measure the attribute's consistency. The local estimate is first smoothed, to give more reliable local estimates of the attribute. For example, for energy, we use a moving average with windows as described above. From that sequence, we can create a consistency measure using:

$$\mathrm{Consistency} = 1 - \frac{\sum_{i=0}^{N-2} |A_{i+1} - A_i|}{\sum_{i=0}^{N-2} A_i}, \qquad (2)$$

where A_i is the attribute value, determined by the smoothed data and centered on the ith 10-second segment of the track.

We improved precision from 85% to 90% using this approach instead of inference on the mean audio embedding, demonstrating the performance improvement possible from aggregating local inferences compared to performing inference on pre-aggregated embeddings. The attribute's consistency measure is also separately useful: for example, it can give playlist curators a deeper description of the acoustic-energy profile, which is needed for task-targeted playlists like "workout" or "focus".

While this approach can be used for other (non-genre) attributes as well, for the results in this paper, we only used it with energy.

2.4 Accuracy of Individual Attribute Detectors

Table 1 describes the accuracy of each of our attribute models.

Energy and valence are regression models. The test set was created from human annotations on a four-point scale. The regression results were evaluated using error thresholds, set according to what was judged acceptable by the curators. Even though the training data for valence used a four-point scale, we used an evaluation threshold that is equivalent to a three-point scale. This coarser scale for valence evaluation was based on the needs of the curators.

Vocalness was trained as a binary classification and was evaluated accordingly.

Attribute	Metric	Quality
Genres: Multi-label classifier.[†]	Human-expert labels[†]	78% precision, 84% recall
Valence (regression, output $\in [0, 1]$)	Prediction < 0.33 from label[‡]	78% accuracy
Vocalness (binary classifier)	Human-labeled ground truth	97% precision, 78% recall
Energy (regression, output $\in [0, 1]$)	Prediction < 0.25 from label[‡]	90% accuracy

[†] The genre classifier was evaluated on the 16 genres used in this paper. The evaluation set was formed from the entries from expert-curated single-genre playlists and their labels were inferred accordingly.
[‡] The thresholds for accuracy were set after consulting with expert human curators who provided musical examples of differences in valence and energy that should be distinguishable.

Table 1. Accuracy of Each Full-Track Attribute Model.

For genre, we created an evaluation set using entries from single-genre playlists authored by curators, with labels inferred accordingly. None of these curated tracks were used in training the genre classifier.

We are able to extract semantic attribute labels from the frozen audio embeddings, both for genre (similar to [6]) and for more qualitative measures (energy, valency, vocalness). For the qualitative measures, this labeling is based solely on the audio embedding.[4] Huang et al. [6] report similar findings. It is somewhat surprising that the semantic information needed to compute these labels are captured by embeddings trained for a completely different task (that is, predicting which songs are listened to together). Based on this observation, we hypothesize that an embedding space formed from these semantic attributes can be used for recommending additions to human-curated playlists. The results that we report in Section 3.2 support this conjecture and strengthen it by suggesting that our attribute-embedding space is better suited for playlist recommendations than the full audio-embedding space.

3. EXPLORING CURATED PLAYLISTS

In this section, we examine the use of our learned musical attributes as a tool for discriminating between and adding to music playlists. In Subsection 3.2, we compare the discriminative power of the attribute-embedding space to that of the audio-embedding space, using the playlists that we describe in Subsection 3.1. Subsection 3.3 then describes a human evaluation of the attribute-based recommendations for playlist extension.

3.1 Corpus of curated playlists

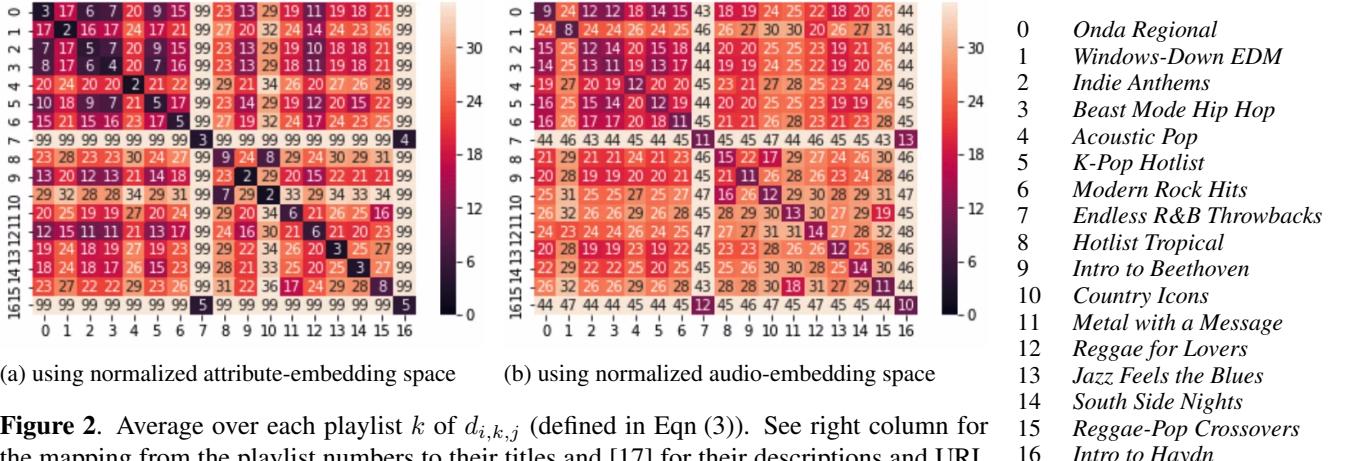
YouTube Music [16] offers playlists with specific themes. Playlist themes are relevant to targeted users or markets and mostly fit into one of the following categories: ephemeral (*e.g.,* event based), seasonal, and canonical. The canonical category includes contextual (*e.g.,* bedtime music), mood (*e.g.,* feel-good favorites), and activity (*e.g.,* workout essentials) playlists. The canonical category is the

most amenable to attribute analysis and automatic augmentation. For this paper, we focused on playlists in the canonical category.

We used several of curated canonical playlists to evaluate how well our attributes characterize and discriminate between the groupings that were created by human experts. Curated playlists are widely served across YouTube Music. All of these curated playlists were publicly available as of April 2020.

For our embedding-space studies, described in Subsection 3.2, we use 17 different human-curated, genre-based playlists. That combined set of playlists had 4,563 entries. To avoid evaluation-set contamination, none of the playlists or their entries were used in the attribute training (Section 2). The names of these 17 playlists are given in Figure 2 and a more complete description is given in [17].

For our playlist-extension studies, described in Subsection 3.3, we use another disjoint set of 5 different human-curated, *vibe*-based playlists. The combined set had 545 entries. General characterizations of these 5 playlists, along with their URL links, are given in [17].

3.2 Analyzing playlists in attribute space


In this section, we investigate how well two different embedding spaces capture the structure of human-curated playlists. The first embedding space is the 128-dimension space generated from [6], renormalized according to the methodology described below. The second is a (renormalized) embedding space formed using the continuous logits that are trained to provide our attribute labels: that is, energy, valence, vocalness, and 16 top-level genres that are typical of music listened to in the US.

We renormalize each space using the Tikhonov-regularized [18] square-root inverse of the pooled variance matrix [19]. The pooled variance matrix is estimated using a sampling of playlists and treating each playlist as a separate cluster (with an independent cluster mean) but with a single shared (pooled) variance matrix. The embedding space is then rotated and scaled, according to the square-root inverse of this pooled variance. We use Tikhonov regularization in this inversion to avoid possible problems with nearly singular variance matrices.[5]

After re-normalization, each playlist is (on average) a Gaussian distribution with an identity-variance matrix, allowing us to directly compare between-playlist distances across the two embedding spaces. We use this distance equivalence throughout this section, to determine how well human-curated playlists are separated in these two embedding spaces. Our hypothesis is that, whichever embedding space gives better separation between authored playlists will also give better suggestions for creating or extending playlists. We will more directly examine how well our suggestions do for playlist generation in the next section. Before moving to that analysis, we compare the mathematical performance of the two spaces in this section.

---

[4] For genre, we provide our networks with information derived from the video content and text in the title and description (see Subsection 2.2.1), as well as the co-listen–based audio embeddings.

[5] We did not observe any near singularities in either the attribute- or the audio-embedding spaces but continued to use it, to avoid issues in the future, when we plan to use a larger group of attributes.

Figure 2. Average over each playlist k of $d_{i,k,j}$ (defined in Eqn (3)). See right column for the mapping from the playlist numbers to their titles and [17] for their descriptions and URL links.

We compared the separation of the 17 different human-curated, genre-based playlists from Subsection 3.1 by examining the distances between each playlist entry and all of the playlist centroids:

$$d_{i,k,j} = ||e_{i,k} - m_j||^2 \qquad (3)$$

where $e_{i,k}$ is the embedding-space coordinates for the ith entry in the kth playlist and m_j is the mean of embedding-space coordinates across all N_j entries in the jth playlist: $m_j = \frac{1}{N_j} \sum_{i=0}^{N_j-1} e_{i,j}$. Figure 2 shows the average of these distances for each playlist: that is, $\frac{1}{N_k} \sum_{i=0}^{N_k-1} d_{i,k,j}$. The larger the distance the less "alike" the two playlists appear in that embedding space. Based on Figure 2, the (normalized) attribute embedding space does a better than the (normalized) audio embedding space at separating the playlists, while keeping each individual playlist compact.

We can look at this separation/compactness of playlists in each embedding space, with one summary statistic per playlist entry. We use $\Delta_{i,k} = \min_{j \neq k} d_{i,k,j} - d_{i,k,k}$: the smallest difference between each entry's distance to the closest, "other" mean and its distance to its own mean. Figure 3 shows the histograms of this relative distance measure for the (normalized) attribute-embedding space and the (normalized) audio-embedding space, as well as the histogram of the paired difference between them. For Figure 3-a and Figure 3-b, highly positive values are best and negative values indicate an entry that is closer to a different playlist's mean than to its own. For Figure 3-c, positive values correspond to the attribute-embedding space giving better separation than the audio-embedding space. Using a single-tail, paired Student t-test [20] on this data indicates that the attribute embedding space is significantly better than the audio embedding space with a probability well over 99% (t = 27.24, p = 3e-151). In order to be certain that this high level of significance does not derive from unequal variances across the two embedding spaces, we also ran a single-tail Welch's unequal-variance t-test [21]: this still showed well above 99% certainty (t = 16.24, p = 5e-58).

(a) $\Delta_{i,k}^{att}$ using normalized attribute-embedding space   (b) $\Delta_{i,k}^{aud}$ using normalized audio-embedding space   (c) paired difference: $\Delta_{i,k}^{att} - \Delta_{i,k}^{aud}$ (matched indices)

Figure 3. Histograms of $\Delta_{i,k}$ using the two different embedding spaces and of their difference.

3.3 Extending playlists using attributes

In this section, we explore the application of the learned-attribute space to generating algorithmic candidates that could be used to refresh or extend human curated playlists in the corpus described in Subsection 3.1. One advantage of using the learned-attribute space is the ability for humans to understand, debug, and tweak the automatic method. We run an experiment where we show professional music curators a set of candidates for a playlist and ask them to assign a rating of whether those candidates sufficiently align with its *vibe*.

3.3.1 Playlist selection

We selected 5 playlists from the corpus for this experiment with the premise that they had *consistent vibe* with focus on *context/mood/activity* rather than, for example, *most popular* or *new releases*. We hypothesize that a semantically meaningful attribute space would be better at generating recommendations closer to the *vibe* of such playlists compared to traditional co-listen–based approaches.

3.3.2 Candidate generation

For each playlist, we aggregated attribute scores across its tracks to create a *recipe* consisting of the following:

- Top-N genres contributing to 80% of the cumulative frequency distribution where a genre is assigned to a playlist if its score was above the threshold determined from evaluation in Subsection 2.4.

Playlist	Rating			Total
	Good	Borderline	Bad	
Classical for Sleeping	36%	38%	26%	214
Classic Sunshine Soul	39%	35%	26%	101
Tranquil Spa Day	37%	63%	0%	27
Feeling Good in the 80's	22%	20%	58%	143
90's Rock Relaxation	11%	24%	65%	85

Table 2. Music-curator ratings on recommendations for playlist extension. See [17] for the description and URL link of each playlist.

- Mean and standard-deviation of the real-valued attributes energy, valence, vocalness. We also included tempo in beats-per-minute computed using APM [22] as an additional attribute.

- Other metadata attributes including top-10 artists, earliest and latest release year of tracks on the playlist. These were added as constraints to weed out recommendations too far away from the playlist premise.

This *recipe* is then used to generate a list of tracks classified into the top genres, with real-valued attribute scores at most one standard-deviation away from mean, release year within the earliest and latest release year and performing artist(s) among the top artists. We sort this list by popularity in the last 365 days and prune to generate a final list of recommendations.

3.3.3 Curator assignment

Music curators were shown these recommendations and asked to assign a rating from below options

- Good - "track is not only appropriate for the playlist premise, but also a high-quality recommendation"

- Borderline - "while track's attributes align with the premise, I would not be excited to program it"

- Bad - "I would never program this track to this playlist, because it does not fit the premise". Raters were also asked to note a reason in this case.

3.3.4 Results

The results of the experiment are tabulated in Table 2. We find that, for playlists defined almost solely by mood and emotional affect, the curators found a majority of the tracks good enough to program onto the playlists and some "bad" tracks. For *Tranquil Spa Day* especially, there were no "bad" tracks in the 27 that were rated. This shows that the recipe based on semantic attributes and metadata constraints was a decent heuristic for playlist extension.

For the decade playlists (last 2 rows) the performance was very poor. To have a better understanding, we analyzed the rater notes and found that 77 out of 83 and 45 out of 56 "bad" tracks for *Feeling Good in the 80s* and *90's Rock Relaxation*, respectively, were due to the curators not feeling that the tracks belonged to the correct decade. On

examination, we found that the metadata was indeed incorrect on those tracks. Discounting these tracks with incorrect metadata, our approach again seems to perform decently on these playlists.

For a qualitative study like this, the strongest support is the overall evaluation by the music curators on whether or not the suggestions are useful to have. Even with around one-in-four playlist suggestions being discarded as incorrect, the music curators found that having these automatically generated suggestions available sped up their work on refreshing and extending the vibe-oriented playlists.

4. CONCLUSIONS

We described a system and method to automatically label musical tracks with semantically meaningful attributes, including musical genre, autonomic arousal, valence, and vocalness. These attributes are inferred using models operating on audio embeddings generated by deep neural networks trained on co-listen data, using triplet loss. The attribute models themselves are trained using smaller amounts of labeled data. We show that precision improvements can be obtained by running attribute inference on temporal segments and fusing those scores into a whole-track score compared to running inference on an averaged embedding. This approach also yields temporal consistency attributes that are useful in and of themselves.

We then define a lower-dimensional embedding space established by these semantic musical attributes. We compare these embeddings with the original audio co-listen–trained embeddings in the context of professionally curated playlists. We find that this space better separates a sample of thematic playlists: it matches the semantic similarity implicit in these professionally curated playlists better than the raw audio embedding space.

Unlike previous studies of playlist extension [23, 24], we used these semantic attributes to generate human-readable and -editable recipes for professionally curated playlists. We used those recipes to automatically extend the playlists and measured the quality of those automatic content refreshes via human evaluation.

ABSTRACT

In this paper we present Aligned Scores and Performances (ASAP): a new dataset of 222 digital musical scores aligned with 1068 performances (more than 92 hours) of Western classical piano music. The scores are provided as paired MusicXML files and quantized MIDI files, and the performances as paired MIDI files and partially as audio recordings. Scores and performances are aligned with downbeat, beat, time signature, and key signature annotations. ASAP has been obtained thanks to a new annotation workflow that combines score analysis and alignment algorithms, with the goal of reducing the time for manual annotation. The dataset itself is, to our knowledge, the largest that includes an alignment of music scores to MIDI and audio performance data. As such, it is a useful resource for a wide variety of MIR applications, from those that target the complete audio-to-score Automatic Music Transcription task, to others that target more specific aspects (e.g., key signature estimation and beat or downbeat tracking from both MIDI and audio representations).

1. INTRODUCTION

As data-hungry deep learning models have become more ubiquitous in the field of MIR in recent years (e.g., [19, 22, 37]), large, well-annotated datasets have become increasingly important. Similar trends towards deep learning methods have been seen in related fields such as natural language processing [42] and computer vision [39]. For many tasks in these fields, large datasets can be automatically scraped from the web, and annotated quickly by non-experts (e.g., [34]). Unfortunately, the same can often not be said for tasks in MIR, for many reasons.

First, producing high-quality audio or MIDI data is a non-trivial task, requiring expert performers and expensive equipment that is not always available. Second, the availability of a high-quality digital ground truth is not guaranteed in many cases, particularly for tasks which require a

musical score [1], e.g., for the complete audio-to-score Automatic Music Transcription (AMT) task (see [1] for a recent overview of AMT). Finally, even in the case when both audio/MIDI data and high-quality digital ground truth scores are available, acquiring an alignment between the two is non-trivial. Automatic alignment methods (e.g., [30]) are often not robust enough to deliver highly reliable results and require time-consuming post-processing and cleaning by expert musicians for advanced data usage.

We introduce the Aligned Scores and Performances (ASAP) dataset [2], containing digital musical scores of Western classical piano pieces as both MusicXML and MIDI, aligned at the beat level with audio (from MAESTRO [17]) and MIDI recordings of over 1000 human performances. Regarding the three difficulties outlined above (data creation, digital ground truth availability, and recording-ground truth alignment), we use (1) publicly available MIDI and audio from expert human performances; (2) publicly-available musical scores scraped from the web; and (3) a new workflow to efficiently produce aligned beat, downbeat, key, and time signature annotations with minimal human correction required.

Although ASAP can be used for many tasks, it was designed with two categories specifically in mind: (1) complete audio-to-score AMT and (2) metrical structure-based tasks (e.g., beat and downbeat tracking, tempo estimation, metrical structure alignment, and rhythm quantization) of classical piano performance, from both audio and MIDI.

While a major goal of AMT is to convert an input audio recording into a form of human-readable music notation, the vast majority of AMT systems fall short of such an output. Rather, they convert the input audio recording into some sort of time-frequency representation: either a frame-based multi-pitch detection, where the presence of each pitch is estimated at each point in the input recording (e.g., [21]); or a note-based output such as a piano-roll or MIDI file, where notes are detected each with a pitch, an onset time, and an offset time (e.g., [16]). [3] For these purposes, the ground truth only needs to contain some aligned

---

[1] Although PDF scores are sometimes available, and the field of Optical Music Recognition (see [3] for a recent overview) involves converting these into digital format, this conversion can add errors, and starting from a clean, digital score is generally better if available.

[2] `https://github.com/fosfrancesco/asap-dataset`

[3] This can be post-processed into a musical score, as in the pipeline approach of [29], but such pipelines tend to add noise at each step.

pitch or note presence data—not a full musical score. Existing datasets such as MAPS [8] and the larger MAE-STRO [17] contain appropriate ground truths for this level of transcription (see Section 2).

In recent years, a few systems have been designed to output a more complete musical score directly (e.g., [5, 35]). While each of these works shows promise on this difficult task, neither includes time signatures or key signatures in their output. One [5] uses synthetically generated scores (and synthesized audio), and the other [35] uses audio synthesized from real scores. Since the eventual goal of AMT is a full transcription from human performance to musical score, a large dataset of non-synthetic human performances (containing the tempo deviations and timing intricacies of human performance, as well as real audio) is needed: synthetic data can be useful in the initial phase of model design, but human performance data is required for a truly reliable evaluation. ASAP provides such a dataset.

To our knowledge, no audio-to-score transcription system exists that requires fine-grained alignments between recordings and ground truths, perhaps due to a lack of available data. However, the use of data with even a coarse alignment has been shown to improve performance on the related task of monophonic note-based transcription [31], suggesting that the same should be true for audio-to-score AMT, if a large enough dataset of aligned recordings and scores was available. ASAP provides this time-alignment between the included recordings and ground truth scores.

Regarding metrical tasks, large audio datasets exist, especially for beat and downbeat tracking, enabling sophisticated systems to be trained (e.g., [2]). However, there is an absence of similarly-sized annotated datasets consisting of MIDI data, resulting in a noted lack of training data for metrical tasks from MIDI input (e.g., [25]). Even in the case of audio, much of the existing data is dance music or from other genres with relatively steady tempi compared to the classical piano music contained in ASAP (see Section 4.3 for an analysis of ASAP's tempo changes).

We produce beat and downbeat annotations for every performance in ASAP with a novel workflow that exploits the precise metrical structure information available in a musical score. Projecting this onto each corresponding performance guarantees a robust means to identify the beat and downbeat positions. Working with MIDI allows us to overcome many difficulties found in similar approaches using only audio data (e.g., [32]). The workflow allows us to drastically reduce the time required for manual annotation.

2. RELATED WORK

Some public datasets similar to ASAP—containing combinations of musical scores, MIDI performances, and audio recordings, for AMT and/or beat tracking—already exist. In this Section, we describe those existing datasets in comparison to ASAP, highlighting specifically where ASAP addresses their deficiencies. Table 1 contains a summary of the largest of these datasets in comparison to ASAP. We first describe those containing musical performances (useful for AMT), and follow that with a brief discussion of available datasets for metrical structure-based tasks.

2.1 Performance datasets

There are two datasets which contain multiple performances of many different pieces. The Vienna 4x22 Piano Corpus [11] consists of 22 different performances of each of 4 different pieces, in both audio and MIDI format, aligned to a metrical grid. The CHARM Chopin Mazurka Project [4] dataset contains many recordings of each of 49 different Mazurkas composed by Frédéric Chopin, although the original audio recordings are only referenced, and not available online (instead, many pre-calculated features are provided). While these datasets are valuable for investigating live performance deviations and comparisons between different performances of the same piece, they are not as useful for AMT, since they each consist of a small number of different pieces, leading to likely model overfitting (only 4 different pieces for Vienna 4x22, and only pieces by a single composer in the Mazurka dataset).

The Saarland Music Data (SMD) dataset [28] contains 50 synchronized audio and MIDI recordings of human performers playing a Disklavier piano. The files are not aligned with any musical scores or beat annotations, and the dataset's size is somewhat small compared to other similar datasets. Likely because of its size, SMD has has not been used for AMT in recent work to our knowledge.

CrestMuse PEDB [15] is a dataset based on audio recordings of multiple piano performances of around 100 unique pieces. However, the original audio recordings are not included. Rather, references to commercial CDs which can be purchased, and on which the recordings can be found are given. After a PDF application and pledge are filled out and submitted, access is granted to download the database in about a week. Provided in the dataset are MIDI files, whose notes have been hand-aligned to the referenced recordings; and digital musical scores in an XML-based format, to which the notes and beats of the MIDI files are aligned (using "deviation" XML tags in the score files). Since its initial release, some audio files have been added. However, these are different from the original score-aligned audio recordings, and in some cases are synthesized from MIDI performance. The difficulty of acquiring the audio recordings makes this database rarely used for audio-based tasks such as AMT.

The piano-midi dataset [5] contains 324 quantized MIDI files whose tempo curves have been manually altered with the goal of becoming more human-like. The MAPS dataset [8] contains 210 of these MIDI files (of 119 different pieces), without key and time signatures, each paired with an audio file—some synthesized and some actual recordings. A-MAPS [41] later augmented MAPS with MIDI files containing key signature and time signature annotations. Since the MIDI data is generated from tempo-varied quantized MIDI, rather than actual performance, the MIDI files and recordings do not contain all of the timing variance that would be present in real performance: note onsets and offsets which lie on the same beat in the original musical score also occur simultaneously in the corresponding

Table 1. An overview of the most relevant datasets for AMT (top section) and metrical tasks (middle section), compared to ASAP (bottom). Alignment refers to the level of alignment between the quantized and performance data. MAPS consists of pseudo-live performance (quantized MIDI with manually altered tempo curves). †MAPS, SUPRA (fully) and CrestMuse-PEDB (partially) include synthesized audio (not real recordings).

MIDI and audio files. In real performance, such events only rarely occur simultaneously. Rather, small timing deviations introduce gaps, overlaps, and other timing variation (see e.g. [26], Figure 4), which are therefore missing (along with ornamentation such as trills, as well as performance errors). Although these datasets contain perfectly-aligned ground truth annotations (which has made MAPS a standard for AMT evaluation since its release), their modest size and the fact that they are not real live performance are drawbacks that we hope to address with ASAP.

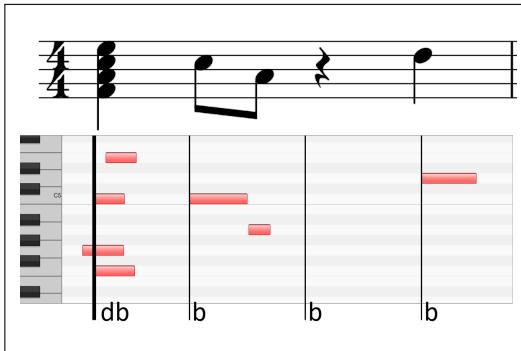
The SUPRA dataset [36] contains 478 MIDI files of around 430 different pieces generated from an archive of piano performances in the form of physical piano rolls. SUPRA also contains synthesized audio recordings of each MIDI file, and labels each with a composer and title, but provides no metrical alignment of the pieces.

The MAESTRO dataset [17] contains 1282 real performances of around 430 different pieces from the Yamaha piano e-competition [6]. Each performance is available as a MIDI file and an audio recording with a fine alignment of around 3 ms. Metadata are available for each performance, including the composer and title of each. MAESTRO's size, fine alignment with ground truth, and the fact that it is real performance have made it an excellent source of training and evaluation data for AMT from recording to piano-roll. However, MAESTRO does not contain any note-, beat-, or even piece-level alignment with digital musical scores, required for the complete audio-to-score AMT task (and which ASAP does contain).

2.2 Metrical structure datasets

For metrical structure-based tasks, from live performance MIDI data, annotated datasets from the previous section (particularly piano-midi and CrestMuse-PEDB) are typically used. However, they are relatively small (especially in terms of unique pieces), and piano-midi files in particular do not contain real live performance, as mentioned. For the same tasks from audio data, large annotated datasets exist, enabling sophisticated models to be designed and trained (e.g., [2]). The largest and most widely used (where

---

[6] http://piano-e-competition.com/


audio files are publicly available, including at least beat annotations) are: GTZAN [38] (1000 audio recordings of various genres with beat, downbeat, and 8th-note annotations), Ballroom [12] (685 audio recordings of ballroom dancing music with beat and downbeat annotations), Hainsworth [14] (222 audio recordings of Western music), and SMC [18] (217 audio recordings of Western music, specifically selected to be difficult for beat tracking). However, the music contained in these datasets tend to have a much steadier tempo than those contained in ASAP (even SMC; see Section 4.3 for a comparison).

3. PRODUCING MUSIC ANNOTATIONS

Annotating a dataset the size of ASAP with ground truth for AMT and related problems such as beat tracking is a time consuming task that can, in principle, only be performed by expert musicians. This severely limits the ease with which one can produce a reliable and finely crafted dataset at the required scale.

For piano music, MIDI and audio performances can be automatically aligned if they are recorded at the same time using an acoustic piano fitted with the proper sensors such as a Disklavier. The main problem then becomes annotating the performances with metrical markings (such as beats and downbeats) and aligning those with a musical score. Holzapfel et al. [18] describe the process used to annotate the SMC dataset in detail, showing how much manual work was required for its beat annotations. ASAP contains more than 92 hours of performance data, and even a skilled musician would need to listen to each multiple times with the proper annotation software in order to annotate it fully (and this time can increase dramatically for complicated pieces with multiple time and key signature changes). Moreover, as highlighted in [40], the manual annotations would still be affected by human subjectivity, requiring a system with multiple annotators and a reconciliation mechanism between them (e.g., [10,18]). We believe that without a large budget and/or the ability to involve a community of expert users willing to spend significant time on the task, producing a large ground truth dataset cannot be achieved through a purely manual approach.

Figure 1. Beat and downbeat annotations produced by our workflow in different cases. The 1st (db) is the median of the onsets of the corresponding notes, the 2nd and the 4th (b) are the onset of the corresponding note, and the 3rd (b) is the mean between the two neighbor annotations.

We therefore propose a workflow (Section 3.1) that allows for the automatic production of annotations from digital musical scores and MIDI performances. The precision of the results is much higher than what would be expected from human-based annotation with a single annotator. Moreover, when the quality of the available scores is high, the workflow does not require any human intervention. Manual intervention is sometimes required to fix problems related to either the digital encoding of the scores or performance errors (Section 3.2).

3.1 Annotation Workflow

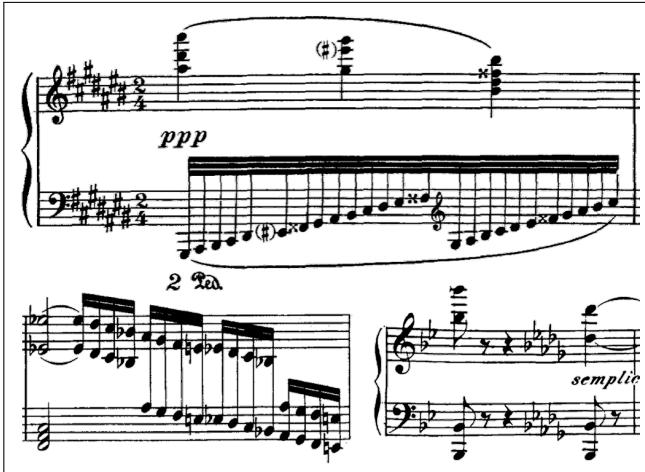
The annotation workflow (Figure 3) takes a MIDI performance and a MusicXML score as input, and produces beat, downbeat, key signature change and time signature change annotations for each. Each annotation is aligned to a position (in seconds) in both the MIDI performance and a MIDI score (generated automatically from the MusicXML score), and each downbeat is further aligned with a measure number from the MusicXML score. The workflow is:

1. Expand any repetitions present in the MusicXML score and extract time and key signature changes using music21 [7].
2. Generate the MIDI score using the MuseScore3 MIDI export function.
3. Extract the times of beats, downbeats, and key and time signature changes from the generated MIDI using pretty_midi [33].
4. Align every downbeat from the MIDI score with a measure number in the XML score.
5. Produce a Score2Performance mapping from each note in the MIDI score to each note in the MIDI performance using the algorithm presented in [30].
6. The performance annotations can then be obtained. For each annotation in the MIDI score (from step 3):

   (a) Take the notes with an onset within 20ms of the annotation (there can be multiple notes, e.g. for the downbeat annotation in Figure 1).
   (b) Use the Score2Performance mapping, to obtain the onset times of the corresponding notes in the performance file.

   (c) Compute the median of the onset times of those notes, and use it as the time of the annotation in the performance.
   (d) If no notes are within 20ms of the MIDI score annotation (e.g., in case of a rest), the position is interpolated from neighboring annotations (e.g., the 3rd annotation in Figure 1)

As shown in [13], annotations on rests or multiple non-simultaneous notes (grace-notes, arpeggios) are inherently problematic, even for human annotators. An inspection of our annotations reveals that our workflow generally produces good results. In particular, our use of the median increases robustness while handling non-simultaneous notes.

3.2 Practical issues with erroneous input


While the mapping between the scores and performances in ASAP is such that they have a very good correspondence in general, local problems can still occur in specific cases. These can be caused either by encoding issues in the XML score, or by performance errors in the MIDI.

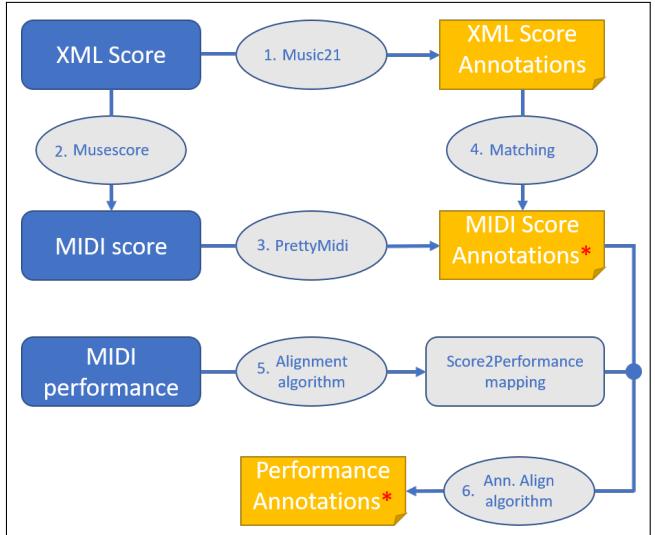
For our automatic workflow to produce good results, the *content* level of the XML score must be correctly encoded, although we can ignore problems at the *graphical* level (we refer to the model of the multiple levels of information in a musical score proposed in [9]). Many of the problems that we encountered during the automatic creation of ASAP's annotations are tricks used by editors to fix problems at the graphical level at the expense of correctness at the content level: for example, grace notes entered as regular notes with a smaller font, invisible barlines inserted mid-bar, invisible notes or rests, or note heads changed for visual reasons inconsistent with their actual duration.

In some cases, editors are forced to use such tricks because the original score itself does not follow standard notation rules. Figure 2 shows two examples of incorrect measure duration: one from Ravel's *Ondine* (top) and another from Mozart's *Fantasie in C minor* (in 4/4; bottom left). There are many ways to handle such cases. Possibilities include having invisible tuplet markings, having a different time signature than the one displayed, and having an overflowing measure. The latter two techniques create problems for automatic beat extraction. Figure 2 (bottom right) is an example of a key change in the middle of a bar in Beethoven's *Sonata No.29, Op.106*, 2nd movement. One way to encode this situation is to split the bar into 2 separate bars, but this also creates problems for automatic beat extraction in the form of an extra downbeat.

Fortunately, such problems are generally easy to detect since they often result in a measure where the sum of the events does not match the duration defined by the time signature. To be able to produce correct annotations even in the case of these "faulty" measures (around 3% of measures in ASAP's musical scores), we introduce a manual correction step for the MIDI score annotations (Figure 3). This prevents the propagation of such problems down to the performance annotations.

The alignment that we use to generate the Score2Performance mapping [30] is robust against small errors and

Figure 2. Examples of problems in musical scores, including incorrect bar length (Ravel's *Ondine* (top) and Mozart's *Fantasie in C minor* (in 4/4; bottom left)) and a mid-bar key change (Beethoven's *Sonata No.29, Op.106*, 2nd movement (bottom right)).

Figure 3. Our annotation workflow; "*" indicates manual correction (see Section 3.2)


note inversions. Nonetheless, small errors in its alignment exist. As the difference between a performance and MIDI score increases, the chance of having an incorrect alignment also increases. This can occur in the case of embellishments (e.g. long trills, or mordents that can be played from the printed note or from the note above) or major performance mistakes. We try to detect these problems automatically by measuring the inter-beat-intervals of each performance and marking the outliers as possible problems. On these outliers (which occurred in around 400 of ASAP's performances), we introduce a final manual correction step. 43 performances contained significant alignment errors that were corrected, and around 2% of annotations had to be moved by less than 1 second.

4. DATASET OVERVIEW

4.1 Dataset content

ASAP contains 222 distinct musical scores and 1068 unique performances of Western classical piano music from 15 different composers (see Table 2 for a breakdown). 548 of the recordings are available as MIDI only, and all the others (520) are provided as MIDI and audio recordings aligned with approximately 3 ms precision. Each score corresponds with at least one performance (and usually more). Every score and performance in ASAP is labeled with metadata including the composer and the title of the piece. We took care to ensure that any two performances of the same piece are labeled with the same title and composer, and no two distinct pieces in ASAP share both.

Each musical score is provided in both MusicXML [7] and MIDI formats. In the MIDI score, the position of all MIDI events are quantized to a metrical grid according to their position in the MusicXML score. Grace notes are represented in MIDI as notes of very short duration. Repetitions in the score are "unfolded" in the MIDI file such

that some sections of the MusicXML score may be duplicated in the MIDI score. Except for performance mistakes, there is a one-to-one correspondence between the notes in a MIDI performance and its associated MIDI score.

For each performance and MIDI score, ASAP provides the positions (in seconds) of all beats, downbeats, time signature changes and key signature changes. Time signature changes are annotated only on downbeats. In the case of pickup measures (and pickup measures in the middle of the score) we delay the position of the time signature change annotation to the following downbeat. Similarly, key signature changes are annotated only on beats. Each downbeat is also mapped to a specific measure number in the MusicXML score, which allows for a clear score alignment, even in the case of repetitions.

The dataset and the code used to generate annotations, along with a detailed description of the specific formatting of the dataset and usage examples are available online [8].

4.2 Origin of the files

The files in ASAP are drawn from multiple sources. The MusicXML scores are from the MuseScore online library [9], created and uploaded by the users of the MuseScore music notation software. They were first collected and associated to MIDI performances from the Yamaha e-piano competition by the authors of [20]. We manually edited the MusicXML scores using MuseScore3 to correct significant notation errors, and generated quantized MIDI files using MuseScore3's MIDI export utility. The paired audio and MIDI performances come from the MAESTRO dataset [17]. We automatically matched as many of the MAESTRO performances as we could to ones collected by [20], thus associating them with musical scores. The unmatched performances from MAESTRO are not included in ASAP. Finally, we modified 5 of the MIDI performances

by inserting a missing note at the beginning, and 277 more have been cut to obtain more homogeneous pieces (e.g., the Bach Preludes are separated from the Fugues, even though they sometimes come from the same performance).

4.3 Dataset Statistics

ASAP contains performances of classical piano music, a style that can be challenging for beat tracking systems due to the large tempo variations that are often present. Here, we compare the tempo variation of the pieces in ASAP to that of the pieces of datasets commonly used for beat tracking from audio [12,14,18,38]. To quantify the tempo variation for each piece, we first compute the BPM at each beat based on the amount of time between consecutive beats. Then, we compute Δ_{BPM} at each beat as the difference between consecutive BPMs. Finally, we compute the standard deviation of the set of all Δ_{BPM} values in a particular piece, which we call $\sigma(\Delta_{BPM})$. Figure 4 presents the distribution of these standard deviations for each dataset as a Cumulative Distribution Function, which shows the probability that a randomly chosen piece from each dataset has a $\sigma(\Delta_{BPM})$ less than the given value. From the plot, it can be seen that Ballroom and SMC have generally steadier tempos than the other datasets, and that ASAP's steadiest 40% and 50% of pieces roughly match those of Hainsworth and SMC respectively. However, a large portion of the pieces in ASAP have significantly larger tempo variation than any of the compared datasets.

In ASAP, differences can be observed between composers. Even though the pieces in the dataset fall under the broad term "classical music", ASAP is very diverse, containing pieces of various styles written across different periods. This can be observed from differences in average $\sigma(\Delta_{BPM})$ for each composer, as is shown in Figure 5. The values in this plot generally match musicological intuitions about tempo variation for the different composers.

Figure 5. Average tempo variation $\sigma(\Delta_{BPM})$ of the pieces by each composer in ASAP.

5. CONCLUSION

This paper presented ASAP: a new dataset of aligned musical scores and performances of classical piano music. Downbeat, beat, time signature, and key signature annotations are produced using a novel workflow that exploits information present in the musical score to drastically reduce manual annotation time compared to fully manual annotation. ASAP contains over 1000 annotated MIDI performances of classical piano music, over 500 of which are paired with audio from the MAESTRO dataset. To our knowledge, it is the largest dataset of that contains such a fine-grained alignment between scores and performances.

This work has only scratched the surface of what can be done with ASAP. Future work will present further statistical analyses on the data and baseline model performance on tasks for which it can be used: complete AMT and beat tracking as presented, as well as others such as expressive performance analysis and rendering [4]. For complete AMT in particular, the evaluation method is still an open problem, although proposals have been made (e.g., [6,27]).

ABSTRACT

The mood of a song is a highly relevant feature for exploration and recommendation in large collections of music. These collections tend to require automatic methods for predicting such moods. In this work, we show that listening-based features outperform content-based ones when classifying moods: embeddings obtained through matrix factorization of listening data appear to be more informative of a track mood than embeddings based on its audio content. To demonstrate this, we compile a subset of the Million Song Dataset, totaling 67k tracks, with expert annotations of 188 different moods collected from AllMusic. Our results on this novel dataset not only expose the limitations of current audio-based models, but also aim to foster further reproducible research on this timely topic.

1. INTRODUCTION

The estimation of moods that a given music track might evoke or empathize with is a relevant task that has been active in the Music Informatics Research (MIR) community for years [20]. This task, which is also known as music emotion recognition, has become even more prominent thanks to the advent of streaming music services with massive collections, where understanding the set of moods of each of their tracks could strongly impact the navigation, discovery, and recommendations of such collections [32]. This task has been typically approached in two different ways: i) regressing a continuous mood space such as the Arousal-Valence one [30], and then clustering such space to obtain a specific mood vocabulary [37]; or ii) classifying a given track into one or more moods, thus becoming a multi-label classification problem with a fixed vocabulary [6], which can be seen as a sub-task of the broader audio tagging problem [27]. In this work, we focus exclusively on the second approach, since it can directly impact search-by-mood applications, while methods like metric learning can potentially overcome the limitation of the fixed vocabulary [5].

Framed under the context of music recommendation, mood recognition is particularly interesting. It has been shown that listener personality correlates not only with musical taste [29, 41], but also with genre [11], which makes the development of psychologically inspired approaches one of the most compelling challenges for recommender systems [32]. Thus, several related techniques have been presented: FocusMusicRecommender [40] makes use of the listener's behavior history to play tracks that are appropriate given the current listener's level of concentration. By incorporating the Five Factor Model [7], collaborative filtering [21] is enhanced with personality embeddings [10]. Moreover, emotions from a microblogging service have been exploited to implement an emotion-aware recommendation system [9]. Such techniques employ data beyond the actual audio signal to enhance mood-based recommenders, inspiring us to make use of listening data to classify moods to potentially improve the navigation and recommendation of large music catalogs.

The contribution of this work to the task of mood prediction is two-fold: i) we assemble a set of 67k tracks from the Taste Profile subset from the Million Song Dataset (MSD) [2] and match them with human-annotated moods available from AllMusic. [1] This is, to the best of our knowledge, the largest expert-annotated mood dataset available. And ii) by running several experiments on this proposed dataset we show how listener data are much more accurate at classifying moods than current audio-based approaches. Similarly to [17], where its authors discuss how lyrics can be useful to predict moods better than actual audio, and following the music recommendation approaches described above, we further argue that listening embeddings yield superior results due to their ability to capture information that is not straightforward to be extracted from pure audio content only.

The rest of the article is structured as follows: in Section 2 we give a formal definition of the mood classification problem. In Section 3 the data employed in this work are described. We then detail the mood classification experiments in Section 4. The results of these experiments are discussed in Section 5. Finally, we draw conclusions and consider potential future directions in Section 6.

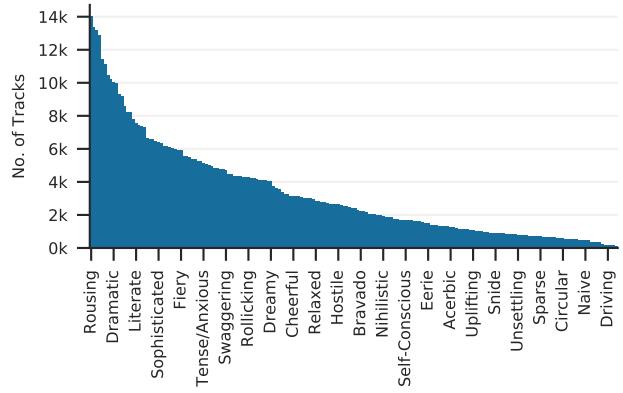
2. MOOD CLASSIFICATION

Predicting moods evoked by music is often treated as an audio classification problem in the MIR community, [2] where audio data are almost exclusively used as input. In this section we give an overview of this task and its current approaches.

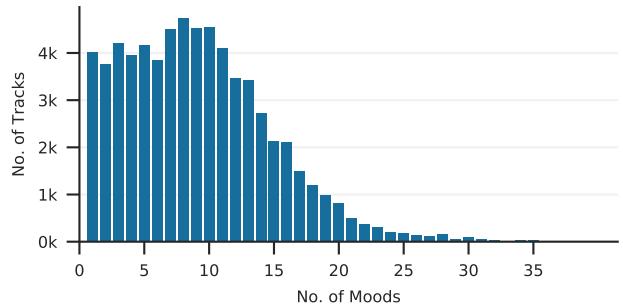
2.1 Problem definition

Mood tagging is a multi-label classification problem, and can be considered a subset of the broader audio tagging task where only those tags that represent moods are considered. Formally, let $\mathbf{x} \in \mathbb{R}^E$ be an embedding representing a given track, where E is the number of dimensions in the embedding. Each track is associated with a set of mood tags from a mood vocabulary $\mathcal{T}$ (e.g., "energetic," "gloomy," "happy"), represented by a binary indicator vector $\mathbf{y} \in \{0,1\}^{|\mathcal{T}|}$. We aim at predicting the set of mood tags associated with the track, using a learnable function f that computes the predicted label vector $\hat{\mathbf{y}} = f(\mathbf{x})$.

Note that $\mathbf{x}$ can be extracted from any source of data representing the track. In our case, we will use audio- and listening-based embeddings.

Other approaches have also framed emotion prediction as a regression problem of an n-dimensional continuous space [37], where the 2D Arousal-Valence model [30] is the most widely used. While this approach has the benefit of considering moods that are not constrained by a specific vocabulary, in this work we focus on the multi-label classification approach due to the direct application to potential user-based scenarios such as search by typing or by voice.


2.2 Current Approaches

The current state of the art largely approaches music mood prediction via audio analysis. Early approaches identified spectral contrast as an informative representation [19], and a number of other authors confirmed this finding as well as a variety of other standard audio features [20, 31, 33, 39]. While the relationship between mood and spectral representations remains non-obvious, previous work has shown that human subjects annotate reconstructions from these representations with reasonable consistency to their original form [35]. Still, the problem remained far from solved.


In moving towards increasing model complexity, most approaches have incorporated deep learning methods that seek to learn their own representations [34]. In addition to prediction, audio-based approaches have also been extended to the problem of segmentation [1]. More recent approaches have expanded to multi-modal representations by combining lyrics [8] and others have focused on interpretability of these complex models [6]. At the time of writing, the authors are not aware of any models which leverage features derived from user interactions to estimate the moods of a music track.

3. DATA

The data we collected for this work are derived from various sources: AllMusic provides mood annotations; The

Figure 1: Number of tracks per annotated mood in the AMS. Due to space limitations, only the names of a subset of mood tags are shown.

Figure 2: Number of moods annotated per tracks in AMS.

Echo Nest Taste Profile [25], mapped to tracks in the Million Song Dataset, adds listening data; finally, 7-digital contributes 30s previews as audio data.

We link AllMusic data to the MSD by fuzzy string matching of artist and track names, and requiring track lengths to be within ± 10s. This results in a dataset of 66 993 matched tracks in total, which we call the AllMusic Mood Subset (AMS). As opposed to other music tagging datasets, such as the LastFM Set [4, 15, 17], AMS provides a large vocabulary of mood tags annotated by music experts. While the AllMusic annotations are proprietary, they can be freely consulted on their website and, moreover, are available to be licensed.

Finally, we randomly split the AMS into 80% training, 10% validation, and 10% test, resulting in 53 585, 6695, 6713 tracks respectively. The splits are available online [3] to ensure comparability of future results.

3.1 Mood Data

The mood information that we employ in this work has been human-annotated by experts from AllMusic. These data were previously employed for mood classification [3, 16] and lyrics sentiment detection [24]. The mood tags are annotated at an album level, and we unfold them such that each track is assigned its album-level moods.

The total number of mood tags available is 188. As previous work noted [16], many tags may describe similar

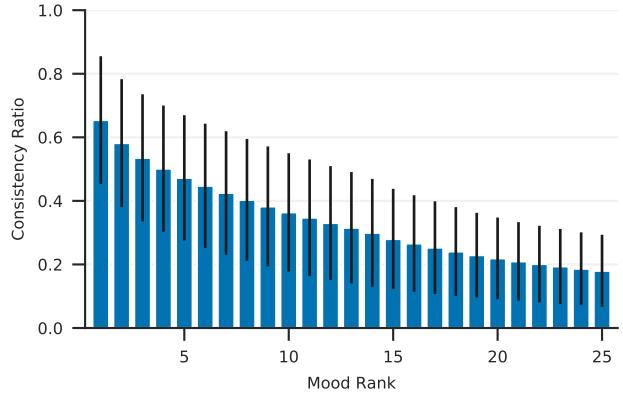
Top	Count	Bottom	Count
Rousing	14 018	Melodic	95
Reflective	13 330	Animated	140
Energetic	13 153	Powerful	148
Earnest	12 873	Driving	163
Passionate	11 438	Introspective	176
Confident	11 092	Flowing	218
Amiable	10 424	Positive	307
Intimate	10 188	Stately	310
Dramatic	10 014	Giddy.	315
Playful	9952	Thoughtful	340

Table 1: 10 top and bottom mood tags based on the number of tracks they have been annotated in the AMS.

Figure 3: Consistency ratios for the top 25 most popular moods for each user in the AMS.

moods (such as "Romantic" and "Sensual"), which tend to co-occur, and can be clustered into a smaller number of groups. While we can confirm this by performing manual and/or data-driven explorations on the co-occurrence matrix, we intentionally kept the original annotations. For one, we expect modern machine learning methods to cope with large and possibly overlapping vocabularies. For another, these tags were curated by expert annotators to specifically describe how music feels; while they might characterize similar concepts, they could also provide a more nuanced view of a song's mood.

To give a better notion of the moods in this dataset, in Figure 1 we depict the histogram of number of tracks per mood tag, which follows a typical long-tail distribution. The 10 top and bottom annotated mood tags can be seen in Table 1. As we can see, "Rousing" is the most frequent mood, which appears in 14 018 tracks. On the other hand, "Melodic" is the least frequent one, associated with only 95 tracks. On average across the dataset, there are 3258.6±2961.3 tracks for each tag, with a median of 2385. Furthermore, Figure 2 shows the distribution of number of mood tags per track. It can be seen that most tracks have 13 moods or less, with an average of 9.1±5.7 tags per track and the median centered at 9.


3.2 Audio Data

Since the AMS is a subset of the MSD, we gather the audio data by obtaining the 7-digital 30 second previews associated with all MSD tracks. These are 128kbps mp3 stereo files sampled at 44.1kHz.

3.3 Listening Data

We make use of the Taste Profile from the MSD to obtain listening data. These data contain over 28 million play counts from undisclosed partners associated with $L = 1\,019\,318$ listeners and $S = 384\,546$ tracks.

We motivate the usage of such data in the context of mood classification by showing the relationship between listening habits and the moods of the tracks played, thus arguing that such embeddings are likely to contain relevant data when predicting moods. By mapping the tracks in this set with the moods from the AMS (and thus reducing the

set of listeners down to 1 012 825, the track set down to 66 993, and the play counts down to ∼9 million) we observe that listeners play music that tends to be consistent in terms of its mood. We define the consistency ratio of a mood as the fraction of times it appears in the listening history of a given user. Figure 3 shows the consistency ratio of the nth most popular moods aggregated across users. More specifically, 65.4% of all plays by a given user contain the most popular mood tag for that user; similarly, around 50.1% of a user's plays are annotated with their 4th most popular mood; etc. This exhibits the potential benefits of using listening data, as we confirm in the results of our experiments described next.

4. EXPERIMENTS

As described in Section 2.1, we treat mood prediction as a multi-label classification problem, with a function f predicting mood tags $\hat{y}$ from an input embedding x. The input embedding can stem from different sources, such as listening- or audio-based features; we will refer to this as the *embedding type*. We will use mostly open models trained on publicly available datasets in this work. As we will see, our conclusions follow from these results alone. Furthermore, we will show results for proprietary models trained on in-house listener feedback data. While we acknowledge that these additional results are hardly reproducible without access to our data and methods, they demonstrate how our findings translate to an industrial scale, and are thus a meaningful addition to this work.

4.1 Evaluation Metrics

Our goal is to compare the predictive performance of each embedding type, *i.e.*, given an input embedding of a certain type, how well the predicted moods $\hat{y}$ resemble the true moods y associated with a track. To quantify this, we will use macro-averaged *average precision* as the main evaluation metric, as is commonly used in multi-label classification. Average precision summarizes the precision-recall curve in a single number, and is defined as

$$AP = \sum_n (R_n - R_{n-1}) \cdot P_n, \qquad (1)$$

where R_n and P_n are the recall and precision at the nth threshold at which the recall changes. Note that we use *macro averaging*—we first compute AP for each mood tag, and then average them to calculate the final result.

In our mood prediction setup, there are two main questions we need to consider: how do we arrive at the input embedding $\mathbf{x}$, and how we model and train f. Let us first explore the various embedding types, before we take a detailed look at f.

4.2 Audio-Based Models

Current mood prediction systems typically use audio-based features as input. In this work, we use several audio models, pre-trained on different datasets with varying sizes. This ensures that our results are not specific to a type of model.

4.2.1 Musicnn

We employ Musicnn [28]—a spectrogram-based convolutional neural network (CNN) for audio tagging—as the main pre-trained audio-based baseline. It is openly available[4] and achieves state-of-the-art results. We compare two variants of this model: a smaller one, trained on ~19k tracks from the MagnaTagATune dataset [22], which we will refer to as *MCN-MTT-A*; and a larger one, trained on ~200k tracks from the Million Song dataset, which we will name *MCN-MSD-A*. Both variants come pre-trained to predict 50 tags, a subset of which can be associated with moods. We refer to Musicnn's documentation for further details on its training scheme.

Musicnn is trained to predict tags for 3-second snippets of audio; however, our setup requires a single *embedding per track*. Thus, instead of the final output, we extract the activation of the penultimate layer of the model as embedding. We first compute embeddings of consecutive non-overlapping audio snippets of 3 seconds, and then average all snippet embeddings to form the track-level embedding. This results in a 200-dimensional vector for MCN-MTT-A, and a 500-dimensional vector for MCN-MSD-A. Such global averaging operations are common for music tagging [27].

4.2.2 Short-Chunk CNN

We train a short-chunk CNN [26] from scratch on the 54k training tracks in the AMS. This simple but powerful model feeds a Mel-spectrogram through a 7-layer CNN with 3×3 filters, 2×2 max-pooling layers, and a fully connected layer before the output. For a detailed look into the training regime and architecture, we refer to the original paper.

Since this model was trained directly for mood prediction on the AMS, there is no need for transfer learning as described in Section 4.4. This is a double-edged sword: although the model is focused on the task at hand, it has to learn a large vocabulary of tags from the limited data provided by our dataset. We will refer to this model as *SCC-A*

---

[4] https://github.com/jordipons/musicnn

4.3 Listening-Based Models

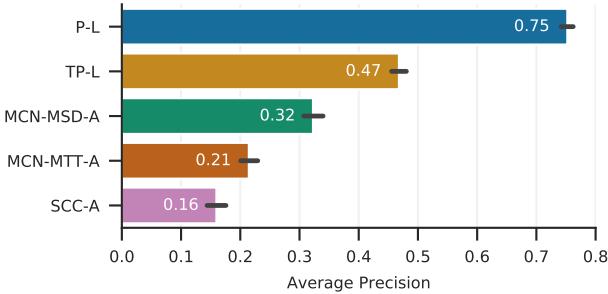
In contrast to audio-based models, listening-based ones consider user-song interaction as source data. This *listening data* comes in the form of a sparse feedback matrix $Y \in \mathbb{N}^{L \times S}$, where $y_{l,s}$ is a cell in Y representing the number of times the listener l has either played or rated the song s. The former is called *implicit* feedback, while the latter is referred to as *explicit* feedback. Factorizing Y using factorization rank E (corresponding to the desired embedding dimensionality) yields dense track embeddings $\mathbf{x} \in \mathbb{R}^E$: the input to our mood prediction model.

4.3.1 Taste-Profile Factorization

We use listening data from the complete Taste Profile of 28M play counts to obtain song embeddings by applying weighted matrix factorization using alternating least squares [18] with a rank of $E = 200$ (chosen empirically). These data contain relevant information about the track defined exclusively with implicit feedback: how many times which listeners have listened to which songs. We will call these embeddings *TP-L*.

4.3.2 Proprietary Factorization

Large music streaming services possess much larger and more detailed listening data than openly available resources. To see how the results on open datasets translate to industrial settings, we derive 200-dimensional embeddings from more than 100B in-house explicit user ratings over the whole music catalog, by applying a weighted matrix factorization algorithm. These embeddings will be referred to as *P-L*.

4.4 Transfer Learning


Having computed track-level embeddings $\mathbf{x}$ from various sources, we need to map them to mood tags using a learnable function f. This is a transfer-learning scenario: the input embeddings are obtained from a model trained to solve a different (but related) task, such as collaborative filtering or general audio tagging, and then applied for mood prediction by learning f.

We model f as a multi-layer perceptron (MLP) with a binary indicator vector as output, such that $\hat{\mathbf{y}} = f(\mathbf{x})$, where $\hat{\mathbf{y}} \in [0,1]^{|\mathcal{T}|}$. Thresholding $\hat{\mathbf{y}}$ gives us the set of predicted moods. We train f for each embedding type by minimizing the binary cross-entropy between predicted vectors $\hat{\mathbf{y}}$ and target vectors $\mathbf{y}$ obtained from the true mood tags.

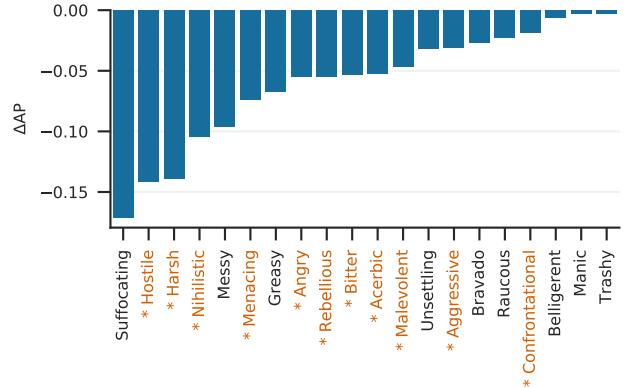
The performance of MLPs heavily depends on the choice of hyper-parameters. To enable a fair comparison, we optimized hyper-parameters for each embedding type individually using Bayesian optimization [36], monitoring average precision on the validation set. To limit the computational cost, we only used TP-L and MCN-MSD-A as input embeddings, since they are the main points of comparison. Each setup enjoyed the same, fixed computational budget of 2 days on a single Tesla M40 GPU, which translates to around 200 trials per setup. Table 2 shows details on the search space and the best found configurations. We

	Domain	TP-L	MCN-MSD-A
Nº layers	[2..4]	4	4
Nº units	[1500..4000]	3909	3933
learning rate	[0.0001, 0.005]	4×10^{-4}	5×10^{-4}
dropout [38]	[0, 0.5]	0.25	0.25
weight decay	[0, 0.0001]	0	1×10^{-6}

Table 2: Hyper-parameters optimized with Bayesian optimization, and best found configurations for each embedding type. Search ranges were defined based on limited initial experiments. For dropout and weight decay, we quantized the interval by 0.125 and 1×10^{-6}, respectively.

Figure 4: Overall results for each model.

see that for both embedding types, the best models reach the upper limit of our search space, which indicates that even larger models might lead to better results. However, we saw diminishing improvements for large models, so we do not expect much further improvement.

We initialize the MLP weights using Kaiming's method [14], and use a rectifier activation function [13] after each layer (the output layer uses a sigmoid). The input is standardized using mean and standard deviation estimated on the training set. We then train f for 100 epochs using a cosine-annealed learning rate [23] (without restarts) and a 1-epoch warm-up phase. During training, we monitor average precision on the validation set to select the best performing model parameters.


The code to reproduce these experiments is available online. [5]

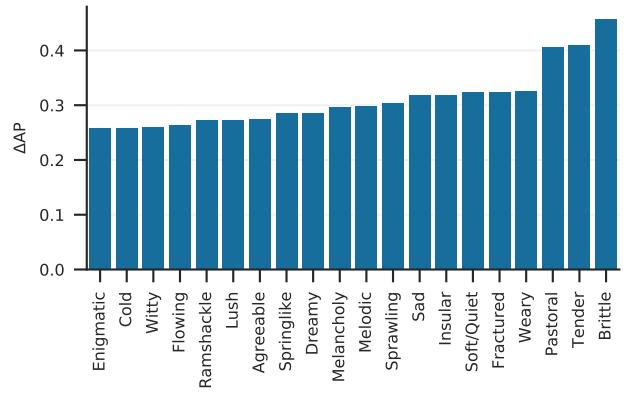
5. RESULTS


Figure 4 shows the overall results of each embedding type. As mentioned before, our main analysis will be based on the results of open models on publicly available data. We will discuss the results of P-L later.

We see that listening-based embeddings easily outperform audio-based ones (TP-L vs. MCN-MSD-A). We also see a variation within audio-based models. Our experiments were not designed to explain this variation, and the usual suspects offer insufficient clues: for example, dataset size might be an issue (200k for MCN-MSD-A vs. 19k for MCN-MTT-A), but SCC-A was trained on the 54k training tracks from AMS with worse results—here, dataset size relative to vocabulary size might have been the issue. Further experiments, out of scope of this paper, are necessary to understand this in depth.

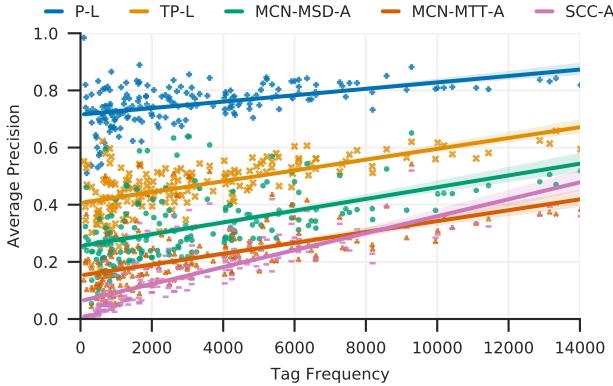
(a) Tags favoring audio-based models.

(b) Tags favoring listening-based models.

Figure 5: Difference of average precision between the best audio-based model (MCN-MSD-A), and the best listening-based model on open data (TP-L). Negative ΔAP means the audio-based embedding performed better. The highlighted tags in (a) belong to the same mood cluster.


5.1 Tag-Wise Results

Even though the overall results are clear, some tags might be easier to predict from audio than from listening data. To explore this, we subtract the tag-wise average precision of TP-L and MCN-MSD-A, and show the results in Figure 5. Indeed, we find 20 tags for which MCN-MSD-A out-performs TP-L. Moreover, these tags seem to describe related moods. To verify this, we clustered the 188 moods using affinity propagation [12], resulting in 13 clusters. We see that 11 out of the 20 mood tags belong to the same cluster, as highlighted in Figure 5a. In contrast, the tags in Figure 5b come from a wider variety of clusters (not highlighted). This indicates that it is a single, coherent "mood subspace" on which audio data is better suited.

5.2 Results by Tag Frequency

As shown earlier, mood tags in the AMS are unevenly distributed: the least popular tag counts only 95 annotations, while the most popular track 14k. It is reasonable to assume that uncommon tags are more difficult to predict than common ones. To evaluate this, we plot the average precision per tag depending on the tag frequency in Figure 6.

Although we see a direct relation between tag frequency and average precision, the extent is less than we expected.

Figure 6: Results per tag frequency. Dots represent the average precision obtained by a tag, that occurs at a frequency shown on the x axis. Lines represent linear regression models, with shades indicating 95% confidence intervals.

Figure 7: Correlation between tag-wise results of different embeddings. We see that audio-based ones correlate strongly with each other, compared to weaker correlations between listening-based ones.

Furthermore, all embedding types seem to be equally affected: with the exception of SCC-A, the regression slopes of both audio- and listening-based models are notably similar. The exception of SCC-A indicates that tag sparsity may be an issue when training audio models from scratch, but not so when transfer-learning a model that has been trained on more balanced data.

5.3 Results of Proprietary Algorithms

So far, we have discussed the results of open methods on publicly available datasets. However, the attentive reader has noticed that Figure 4 and 6 demonstrate how P-L performs even better than TP-L. To explain the gap between TP-L and P-L, we can point to the different nature and amount of data they were trained on—28M implicit plays for the former, but more than 100B explicit ratings for the latter. The sheer amount of data (a factor of ∼3500) and the stronger signal provided by explicit feedback seem to be remarkably beneficial.

5.4 Consistency of Audio-Based Models

We have shown that listening-based models clearly outperform audio-based models in mood prediction. To demonstrate this, we selected a wide variety of audio models that differed in multiple aspects: network architecture, training datasets, and training regime (pre-trained and trained from scratch). Given these differences, we can ask if there are aspects of mood that current audio models are not capable to capture, but listening-based models can. We try to answer this question by exploring which embeddings capture similar mood information. If an embedding captures similar aspects of mood as another embedding, their tag-wise performance should be correlated—but not necessarily similar in magnitude, as one embedding might just perform better than the other.

We show the correlation in tag-wise performance in Figure 7. The remarkable result is that regardless of their differences, the tag-wise results of all audio-based models are much more correlated than between audio- and

listening-based embeddings. This indicates that audio-based models do capture similar aspects, even if they might not capture it equally well (as the difference between MCN-MSD-A and SCC-A shows). This does not mean that the aspects current audio-based models are missing are not present in the audio at all—just that current models are not able to extract them.

We do not observe a similar pattern for listening-based embeddings: TP-L and P-L show weaker correlation. At this time, we cannot provide a better explanation than referring to the different nature of explicit and implicit feedback data and the sizes of the two datasets.

6. CONCLUSIONS

In this work we have associated 66 993 tracks from the Million Song Dataset with the AllMusic set to yield the AMS, the largest dataset available with the following data modalities: high quality human mood annotations, audio content, and listening data. Furthermore, we have shown how listening data surpass audio-based embeddings when classifying moods in the proposed dataset. The notable differences in performance between listening- and audio-based models suggest that either i) current state-of-the-art audio models are not capable of successfully extracting certain mood information about a given track; and/or ii) such mood information is not necessarily present in the audio content, and thus the usage of other signals such as listening information may be required to obtain more accurate results. With these findings, we encourage researchers to employ data beyond audio content when estimating the mood of a track. In the future, we look to further scrutinize the tags to better understand which moods might be more suitable to be extracted by which type of input representation. Moreover, and along these lines, we would like to address this task in a multi-modal manner, combining different sources to potentially improve performance of this compelling and timely problem.

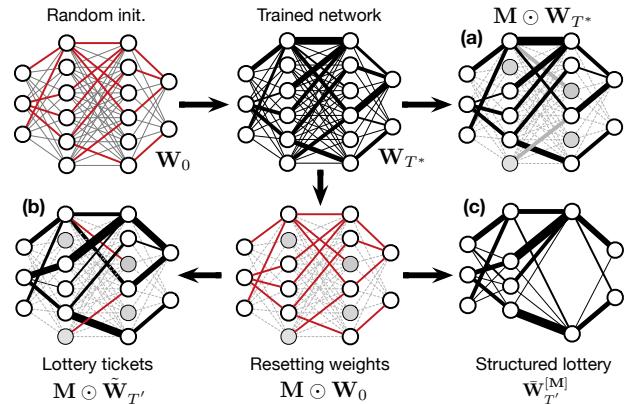
`esling@ircam.fr`

ABSTRACT

Current state-of-the-art results in Music Information Retrieval are largely dominated by deep learning approaches. These provide unprecedented accuracy across all tasks. However, the consistently overlooked downside of these models is their stunningly massive complexity, which seems concomitantly crucial to their success.


In this paper, we address this issue by proposing a model pruning method based on the *lottery ticket* hypothesis. We modify the original approach to allow for explicitly removing parameters, through *structured trimming* of entire units, instead of simply masking individual weights. This leads to models which are effectively lighter in terms of size, memory and number of operations.

We show that our proposal can remove up to 90% of the model parameters without loss of accuracy, leading to ultra-light deep MIR models. We confirm the surprising result that, at smaller compression ratios (removing up to 85% of a network), lighter models consistently outperform their heavier counterparts. We exhibit these results on a large array of MIR tasks including *audio classification*, *pitch recognition*, *chord extraction*, *drum transcription* and *onset estimation*. The resulting ultra-light deep learning models for MIR can run on CPU, and can even fit on embedded devices with minimal degradation of accuracy. [1]

1. INTRODUCTION

Over the past decades, Music Information Retrieval (MIR) has witnessed a growing interest, with a wide variety of tasks such as *genre classification*, *chord extraction* and *music recommendation* [1] being increasingly implemented in end-user products. Recently, MIR has predominantly improved with machine learning, and almost all state-of-art accuracies are obtained by deep learning models [2]. Although these approaches provide unprecedented results, the major issue in modern deep learning lies in the tremendous complexity and immense size of the models employed. Indeed, deep networks for images can reach up

---

[1] Supplementary results and code to reproduce experiments are available at https://github.com/acids-ircam/lottery_mir

Figure 1. Comparing (a) traditional pruning with (b) the lottery ticket hypothesis, and (c) our structured lottery approach to obtain ultra-light deep networks.

to billions of parameters and new leaps in accuracy seem to only come by worsening this situation. As a showering example of this complexity [3], the inference on a single image in the pervasive ResNet model [4] requires 7.7 GFLOPS [2] . This exploding size leads to profound issues in both the use and understanding of these models. As they are extremely demanding in computation and memory, it precludes their implementation in end-user embedded systems which prevails in audio applications, and also raises some serious environmental issues. Finally, such complexity decreases the potential interpretability of these models.

The idea of eliminating unnecessary weights (*pruning*) was proposed early for neural networks [5]. Most methods are based on masking the smallest-amplitude weights from a large network, as depicted in Figure 1. Other approaches such as *quantization* [6] or *knowledge distillation* [7] have been proposed to decrease the size and energy consumption of trained models with equivalent accuracy. However, keeping the original accuracy of complex large models seems only possible at low compression rates [8]. Furthermore, recent benchmark studies [9] pointed out that most of the proposed methods seems to achieve a similar efficiency in both accuracy and model size.

Recently, the *lottery ticket hypothesis* [10] suggested that randomly-initialized neural networks already contain powerful subnetworks (called *winning tickets*) that could reach the same or higher accuracy than the original networks if they were trained in isolation. Hence, by finding these subnetworks, we could drastically prune most of the

---

[2] FLOPS: floating point operations

weights in large networks and still obtain the same level of accuracy. This implies that the same task could be solved in a very lightweight, memory and energy-efficient way. Furthermore, these subnetworks could be easier to analyze, which could simplify further works towards explainability [11]. Several studies have analyzed different properties of this hypothesis [12–14], as it raises the exciting prospect to obtain much smaller networks that provide a similar accuracy compared to the typically larger state-of-art models. However, this method has two major flaws. First, it has a large training cost, as finding winning tickets seems to only be stable when the training is repeated multiple times over iteratively smaller networks [15]. Second, pruning is done by *masking* the weights, which means that the resulting networks retain the size and computation cost of the original ones, even if most of the weights are unused.

In this paper, we extend the lottery approach to effectively remove weights, obtaining models with a lower size and inference time, while still maintaining a commensurate accuracy. To do so, we introduce a method based on the lottery ticket hypothesis, and we replace the masking operation with a structured pruning operation (termed *trimming* here). The original network capacity is reduced by removing entire computation units (or convolutional channels). This alleviates issues of the original lottery ticket method as, although we still need to repeat the training, it becomes faster at each iteration. We discuss different criteria for selecting the units and their differences to the original lottery ticket hypothesis. Notably, unstructured masking allows to work on local connectivity patterns, whereas trimming can only impact this aspect if we perform *global* selection (ranking units across the network). We show that this approach can be successfully applied across MIR tasks, leading to *ultra-light* deep MIR models. We evaluate the efficiency of replacing the masking operation by our trimming criterion and show that we still obtain commensurate accuracy when removing up to 90% of the model parameters. We also maintain the surprising result [10] that lighter models (removing up to 85% of the network) obtain higher accuracy, while we effectively reduce the model size. We evaluate these results on a large array of MIR tasks including *instrument* [16] and *singing voice classification* [17], *pitch recognition* [18], *automatic chord extraction* [19], *drum transcription* [20] and *onset estimation* [21].

2. STATE-OF-ART

2.1 Model compression and pruning

Various approaches have been proposed for reducing the size of neural network models, while trying to maintain accuracy [5]. These approaches can be globally divided between *pruning* or *compressing* networks. We group in the *compression* category the *distillation* [7] (training a smaller model to fit the internal representations of a larger one) and *quantization* [6] (reducing the size of networks by using lower-resolution weights or binary numbers) approaches. Here, we focus on *pruning*, but note that compression and quantization can be further applied on pruned models.

The goal of *pruning* [5] is to identify and remove weights of a network that are not critical to its accuracy. The original approach to pruning starts by fitting a large and overparametrized network to completion. Then, we aim to mask the less relevant weights in this trained model based on a given selection method. This criterion tries to analyze the usefulness of different parameters, commonly based on their magnitude [22]. Finally, the resulting masked network is *fine-tuned*, trying to restore the accuracy of the original network [9]. Hence, the critical aspect in this approach lies in the method of weight selection. This criterion can perform either a *structured* or *unstructured* and *local* or *global* selection. *Unstructured* pruning acts on individual parameters separately, *structured* pruning aims to effectively remove parts of the networks. Hence, unstructured methods are mostly based on *masking* the weights based on their magnitude [5, 22]. Oppositely, structured pruning aims to remove entire *hidden units* or *convolutional channels* from a network [8, 23].

However, recent studies showed that most pruning methods are mostly equivalent [8]. These approaches usually lead to smaller accuracy than the large network and at low pruning rates, with performance degrading with the amount of weights removed [9], although some are able to maintain (but not outperform) the original accuracy [8].

2.2 Lottery ticket hypothesis

The recently proposed *lottery ticket hypothesis* [10] states that inside a randomly-initialized network, there already exist some considerably smaller subnetworks which would be extremely efficient if trained in isolation. Hence, parts of the weights drawn by random initialization before training already provide a specific topology and parameter configuration that make training particularly effective. The major difference between this approach and the previous magnitude-based selection from which it is inspired [22] is that the selected weights are *reset* to their initialization value before retraining the smaller architecture. Doing so, very small subnetworks (less than 1% of the original network size) could be found across several architectures, even outperforming the larger networks at smaller pruning ratios. For deeper architectures, they further showed [12] that winning tickets should be *rewound* to a given iteration, rather than to initialization values. Interestingly, this seems to confirm that overparameterization is needed to find an optimal solution, but that a lighter solution exists, which is optimized in the compression phase of the training [13,24].

2.2.1 Formalization

We consider a network as a parametric function $f(\boldsymbol{x}; \boldsymbol{W})$, with a set of weights $\boldsymbol{W} \in \mathbb{R}^D$ that are first initialized through sampling $\boldsymbol{W}_0 \sim p(\boldsymbol{W})$. The weights are updated by using a training *algorithm* $\mathcal{A}(i, \boldsymbol{W}_0)$ which maps initial weights $\boldsymbol{W}_0$ to weights $\boldsymbol{W}_i$ at iteration $i \in \{1, .., T\}$, by performing successive updates similar to

$$\boldsymbol{W}_{i+1} = \boldsymbol{W}_i - \eta \nabla_{\boldsymbol{W}} \mathcal{L} \tag{1}$$

with a given loss function $\mathcal{L}$ and learning rate η.

A *subnetwork* of the original network $f(\boldsymbol{x}; \boldsymbol{W})$ can be defined as a tuple $(\boldsymbol{W}, \boldsymbol{M})$ of the original weights $\boldsymbol{W} \in \mathbb{R}^D$ and a mask $\mathbf{M} : \{0, 1\}^D$. Hence, the subnetwork computes the function $f(\boldsymbol{x}; \boldsymbol{M} \odot \boldsymbol{W})$, where $\odot$ denotes the element-wise product.

Lottery Ticket Hypothesis. Given a randomly initialized network $f(\boldsymbol{x}; \boldsymbol{W}_0)$ with $\boldsymbol{W}_0 \sim p(\boldsymbol{W})$, that is trained to reach accuracy a^* in T^* iterations, with final weights $\boldsymbol{W}_{T^*}$, there exists a subnetwork $(\boldsymbol{W}_k, \boldsymbol{M})$ with a given mask $\boldsymbol{M} \in \{0, 1\}^{|\boldsymbol{W}|}$ and iteration $k \ll T^*$, such that if we retrain this subnetwork, it will reach a *commensurate accuracy* $a \geq a^*$ in *commensurate iterations* $T \leq T^* - k$ and *fewer parameters* $\|\boldsymbol{M}\|_0 \ll |\boldsymbol{W}|$.

These highly efficient subnetworks (called *winning tickets*) depend on the original initialization, and can only be identified after full training [12]. Thus, the selected weights and remaining topology form the architecture of the winning ticket. These weights are *reset* to their initialization values *before* the network was trained or *rewound* at an early iteration. The resulting architecture is then retrained until completion, and the whole process is repeated, as described in Algorithm 1.

Algorithm 1 Lottery ticket training with rewinding

1: $\boldsymbol{W}_0 \sim p(\boldsymbol{W})$ ▷ Random initialization
2: $\boldsymbol{M} = \mathbf{1}_{|\boldsymbol{W}|}$ ▷ Initial mask
3: $\boldsymbol{W}_k = \mathcal{A}(k, \boldsymbol{W}_0 \odot \boldsymbol{M})$ ▷ Training for k iterations
4: **while** $\mathcal{C}(\boldsymbol{M}, a, \boldsymbol{W})$ **do**   ▷ Stopping criterion $\mathcal{C}$
5:    $\boldsymbol{W}_T = \mathcal{A}(T, \boldsymbol{W}_k \odot \boldsymbol{M})$ ▷ Train until completion
6:    $r = \mathcal{R}(\{\boldsymbol{W}_{T^*}\})$ ▷ Ranking criterion $\mathcal{R}$
7:    $\boldsymbol{M} = \mathcal{M}(r, \{\boldsymbol{W}_{T^*}\})$ ▷ Masking update $\mathcal{M}$

In their original paper [10], the authors underline the difference between *one-shot* pruning (masking is applied all at once) and *iterative pruning* (repeatedly pruning small parts of the network). They demonstrated that iterative pruning finds smaller architectures that reach higher accuracy than the original network and converge at earlier iterations. They showed on the MNIST dataset, that it was possible to keep the accuracy of large networks, even when masking up to 96.5% of the weights. Their most intriguing result is that smaller networks consistently reach *higher accuracy* than the original ones, even while removing up to 80% of the weights. In a follow-up study [12], they showed that these results could be obtained for deeper architectures, but only through the *rewinding* operation. Another exciting prospect of this hypothesis, is that the resulting subnetworks might encode implicit *inductive biases* for a given task or type of data. In that case, winning tickets could be *transferred* and trained on new tasks, even directly from their extremely lightweight versions [14].

2.3 Music Information Retrieval

Music Information Retrieval (MIR) encompasses all tasks aimed at extracting high-level knowledge from music data. This field has witnessed a flourishing interest, with multiple tasks being increasingly tackled such as *chord extraction*, *drum transcription* and *musical audio classifica-*

tion [1]. Originally, most MIR researches revolved around the idea of extracting a set of hand-crafted features from the signal (such as the Mel-Frequency Cepstral Coefficients), in order to use these as input to machine learning algorithms [25]. Feature-based techniques have been challenged by the advent of deep learning approaches [26], which have shown impressive capacities to learn high-level features on complex data. They simultaneously set new state-of-art results across a wide range of MIR tasks, while opening the path towards unprecedented applications [27].

In this work, we consider a rather broad spectrum of MIR tasks where deep learning approaches are applied. Specifically, we address (i) *audio classification* [17] (finding the class label of audio signals inside a predefined set), (ii) *pitch recognition* [18] (extracting the fundamental frequency of a monophonic audio recording), (iii) *chord extraction* [19] (annotating audio with a given vocabulary of chords), (iv) *onset estimation* [21] (finding events in an audio stream) and (v) *drum transcription* [20] (transforming drums audio signal into a score). We redirect interested readers to [28] for a comprehensive review.

One of the common denominator in deep learning methods applied across all MIR tasks is that their unprecedented accuracy comes at the expense of an increasing size and complexity. Indeed, deep networks for images now reach billions of parameters and leaps in accuracy seem to only come by worsening this situation. An example of this trend in MIR can be seen in the recently proposed CREPE model [18] for pitch extraction. This task was largely handled through the YIN algorithm [29], an extremely simple algorithm, with few parameters and running with very low latency on CPU. For a modest gain in accuracy on the same task, CREPE requires *22 million parameters*, 2.82 GFLOPS and 2.36 seconds on CPU to compute the pitch of a single 4-seconds sample. This exploding size leads to profound issues in both the use and understanding of these models. First, they are extremely demanding in energy consumption and memory, which precludes their implementation in end-user interfaces and also raises serious environmental issues. Furthermore, this complexity stands in the way of any potential interpretability of such models.

3. METHODOLOGY

Here, we first discuss different selection criteria for structured network *trimming*. Then, we discuss different normalization strategies that can allow to perform global selection of units across layers.

3.1 Trimming criteria

In order to perform structured pruning, we need to evaluate the efficiency of *entire units* of computation, rather than individual weights. In the case of convolutional networks, this would amount to analyze the *channels* of each layer. Indeed, channel pruning appears more hardware friendly, and also allows to truly reduce the size of the final model. In the following definitions, we consider that any computation layer can be seen as a weighted transform $f(\boldsymbol{x}, \boldsymbol{W}^{(l)})$,

with a matrix $\boldsymbol{W}^{(l)} \in \mathbb{R}^{n_{out} \times n_{in}}$. Note that we intentionally simplify the notation for more complex layers (*convolutional* or *recurrent*), which embed more complicated matrices. However, we consider in the following that the selection criteria $\mathcal{C}(\boldsymbol{W}^{(l)})$ is computed across the n_{in} dimensions, and that it should produce a vector of n_{out} dimensions. This vector is used to rank the usefulness of different computation units. Hence, after each training iteration, we replace the masking criterion by directly removing parts of the weight matrix for each layer

$$\boldsymbol{W}^{(l)} = \boldsymbol{W}^{(l)}_{[C(\boldsymbol{W}^{(l)}),C(\boldsymbol{W}^{(l-1)})]}. \tag{2}$$

Note that we need to carry the pruning criterion from the preceding layer $C(\boldsymbol{W}^{(l-1)})$ in order to reflect potential changes in the structure of the network. All layers in the network that must maintain a given output dimensionality (such as the last layer) are defined as *unprunable*. Following a similar approach than the lottery ticket hypothesis, the remaining weights in the resulting matrix $\boldsymbol{W}^l$ are *rewound* to their values from an earlier iteration [13].

Magnitude. We define a *magnitude-based* criterion, similar to the original lottery [10]. However, we evaluate the overall magnitude of the weights for a complete unit as

$$\mathcal{C}_{mag}(\boldsymbol{W}^{(l)}_i) = \sum_{j=1}^{N_{in}} \left| W^{(l)}_{i,j} \right|. \tag{3}$$

Activation. We can rely on the activation statistics of each unit to analyze their importance. Hence, akin to the previous criterion, we perform a cumulative forward pass through the network after training the model and compute

$$\mathcal{C}_{act}(\boldsymbol{W}^{(l)}_i) = \sum_{k=1}^{\mathcal{D}_v} \left| f(\boldsymbol{x}_k, \boldsymbol{W}^{(l)})_i \right| \tag{4}$$

where we sum across examples of the validation set $\mathcal{D}_v$.

Normalization. An interesting direction proposed in [15] is to consider the *scaling* factor γ in batch normalization layers to evaluate the significance of each layer output. In this criteria, we rely on this *scaling* coefficient as a proxy to the importance of each unit

$$\mathcal{C}_{norm}(\boldsymbol{W}^{(l)}_i) = \left| \gamma^{(l)}_i \right|. \tag{5}$$

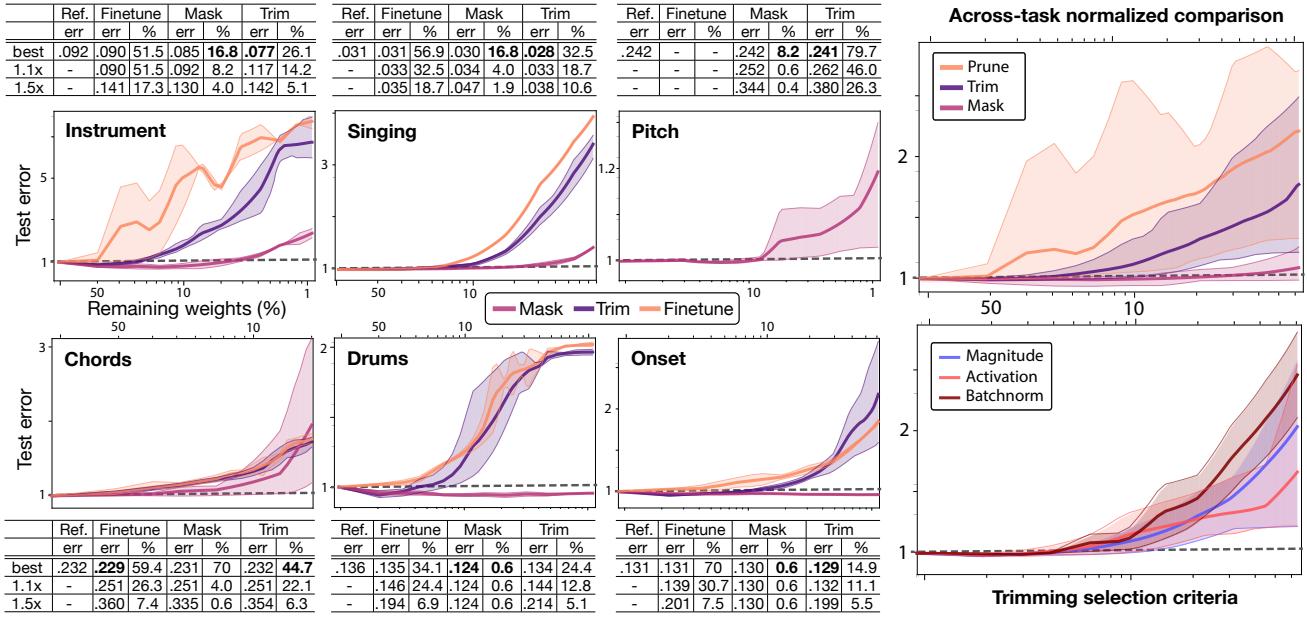
Note that this criterion forces each layer to be followed by a normalization layer, from which it can be computed.

4. EXPERIMENTS

We briefly detail the tasks on which we evaluate our method for ultra-light deep MIR. As we address a wide variety of models and datasets, we only provide essential explanations for each. However, unless stated, we follow all implementation details presented in the original papers.

4.1 Tasks

4.1.1 Audio (instrument and voice) classification

Audio classification is one of the seminal and most studied task in MIR [30]. We separate the evaluation into two in-dependent sub-tasks of *singing voice* and *instrument* classification. For both tasks, the model is adapted from the baseline proposed in [17]. The raw input waveform is processed with a stack of 4 dilated 1-dimensional convolutions with batch normalization, ReLU and dropout, followed by 4 fully-connected layers that map to a *softmax*, which outputs a vector of class probabilities. The ground-truth label prediction is optimized with a *cross-entropy* loss. Singing voice classification is performed on mono audio inputs of 3 seconds at 44,100Hz for 10 vocal techniques and a given train/test split ratio [17]. For instrument classification, we rely on the 13 orchestral instruments from URMP [31] and the corresponding recordings from MedleyDB [32]. After silence removal, the combined datasets amount to a total of about 8h30 of isolated instrument recordings. Classification is done on audio inputs of 1.5 seconds at 22,050Hz extracted from the isolated tracks with a single label corresponding to the instrument played.


4.1.2 Pitch estimation

The goal of *pitch estimation* is to extract the fundamental frequency of an input audio. For this task, the recently proposed CREPE model [18] requires several large datasets, some of which are not publicly available. However, we only rely here on the open source *NSynth* dataset, which contains single note samples from a range of acoustic and electronic instruments [33]. This leads to 1006 instruments, with different pitches at various velocities available as raw waveforms. All samples last 4 seconds with a sampling-rate of 16kHz. As this incurs an extremely large training time, we use a subsampled dataset, randomly picking 10060 samples (ten notes per instrument). Finally, we trim all samples to their first two seconds to remove silent note tails, ensuring that most inputs to the model are voiced. CREPE is a 6-layer CNN operating directly on waveforms, followed by a single fully connected layer. The model is trained via binary cross-entropy to perform classification over a 360 bin logarithmic frequency scale spanning six octaves from pitch $C1$ to $B7$. The model operates on frames of 1024 samples, which we individually label with the note pitch. We use the *medium* architecture from the CREPE repository [18].

4.1.3 Chord extraction

Automatic chord extraction is defined as labeling segments of an audio signal using an alphabet of musical chords. We perform our experiments based on the model and datasets detailed in [19]. We use the *Beatles* dataset, which contains 180 songs annotated by hand. We rely on a CQT input with hop size 2048, mapped to a scale of 2 bins per semi-tone over 5 octaves starting from $C1$ and containing a total of 105 bins. As input we take 15 successive frames, corresponding to a temporal horizon of approximately 0.7 seconds. We augment the available data by performing all transpositions from -6 to +6 semi-tones. As baseline model, we rely on the CNN architecture described in [19], and evaluate the global accuracy measure.

4.1.4 Drum transcription

The *drum transcription* task aims at labelling an input audio with onsets of different drum sounds. We rely on an architecture inspired from [21]. The network takes mel-spectrogram inputs processed by 4 layers of 256 padded 2D convolutions of kernel size 5, with unit stride, followed by batch normalization and ReLU. We apply max-pooling at each layer along the frequency dimension. The resulting vector is processed by two linear layers with batch normalization and dropout. Finally, a specific output network of 3 linear layers for each drum sound produces onset probabilities, trained on binary vectors for each drum activation.

To train the network, we use the approach proposed by [34], using a subset of 5000 MIDI drum tracks that we map to random drum sounds to generate waveform recordings. We further rely on the SMT-Drums dataset [35], which provides 104 supplementary polyphonic drum set recordings. For both datasets, we compute a mel-spectrogram of 64 bins, ranging from 20 to 11025 Hz, based on a FFT of window size 2048 and hop size 512.

4.1.5 Onset estimation

Onset estimation [21] aims to detect events in a given audio input. In order to evaluate this task, we rely on the same network presented in the previous section for drum transcription. However, for this task, the last part of the network maps to a single detection subnetwork. We rely on the same drums dataset, but merge all labels to detect event onsets, rather than specific elements of the drumkit.

4.2 Training

All models are trained following their respective procedure and hyperparameters. However, we use a common mini-batch size of 64, the ADAM optimizer with a weight decay penalty of $2e^{-4}$, and an initial learning rate of $1e^{-3}$, which is halved every 10 non-decreasing epochs. We train the models for a number of epochs that is fixed for each task (following the original papers) and keep the model with the best validation score. For the lottery training, we perform *masking* or *trimming* of 30% of the weights at each pruning iteration. We rewind the weights to their values at half of the training epochs. We repeat this process 15 times, leading to models with up to 99.5% of weights removed. This whole lottery training is repeated 5 times, providing the variance and impact of the initialization on the results.

5. RESULTS

5.1 Global evaluation

First, we provide a global evaluation across different tasks, by plotting the respective evolution of the test error as we iteratively remove weights either by classical *fine-tuning*, using the original lottery with *masking*, or our proposed *trimming*. We report for each task the *best* model (lowest test error), *smallest* model (test error at most 1.5 times the original one), and *optimal* model (error at most 1.1 times the original). Results are displayed in Figure 2.

As we can see, classical *fine-tuning* is mostly unable to find more efficient lighter networks and only works at very low pruning rates. Oppositely, our *trimming* approach is able to consistently find networks that are both much smaller and more accurate than reference models. In this regard, the best performances are obtained for *onset detection*, where we find a network with only **14.9%** of the original weights (removing **85.1%** of the weights), while having an error rate of **0.129** (compared to 0.131 for the original). These results hold for almost all tasks: most networks where we trim up to **75%** of the weights pro-

duce lower errors, and we can remove up to **85**% of the weights with minor damage to the test error. Interestingly, the results of *chord extraction* seems to produce the smallest enhancement. This could be explained by the fact that the model has the lowest original number of parameters. Hence, this underlines the crucial need to rely on *largely overparametrized* models to find efficient subnetworks. Regarding the *smallest* models, we are able to remove on average up to 95%, while having a reasonable test error. When comparing our approach to the original lottery *masking*, it seems that masking consistently produces better performances at higher pruning rates, confirming the original results [10] for MIR tasks. However, note that the weights in the masking approach are not removed (however, a fraction of these weights could be removed in a post-processing step). We hypothesize that this resilience to larger pruning ratios stems from the fact that *masking* is able to work on local connectivity patterns, whereas our approach cannot.

5.2 Across-task comparison

5.2.1 Pruning approaches

The lottery ticket hypothesis crucially depends on initialization values for training efficient subnetworks. To evaluate this property across different tasks, we perform the normalized comparison shown in Figure 2 (right, up).

Here, we normalize the error of each task by dividing it by the error of the reference large model, so that its test error is 1. As we can see, using fine-tuning, the approach is unable to obtain subnetworks with higher accuracy, and the error quickly degrades as we remove more weights. Furthermore, it appears that the results are rather unstable, producing large variations in the final test error. Instead, by *rewinding* the weights and *trimming* we consistently obtain smaller subnetworks (up to 75% of the weights removed) that outperform the original models. We are able to apply extensive trimming before the error starts to degrade, globally around 90% across tasks. Hence, it appears that efficient subnetworks can be found solely through the correct combination of connection topology and weights.

5.2.2 Selection criteria

The success of pruning methods depends on the criterion selecting *which* weights should be kept or pruned. Hence, we perform a normalized comparison of different criteria for *trimming*, and display results in Figure 2 (right, down).

Although the global trend seems to be equivalent for most criteria at low pruning ratios, their differences amplify as we remove an increasing amount of weights. Overall, it seems that the *activation* criterion provides the most stable results. Furthermore, it allows to maintain lower error rates, even at higher pruning ratios. However, at lower pruning ratios, it seems that the *magnitude* criterion produces slightly better and more stable results. Finally, the *batchnorm* criterion seems to provide an interesting alternative at low pruning ratios. However, its performance degrades faster than other criteria at very high pruning rates.

Table 1. Comparison between reference models and our trimmed models on *test error*, *number of parameters*, *disk size*, *inference FLOPS* and *memory used* across tasks.

5.3 Resulting model properties

We provide a detailed analysis of the gains provided by our *trimming lottery* for each task. We compare the reference model to the *optimal* one (smallest model within 1.1 times the original test error) found by trimming. We evaluate their *test error*, *number of parameters*, *disk size*, *FLOPS* (required to infer from a single input example) and *memory used* for different MIR tasks, as detailed in Table 1. As discussed previously, we are able to obtain models maintaining the error rates, while having only a small portion of the capacity of the very large models. This can be witnessed in the final properties of the trimmed models. A very interesting observation is that this decrease in parameters amounts to an even larger decrease in the *memory* and *computation power* required. Indeed, while most trimmed models are 10 times smaller than original large models, they use 20 to 50 times less computation power and memory requirements. This can be explained by the fact that most operations are processed across the dimensions of the previous layer. Hence, even small gains in number of parameters can lead to dramatic gains in computation.

6. CONCLUSION

In this paper, we presented a method to obtain ultra-light deep models for MIR, by extending the lottery ticket hypothesis to effectively trim the networks. We have shown that these efficient trimmed subnetworks, removing up to 85% of the weights in deep models, could be found across several MIR tasks. We have also shown that extremely small networks could be found by relying on *masking*, but these do not provide actual enhancement in terms of computation or memory requirements. Oppositely, we have shown that given the non-linear relationship between the number of parameters and computation required, we could find extremely light networks through trimming. These results encourage the crucial implementation of MIR models in embedded audio platforms, which would allow broader end-user applications. The major downside of this approach is its training time, which we partly address by decreasing the cost of each pruning iteration. However, the intriguing prospect of *ticket transfer* [14] could provide such initializations right *at the onset* of training.

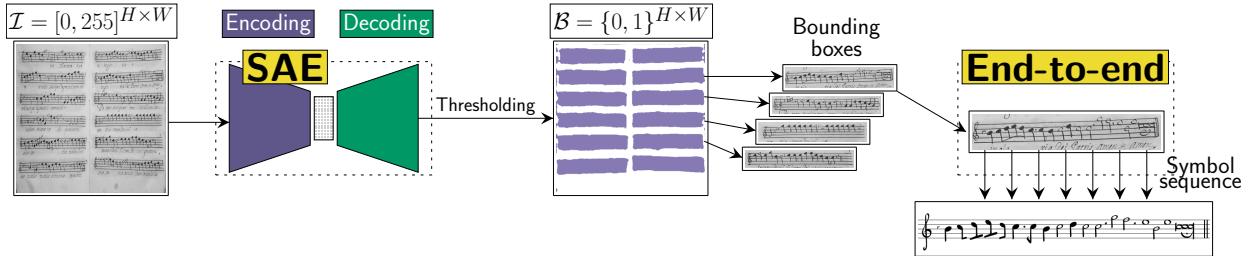
ABSTRACT

The digitization of the content within musical manuscripts allows the possibility of preserving, disseminating, and exploiting that cultural heritage. The automation of this process has been object of study for a long time in the field of Optical Music Recognition (OMR), with a wide variety of proposed solutions. Currently, there is a tendency to use machine learning strategies based on neural networks because of their high performance and flexibility to adapt to different scenarios by changing only the training data. However, most of the recent literature addresses only specific parts of the traditional OMR workflow such as music object detection or symbol classification. In this paper, we progress one step further by proposing a full-page OMR system for Mensural notation scores that consists of simply two processes, which are enough to extract the symbolic music information from a full page. More precisely, our pipeline uses Selectional Auto-Encoders to extract single staff regions, combined with end-to-end staff-level recognition based on Convolutional Recurrent Neural Networks for retrieving the music notation. The results confirm the adequacy of our method, reporting a successful behavior on two Mensural collections (CAPITAN and SEILS datasets) with a straightforward implementation.

1. INTRODUCTION

The digitization of the content within documents [1] is a process that helps to preserve cultural heritage and enables easier dissemination and knowledge creation. Traditionally, this content digitization is done manually, with an undeniably high cost that is very prone to introduce mistakes as well. In the music context, the development of Optical Music Recognition (OMR) systems promises to perform this task automatically with minimum human involvement. Research efforts have promoted the progress in this field achieving excellent, yet partial results [2–4]; therefore, full digitization of music documents is still to be studied in practical contexts.

Recent advances in machine learning enable new approaches in the OMR field [5]. The use of deep neural networks provides novel ways of avoiding complex multi-step workflows that are considered in legacy OMR research [6]. A successful example of this new trend is the so-called end-to-end approach, that operates at the staff level; in other words, a single step that completely processes the image of a single staff and retrieves the series of symbols that appear therein [7].

While end-to-end strategies can be used to read a sequence of symbols at the staff level, it is still necessary to previously detect all the staves contained in the documents as region blocks, for then transcribing the music content. This staff detection task has been addressed in recent literature [8, 9]. However, these works only assess staff detection as a computer vision problem—i.e., how accurate is, in geometric terms, the region extracted, without considering how useful it is for the subsequent steps. These partial results are not sufficient to determine with certainty the goodness of the approaches within a complete OMR pipeline.


In this work, we carry out a study to determine how the recent advances in OMR interact with each other. Also, we eventually offer, for the first time, results that validate that only two steps—the staff-region detection combined with an end-to-end method—are sufficient to develop a complete page-level OMR system with excellent recognition rates through neural networks.

As we will explain later, this approach is successful if the graphical complexity of the scores follows certain criteria: single-staff systems with a single voice in each. That is why our experiments are restricted to Mensural manuscripts, of great historical interest, where these requirements are common.

2. BACKGROUND

Although the term OMR covers a wide range of scenarios—different research might be carried out according to the notational type or the engraving mechanism of the manuscripts—there has been a general pipeline that addresses the challenge through a series of independent stages that work on different parts of the problem [5].

Traditionally, individual challenges were very complex, so procedures were developed to work on specific manuscripts [10–13]. However, the systems ended up be-

Figure 1: Scheme of the considered methodology.

ing very specific, so previous efforts were hardly reused. In other words, there was little scientific progress in the field.

Recently, the early stages of the process have been reformulated as object detection tasks [14], thus bypassing some of the stages of the traditional workflow. Pacha et al. [15] provided a baseline for direct music-object detection in music score images, experimenting with several models and corpora of different typology.

At the same time, there have been approaches for end-to-end OMR. Such models perform the complete recognition of musical notation from an image, directly providing the sequence of music symbols present therein as output. In addition to high performance, this prevents the need for the training set to be annotated at the symbol-level position and post-process strategies that convert the individually detected elements to the actual music notation. Concerning this formulation, Pugin [16] pioneered the end-to-end approach for printed Mensural notation using Hidden Markov Models (HMM) with the Aruspix system. However, although HMMs represent models that fit perfectly well with the task at issue, other tasks of a similar nature, like handwritten text recognition, experienced a leap in performance using deep neural networks [17]. It has been demonstrated that neural approaches outperform those based on HMM for end-to-end OMR as well [7].

To date, however, there is no existing end-to-end approach that works at the full-page level, but only at the single-staff level. It is not only a challenge to be solved in the field of OMR but also in text recognition—a task that we could consider even simpler. In text recognition, the end-to-end approaches face the recognition process at the line level [18]. For this, there exist line extraction algorithms [19], which enable working at the page level in combination with the line-level end-to-end neural networks. In the case of music, a similar idea is to use staff extraction algorithms combined with the end-to-end staff-level recognition.

Recently, several methods have been proposed to solve the staff detection task [8, 9, 20]. The problem with these works is that they only studied the extraction of staves as a computer vision challenge. Similarly, the end-to-end staff-level neural networks for OMR only experimented with staves detected manually. Therefore, it is not known how well the combination of staff retrieval with staff-level end-to-end neural networks performs in real scenarios.

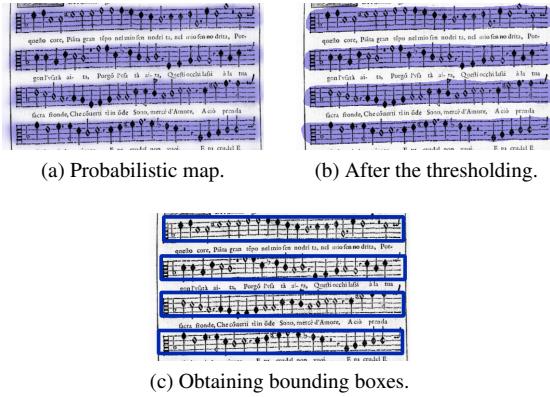
For all the above, this paper fills a gap in the existing literature and presents, for the first time, a neural full-page

OMR system that takes advantage of recent advances in deep learning to solve the task in just two steps: staff retrieval and end-to-end staff-level recognition. As we will see later, this allows us to provide a general approach that works successfully in different manuscripts by simply providing training data.

3. METHODOLOGY

The proposed methodology outlines an approach by which to evaluate a full page-level OMR system using only two procedures: staff retrieval and end-to-end staff-level recognition. Both of them are solved in a single step each by using deep neural networks. A graphical overview of the complete methodology is shown in Figure 1.

One of the main advantages of our methodology is that it is completely based on machine learning: it is enough to provide annotated examples (of each task) to build new and accurate models—which is usually easier and cheaper than developing a pipeline anew.

Although this approach might not work for arbitrary types of music scores—e.g., recognizing each staff separately does not make that sense for scores that include multi-staff systems—we believe it is worth studying and providing simple, generalizable, and effective solutions in those cases where the structural complexity of the scores makes it possible. Furthermore, our approach is not necessarily restricted to the case of monophony but can be applied in the case where only one voice appears on each staff. In our case study, whose details are available in Section 5, we will apply our methodology to vocal polyphony scores in Mensural notation—where different voices appear independently.


3.1 Staff retrieval

The first step in the considered methodology needs to detect and extract the individual staves. With the premise that all individual staves are compact blocks within the image, we can apply a layout analysis to estimate the probability of each pixel to belong to one of the staves. Previous work [21] presented a Selectional Auto-Encoder (SAE)-based framework focused on performing layout analysis by patches to split the image into different information layers: staff lines, symbols, lyrics and background. Here, we adapt that method to directly detect staff regions. Since the staff blocks are extensive and compact, a patch-wise model may introduce additional errors in their detection. For avoiding

that, we propose to adjust the original image to the input size requirements of the model, being this new resolution enough to discern the different staves.

Let $\mathcal{I} = [0, 255]^{H \times W}$ be a grayscale image [1] with height H and width W in terms of pixels. The SAE model processes $\mathcal{I}$ to return another image $\mathcal{S} = [0, 1]^{H \times W}$ such that $\mathcal{S}_{i,j} \equiv P(\mathcal{I}_{i,j} = \text{'staff'})$—i.e., $\mathcal{S}$ stands for an image with the same size of $\mathcal{I}$, and whose values represent the probability of each pixel of belonging to any staff region. Note that the SAE model is trained through supervised learning mechanisms, hence a set of documents annotated with the location of each staff is required.

After obtaining $\mathcal{S}$, a threshold $\tau \in [0, 1]$ is applied to obtain a binary map $\mathcal{B} = \{0, 1\}^{H \times W}$. Then, the staff regions can be retrieved by performing a connected-component analysis over the map $\mathcal{B}$. Afterwards, we compute the rectangular coordinates of each component for retrieving the bounding boxes. An example of this process can be found in Figure 2.

(a) Probabilistic map.　　(b) After the thresholding.

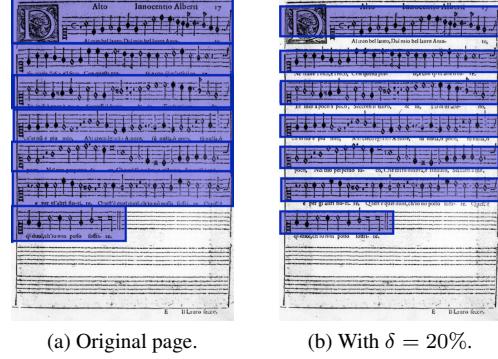
(c) Obtaining bounding boxes.


Figure 2: Example of staff-region prediction, with the probabilistic map obtained by the SAE model, the result of applying a threshold to determinate the areas most likely being staves, and finally the bounding box retrieval.

A drawback to this approach is that it requires that the different staves do not overlap with each other, as shown in Figure 3, as that would prevent distinguishing them once $\mathcal{B}$ has been computed. To reduce this possibility, we propose to apply a vertical reduction factor δ, with which the bounding boxes in the ground truth will be trimmed vertically, largely avoiding the overlapping in the annotated documents. Note that, since clipping is necessary to make the subsequent prediction easier, the bounding boxes obtained by the SAE model should be expanded by the same factor after being retrieved. In this way, ideally, the detected bounding boxes will cover the staves completely.

3.2 End-to-end staff-level recognition

Once individual staves are extracted, the symbol recognition at this level can be performed by an end-to-end methodology based on deep neural networks. Within the many options for this, we consider the approach initially

---

[1] This is with no loss of generality, as the approach can be easily extended to deal with color images as well.

(a) Original page.　　(b) With $\delta = 20\%$.

Figure 3: Example of ground truth with overlapping that can be solved by means of applying a reduction factor ($\delta = 20\%$, i.e. 20% top and bottom trims).

proposed by Shi et al. [17], given that it outperformed competing methods for OMR [7].

Given an image $\mathbf{x}$, corresponding to a single-staff region, we want to retrieve the most probable sequence from a fixed alphabet Σ of music symbols. $\mathbf{x}$ can be interpreted as a sequence of frames (single image columns), so the aforementioned problem can be solved by using a recurrent neural network [22]. These networks can provide a probability per frame $P(\sigma \mid x_i), 1 \leq i \leq |\mathbf{x}|, \sigma \in \Sigma \cup \{\epsilon\}$, where ϵ is a special token required to separate consecutive predictions of the same symbol [23].

This stochastic representation of $\mathbf{x}$ can be decoded into an actual sequence of music symbols by first retrieving the most probable sequence of symbols per frame

$$\sigma_i = \arg \max_{\sigma \in \Sigma \cup \{\epsilon\}} P(\sigma \mid \mathbf{x}_i)$$

and then following a greedy approach which merges consecutive frames with the same symbol and removes the frames whose predicted symbol is ϵ [7].

In our case, we add a convolutional neural network on top of the recurrent neural network to automatically learn features that are appropriate for the specific music manuscript at issue [24].

The joint Convolutional Recurrent Neural Network (CRNN) can be trained in an end-to-end fashion by using the so-called Connectionist Temporal Classification (CTC) loss function [23]. Given a ground-truth sample consisting of a single-staff region $\mathbf{x}$ and its corresponding sequence of music symbols σ, CTC is used to modify the network's weights to maximize the probability of retrieving σ from $\mathbf{x}$ without the need of providing a framewise localization of the symbols.

4. EXPERIMENTAL SETUP

4.1 Parameterization of the Neural Networks

In this section, we present the setup of the neural models for both staff retrieval and staff-level symbol recognition. For the first one, we considered the use of SAE due to its high performance and efficiency in the document analysis

Input	Encoding	Decoding	Output
$[0, 255]^{512 \times 512}$	Conv2D$(128, 5 \times 5, $'ReLU'$)$ MaxPool(2×2)	Conv2D$(128, 5 \times 5, $'ReLU'$)$ UpSamp(2×2)	$[0, 1]^{512 \times 512}$
	Conv2D$(128, 5 \times 5, $'ReLU'$)$ MaxPool(2×2)	Conv2D$(128, 5 \times 5, $'ReLU'$)$ UpSamp(2×2)	
	Conv2D$(128, 5 \times 5, $'ReLU'$)$ MaxPool(2×2)	Conv2D$(128, 5 \times 5, $'ReLU'$)$ UpSamp(2×2)	
		Conv2D$(1, 5 \times 5, $'sigmoid'$)$	

Table 1: Detailed description of the selected SAE architecture, implemented as a Fully-Convolutional Network (FCN). 'ReLU' and 'sigmoid' denote the Rectifier Linear Unit and Sigmoid activations, respectively.

task [21]. As of the second process, the symbolic music sequence is obtained by means of a CRNN.

The following notation will be used for the specifications given below: Conv2D$(n, h \times w, $'act'$)$ indicates a two-dimensional convolution operator of n filters and kernel size of $h \times w$ with 'act' denoting the actual activation function; MaxPool$(h \times w)$ represents a down-sampling max-pooling operation with a $h \times w$ window; UpSamp$(h \times w)$ denotes an up-sampling operator of h rows and w columns; BLSTM(n) stands for a bidirectional Long Short-Term Memory unit of n neurons; Dropout(p) represents a dropout operation with a ratio of p neurons; Dense$(n, $'act'$)$ indicates a dense layer of n neurons with 'act' denoting the actual activation function.

4.1.1 Selectional Auto-Encoder

The SAE configuration used in this work is set according to previous works for layout analysis, whose details are given in Table 1. In the staff analysis, the model does not need to predict small details since staves are extensive and compact within the document. For this, we can rescale the original image to the size of the input model, being of enough resolution to differentiate the staves of the ground truth. After some informal testing, we configured the input as an image of 512×512 px. The image rescaling was performed through the OpenCV library.

In addition, as discussed in Section 3.1, a vertical reduction factor δ and a threshold τ to determine the pixels belonging to a staff are necessary. We set $\delta = 20\%$, so the ground-truth staves are top and bottom trimmed by that factor, and $\tau = 0.5$ to indicate that a probability higher or equal to 50% is assumed to represent a pixel from a staff. In our preliminary experiment experiments, δ played an important role for avoiding overlapping, whereas the model was quite robust against different values of τ.

4.1.2 Convolutional Recurrent Neural Network

The CRNN follows the best architecture from the work by Calvo-Zaragoza et al. [7]. It consists of four convolutional layers and max-pooling down-sampling, connected with a recurrent block of two Bidirectional Long Short-Term Memory (LSTM) layers. The specifications of the model are given in Table 2.

Input: $[0, 255]^{64 \times \mathcal{W}}$
Conv2D$(64, 5 \times 5, $'ReLU'$)$, MaxPool$(2 \times 2)$
Conv2D$(64, 5 \times 5, $'ReLU'$)$, MaxPool$(2 \times 2)$
Conv2D$(128, 3 \times 3, $'ReLU'$)$, MaxPool$(2 \times 1)$
Conv2D$(128, 3 \times 3, $'ReLU'$)$, MaxPool$(2 \times 1)$
BLSTM(256), Dropout(0.5)
BLSTM(256), Dropout(0.5)
Dense$(|\Sigma \cup \{\epsilon\}|, $'softmax'$)$

Table 2: Architecture of the CRNN considered for staff-level recognition. 'softmax' indicates the Softmax activation, that normalized the output to a probability over the set of symbols (plus the 'blank' symbol denoted by ϵ). Given that the images are of variable width, this dimension of the input is not specified (indicated as $\mathcal{W}$).

4.2 Corpora

To evaluate our method, we consider the following corpora of Mensural manuscripts:

- The CAPITAN dataset, which encodes a complete *Missa* composed during the second half of the 17th century. Annotations are specifically provided for OMR [25].

- The Symbolically Encoded Il Laurro Secco (SEILS) dataset, which consists of scores from the 16th-century anthology of Italian madrigals *Il Lauro Secco*. Among many formats, the dataset includes the required format to perform OMR [26].

	CAPITAN	SEILS
Engraving	Handwritten	Printed
Pages	97	150
Staves	737	1 278
Running symbols	17 112	31 589
Symbol categories	53	33

Table 3: Corpora statistics.

Page samples from these corpora can be seen in Figure 4. As observed, CAPITAN is handwritten and SEILS is printed. This heterogeneity benefits the verification that the proposed methodology is generalizable to a variety of manuscript types. In addition, some descriptive statistics about the corpora are provided in Table 3.

(a) CAPITAN

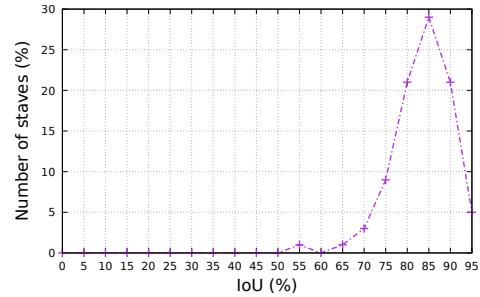
(b) SEILS

Figure 4: An example page image from of each dataset considered in the experimentation.

4.3 Evaluation protocol

As of the experimentation, the results have been computed using a 5-fold cross-validation technique (5-CV), each of which takes three data partitions—training, validation and testing—with 60%, 20% and 20% of the whole set of documents, respectively. The training process was performed during 100 epochs, monitoring with the validation partition and reporting the results on the test partition. The experiments have been performed using the Keras v.2.3.1 [27] library with TensorFlow v.1.14 as backend.

In the literature, the experiments are commonly evaluated partially, focusing only on individual processes, regardless of the impact they may have on the transcription into a digital format, which is precisely the ultimate purpose of the OMR field. The main goal of this paper is to evaluate a full-page OMR system combining a staff-retrieval method based on SAE and an end-to-end staff-level recognition. Therefore, we will be able to analyze the effect of staff retrieval in the symbol recognition step.

Nevertheless, experiments have been divided into two parts: an assessment of the staff bounding-box recognition, in which we will present the computation of the average of Intersection over Union (IoU), which provides a measure of the overlapping between the set of retrieved staves and the ground-truth ones (the higher, the better). With regard to the second step of the proposal, the objective is to check the recognition of the sequence of symbols within each staff obtained in the first step. In practical OMR systems, a critical factor to be considered is the number of corrections the user has to perform. Hence, we decided to report the final results in terms of Symbol Error Rate (SER), which is computed as the ratio of editing operations needed to correct the transcription of the symbol sequence (the lower, the better).


5. RESULTS

Concerning the staff retrieval itself, this step detected all of the 737 staves that CAPITAN contains (considering all the test partitions within the 5-CV) but also retrieved an additional box that did not correspond to a staff. Similarly, the model for SEILS retrieved correctly all the $1\,278$ staves, while 152 regions were detected where there were none. Therefore, whereas all real staves are retrieved, the process also yields some *false positives*, that are supposed to be easily removed in an interactive environment. As a reference in geometric terms, the model for CAPITAN obtained 86.3% of IoU, while SEILS achieved 79.7%. This indicates that the retrieved boxes generally fit well the ground-truth location of the staves. We will see below that this is accurate enough for the task of retrieving the inner symbol sequences.

To complement these numerical results, Figure 5 contains an example of a comparison between a ground-truth staff with the predicted one. Note that, although the IoU obtained in that example is 80.5%, the retrieved staff properly covers the music information. As evidenced in Figure 6, most of the predicted bounding boxes have an IoU between 70% and 95%.

Figure 5: Example of a retrieved staff from SEILS, colored in yellow, compared with the ground-truth box, colored in blue. For this example, the IoU reaches 80.5%.

Figure 6: Average histogram of staves predicted by the SAE model and ordered by IoU (with a granularity of 5%).

We now proceed to present the results of the symbol recognition step. To fully evaluate the two-step proposed method, we should first take into account two main points: first, the staff retrieval SAE can only be trained with ground-truth data, since it constitutes the earlier step in the approach; and second, the end-to-end model would be ideally trained with the bounding boxes predicted in the last step—closer to the real scenario—but it is also possible to directly use the ground-truth staves. While in all cases the sequence of music symbols to be predicted is the same, we can compare the results with different configurations of the input images provided for training the CRNN: ground-truth staff regions (GT); staff regions predicted by the SAE, once trained (Pred.); both ground-truth staff re-

gions and staff regions predicted by the SAE, once trained (GT+Pred.).

Likewise, for the test partition, a real case only contemplates evaluating with the automatically detected staves (real scenario); however, we have also evaluated on ground-truth staves to provide a reference of the loss caused by the automatic staff retrieval.

We report in Table 4 the results of the end-to-end staff-level recognition of symbols, which has been tested with both CAPITAN and SEILS datasets, and each one in turn evaluated with the cases mentioned above.

Data		CAPITAN	SEILS
Training staves	Test staves		
Real scenario			
GT	Pred.	16.8 ± 3.7	5.2 ± 1.4
Pred.	Pred.	14.8 ± 3.6	4.4 ± 0.5
GT+Pred.	Pred.	$\mathbf{11.5 \pm 2.2}$	$\mathbf{3.7 \pm 0.8}$
Reference			
GT	GT	13.2 ± 1.1	4.4 ± 1.2
GT+Pred.	GT	$\mathbf{10.8 \pm 1.1}$	$\mathbf{3.6 \pm 0.9}$

Table 4: Average $\pm$ std. deviation results in terms of SER (%) of a 5-CV experiment for the staff-level end-to-end recognition with different combinations of training and test data during the staff retrieval stage. GT stands for ground-truth staves, while Pred. represents the predicted ones.

First, we focus on the results obtained in the real scenario, i.e. those in which the test staves have been provided by the staff-retrieval step. It can be observed that training with GT achieves successful outcomes, being the SER metric 16.8% and 5.2% for CAPITAN and SEILS, respectively. Results are improved if the training data contains predicted staves instead of GT, with figures that reach 14.8% for CAPITAN and 4.4% for SEILS. The reason behind this phenomenon may come from what is seen in Figure 5: the staff is correctly detected but the box is actually different from the ground-truth one. Therefore, if this difference is also introduced during training, the model is better prepared for what occurs in the real case. Despite this, the experiments reveal that the robustness of the end-to-end model is optimized if a combination of GT and Pred. is performed in the training process, allowing to reduce the symbol error rate until 11.5% and 3.7% for CAPITAN and SEILS datasets, respectively. This combination in the training data seems similar to the typical machine learning strategy called data augmentation [28, 29], given that the Pred. boxes depict variations with respect to the GT ones.

If we analyze the reference results, i.e., those obtained by the end-to-end step tested with GT boxes, we observe that the end-to-end model outperforms the real case, as both training and test data are part of the annotated bounding boxes by the user. Similarly, the data augmentation strategy allows to even improve the results. When comparing to the real scenario, the reference case reports slightly better results, with negligible differences (from 11.5% to 10.8% for CAPITAN and from 3.7% to 3.6% for SEILS, at best).

What is important about the figures above is that they demonstrate that introducing an automatic staff detection step barely affects the overall performance of the system—according to the best values obtained with predictions compared to the best values obtained with ground-truth boxes. Therefore, we can validate our methodology as suitable to deal with the complete recognition of Mensural manuscripts or even any type of musical document that depicts a comparable structure.

Finally, although this is not of special relevance within the scope of this paper, we see that the machine learning models find it easier to deal with printed manuscripts, as the error figures from SEILS are clearly below those from the CAPITAN one. Probably, the regularity of the printed symbols makes the task easier than in the handwritten case.

6. CONCLUSIONS

OMR is an interesting field of study, but most of its research focus on individual steps that avoid evaluating the impact within the full system. In this paper, a full-page OMR system with neural networks has been presented. It is based on the combination of staff-retrieval and symbol sequence recognition steps.

The first step—staff retrieval—has been implemented as a SAE model based on a successful architecture used in previous work for layout analysis. This neural network predicts staff regions as compact blocks, processing the whole image in only one step, and then bounding boxes of predicted staves are extracted. The second step—end-to-end staff-level recognition—transcribes the content of the predicted staves into a digital format, which is the main goal of OMR.

The paper includes a study of the impact of the first step in the final performance in the digitization for two Mensural manuscripts. The methodology has been assessed in terms of SER, which determines the number of corrections that a user should make to have the correct sequence transcribed. The results reveal that ground-truth staves are not the best option for training the end-to-end model in a real case, in which the transcription will be performed from predicted staves. The assessment of the model trained with predicted staves shows performances as good as in the ideal case, in which the training and the test datasets consist of ground truth regions. This means that the precision in staff retrieval is not the most important issue in the symbol recognition task. Furthermore, we observed that training the end-to-end symbol recognizer with a combination of predicted and ground-truth staves provides the best results for both, real and ideal situations, with non-significant differences between them. Therefore, between a fully automatic OMR system and other where the bounding boxes are annotated by the user, the performance hardly varies. We can then conclude that our approach allows transcribing reliably the music content with minimum human effort.

In future works, we plan to keep on researching simple and generalizable strategies for more complex manuscripts, such as those corresponding to polyphonic scores in Western modern notation.

ABSTRACT

The human response to music combines low-level expectations that are driven by the perceptual characteristics of audio with high-level expectations from the context and the listener's expertise. This paper discusses surprisal based music representation learning with a hierarchical predictive neural network. In order to inspect the cognitive validity of the network's predictions along their time-scales, we use the network's prediction error to segment electroencephalograms (EEG) based on the audio signal. For this, we investigate the unsupervised segmentation of audio and EEG into events using the NMED-T dataset on passive natural music listening. The conducted exploratory analysis of EEG at locations connected to peaks in prediction error in the network allowed to visualize auditory evoked potentials connected to local and global musical structures. This indicates the potential of unsupervised predictive learning with deep neural networks as means to retrieve musical structure from audio and as a basis to uncover the corresponding cognitive processes in the human brain.

1. INTRODUCTION

Studying the human perception of music has received increased interest in Music Information Retrieval (MIR). As humans solve tasks such as beat tracking, genre identification or musical prediction with ease, many MIR methods rely on computational models inspired by human perception. At the same time, studying the brain's response to auditory stimuli is still limited by the lack of resources that map complex musical stimuli to neural processes. Studies in cognitive neuroscience and brain computer interfacing (BCI) on auditory evoked brain states require labor intensive manual preparation and often focus on isolating particular brain responses using sparse stimuli presented individually [1, 2]. While datasets on brain states evoked by natural music exist, they often lack fine-grained annotations of the event structure and corresponding neural activity [3–5].

This entails a demand for efficient and unsupervised mapping techniques between natural music and evoked brain states. Furthermore, there is a need for biologically plausible and multi-modal models for such mapping, as induced brain states are a mixture of stimulus-derived and subjective, cognitive or contextual factors.

We address these challenges with predictive coding, one of the most dominant theoretical frameworks of human perception [6, 7]. Predictive coding offers a comprehensive description of how humans parse and predict sounds and map auditory stimuli to musically meaningful and hierarchically organized units [8]. In predictive coding, the neural response to music is shaped by hierarchically organized expectations [7]. This hierarchy of expectations connects predictions about low-level auditory features to more global context, such as the listener's musical expertise or levels of entrainment during listening [8]. The underlying dependencies between expectancy and uncertainty in predictive coding are particularly interesting in the context of music perception, as music perception can be described as continuously resolving uncertainty and forming new expectations [9–11]. This is in line with evidence on the predictive nature of human music perception, especially within studies on unexpected stimulus deviations and the influence of the listener's expectancy on attention and perceptual precision [9, 11].

Predictive coding offers an efficient algorithmic motif that allows unsupervised learning. Learning in predictive coding systems can be seen as a hierarchy of predictive modules that form predictions over various temporal scales. These predictions can either be about future states in the stimulus domain or about the future of internal states of the systems and are often cast in the context of Bayesian (i.e. probabilistic) inference [12]. In this hierarchical generative model of perception, long-term expectations from temporally stable aspects of music, such as genre or tempo form top-down predictions about the activity of layers closer to the actual auditory information [8]. By propagating the deviations between predictions and observations, the generative model and with that the model of the processed stimulus is updated [7].

Here, we connect predictive coding as a algorithmic motif for unsupervised stimulus representation with deep neural networks and recurrent variational inference in order to segment natural music into units that are musically meaningful. Following the assumption that hierarchical

predictive coding of music explains a substantial amount of evoked brain states, we analyse the retrieved musical structure in terms of the induced neural activity in electroencephalographic signal (EEG). Using the Naturalistic Music EEG Dataset—Tempo (NMED-T) of passive listening to natural music we the demonstrate that the approach allows to locate and visualize event related potentials (ERPs) on local and global scale [3].

2. RELATED WORK

Within the field of MIR, the capacity of predictive coding algorithms to compress and represent auditory information on the sensory level has been exploited for various tasks such as speech re-synthesis or audio compression since many years [13, 14]. The human brain, however, augments such low-level sensory representations with a hierarchy of more abstract, semantic predictions from other brain areas [7]. This aspect of hierarchical predictive learning has found traction in the domain of deep neural networks (DNNs), but so far has been applied mostly to images and video processing [15, 16]. Furthermore, most popular implementations of deep predictive coding often only rely on non-linear transformation of the sensory error and not yet abstract away from pure sensory prediction. Autoregressive modeling of audio has seen tremendous progress in recent years, with a plethora of models performing tasks such as sample level audio prediction or speech synthesis, often with impressive results [17–19]. However, such autoregressive models are computationally expensive and sample-level models still tend to struggle with incorporating more abstract and long-term musical features.

2.1 Auditory evoked potentials and musical structure

Recent years have shown a variety of approaches to studying the human brain's response to auditory stimuli, especially with functional magnetic resonance imaging (fMRI) and electroencephalography (EEG). EEG is especially adequate in the context of music due to its higher temporal resolution. A multitude of auditory features, such as loudness, frequency, tempo and rhythm have been traced in EEG recordings of brain activity during music perception [20–23]. Next to these stimulus-derived aspects, recorded brain activity has further been analysed with respect to more contextual aspects of music perception, such as the listener's attention, which is modulated by aspects such as expertise or engagement [24]. Two extensively researched aspects of the neural response underlying perception potentials are event-related potentials (ERPs) and steady-state evoked potentials (SSEPs) [25, 26]. ERPs and SSEPs differ mainly in their temporal scope: While ERPs are aligned to a single loation (typically the onset of a particular event), SSEPs show frequency alignment to stimulus periodicity over longer time frames [27]. For ERPs, the brain response aligned to the event type of interest is analysed after averaging large amounts of trials [28]. Auditory event-related potentials (AEPs) are modulated by aspects such as rhythm, pitch, timbre or the duration of musical

events, all of which play an important role in human audio segmentation [25, 29–33]. Many of these evoked potentials have been explained in the context of predictive coding as a mixture of bottom-up and top-down mechanisms that are modulated both contextual expectations and the auditory stimulus itself [34, 35]. Similar to ERPs, SSEPs are inspected after averaging over many trials, but don't require zero valued phase offset between stimulus and response. Instead, SSEPs characterize periodic mappings between auditory features and brain response, such as phase locking to perceived frequencies or loudness envelopes. Both ERPs and SSEPs can be related to predictive cognitive processes aiming at structuring the incoming sensory signal into meaningful events in a hierarchical fashion [35, 36].

3. A HIERARCHICAL PREDICTIVE CODING MODEL FOR MUSIC

Predictive coding describes hierarchical predictions of sensory states and hidden states of the network across various time-scales. Sample based predictions about audio requires a model with high temporal resolution that captures the causal dependencies between adjacent samples. Thus, a desired predictive coding model for audio connects low-dimensional predictions over many time-steps with fine-grained predictions at the sensory level. Transforming audio features to high-level representations is a complex task, which is often solved with the non-linear processing found in DNNs. We approach these requirements with a recurrent DNN that generates autoregressive predictions based on long short-term memory (LSTM) [37]. Instead of predicting individual frames, we process mel spectrogram representations of audio. The reduced temporal resolution of spectrograms helps reducing the computational complexity while still capturing fine-grained auditory information. As spectrograms extend into time and frequency, we employ convolutional neural networks (CNNs) to extract features from the spectrograms.

3.1 Autoregressive predictive coding

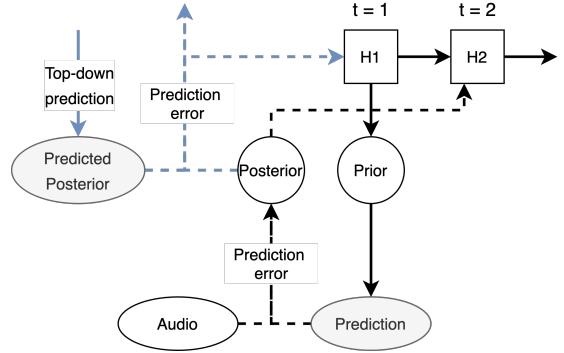
In order to enable hierarchical predictions across multiple time-scales, we stack multiple LSTM layers and allow each layer to predict the future states of the next lower layer. In line with Bayesian views on brain function and research on the effectiveness of probabilistic recurrent modelling, we express the current state in each layer as Gaussian prior distributions, parameterized by mean and variance parameters [12, 38]. While the lowest layer predicts future audio signal, the network's hidden layers predict future states of the lower layer's representations. More specifically, we first sample the prior distribution of each layer and transform the resulting activation with a convolutional decoder network. The decoder of the lowest layer parameterizes the prediction of expected next spectrogram input window. The decoders in hidden layers output predictions about the mean and variance parameters of the next lower layer. In contrast to the related class of recurrent variational autoencoders (VAE), we do not employ an

encoder network that directly transfers observations to a posterior distribution [39]. Instead, the network processes only the deviation e_t between predicted p_t and observed values o_t with a error encoder network:

$$e_t = p_t - o_t \qquad (1)$$

3.2 Variational inference with deep neural networks

With the previously introduced decoder, error encoder and recurrence networks, the model can be trained to perform variational inference by constructing a variational bound on the data log-likelihood. More specifically, the model is trained to maximize the evidence for its current inferred state, the network's "belief" about what causes an observation. Mathematically speaking, maximizing the model evidence can be expressed as minimizing the complexity of the model's generative model while providing maximally accurate predictions for future audio inputs. The model thus reduces the complexity of states with respect to observations o_t and states s_t at a discrete time step t:

$$Complexity = E_{q(s_{t-1}|o_{\leq t-1})}[KL[q(s_t|o_{\leq t})\|p(s_t|s_{t-1})]] \qquad (2)$$


Simultaneously, the accuracy of predicted observations maximized:

$$Accuracy = E_{q(s_t|o_{\leq t})}[\ln p(o_t|s_t)] \qquad (3)$$

The observations in the lowest (sensory) layer refer to the observed audio, while observations in the hidden layers refer to the observed state posteriors in terms of mean and variance. The model optimizes both terms simultaneously for all layers. For this the approximate state posteriors $q(s_{1:T}|e_{1:T}) = \prod_{t=1}^T q(s_t|e_{t-1})$ are inferred by filtering past prediction errors $\{e_t\}_{t=1}^T$. By selecting a pair of adjacent layers and minimizing the accuracy and complexity term between them, this structure allows to form predictions that are consistent between layers, i.e. show small or no top-down prediction error. Such a design prevents error propagation across many layers in a single step. This is a potential drawback and could be improved in future iterations. Throughout all experiments, we used a network with three predictive coding layers. We model $q(s_t|e_{t-1})$ as diagonal Gaussian for all layers with mean and variance parameterized by a convolutional neural network (CNN) with two layers of 64 and 128 units each. The convolutional layers were followed by a dense network of 1024, 512 and 256 units respectively.

3.3 Deterministic transitions with a probabilistic step

The LSTM states of the network are conditioned on its previous states $\{h_t\}_{t=1}^T$, top-down predictions $\{e\_td_t\}_{t=1}^T$ from the next higher layer as well as the prediction error of the last outgoing prediction, the bottom-up prediction error $\{e\_bu_t\}_{t=1}^T$. At each time-step, the bottom-up prediction error is forced to pass a sampling step when updating the prior to the posterior distribution. This means that any incoming sensory information $\{e\_bu_t\}$ must pass

Figure 1. Transitions in a single layer of the predictive coding network. The black pathways show transitions in the lowest layer of the network. Predictions about future audio are conditioned on past states and prediction errors. The blue pathways indicate top-down posterior predictions, which allow to predict the states of lower layers in the network in terms of mean and variance parameters. Multi-step predictions can be generated by updating the recurrent states without sampling new observations.

a stochastic step before being integrated into the deterministic memory states $\{h_t\}$. Figure 1 shows an overview of the transitions in a single layer and the connection to the top-down predictive pathway.

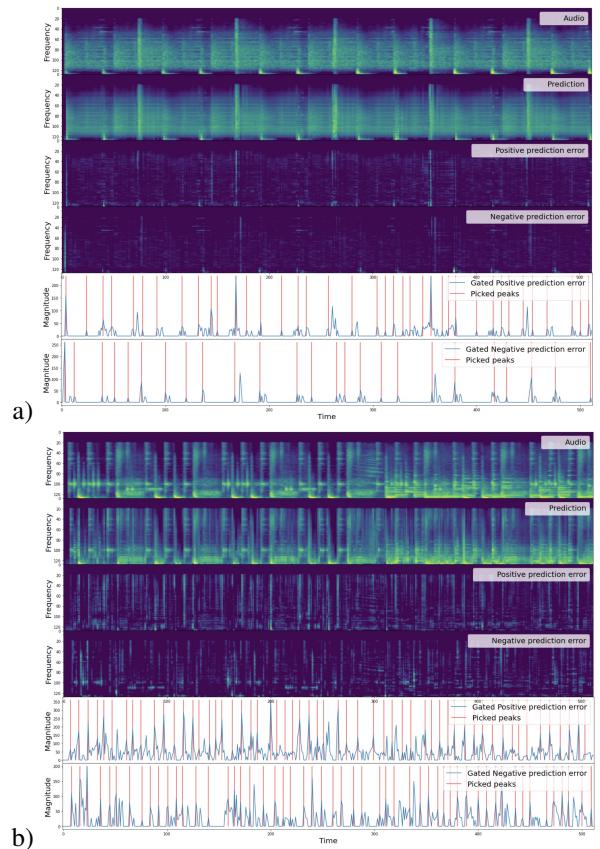
3.4 Model training

The model is trained using a timestep-wise variational evidence lower bound (ELBO) that combines the previously introduced complexity (2) and accuracy (1) terms. Similarly to the objective function in recurrent VAEs [40], the model maximes the ELBO for the approximate posteriors in each layer by accumulating evidence over past timesteps:

$$ELBO(q) = \sum_{t=1}^T \Big(o_{q(s_t|o_{\leq t})}[\ln p(o_t|s_t)]$$
$$- o_{q(s_{t-1}|o_{\leq t-1})}[KL[q(s_t|o_{\leq t})\|p(s_t|s_{t-1})]]\Big) \qquad (4)$$

This structure can be viewed as a hierarchical Kalman filter, making the connection to predictive coding as a Bayesian update scheme or generalized Kalman filtering apparent. We used ReLU activations for all CNNs and hyperbolic tangent activations for the decoder's output layer [41]. In each layer, the prediction error was computed with respect to positive and negative prediction error. Each layer was then ReLU activated before propagation to the encoder networks. For all presented experiments, we trained the model to convergence of the input layer reconstruction loss. For this, we used the Adam optimizer with a learning rate of 10^{-3} [42]. The KL divergence terms for each layer were scaled proportionally to the prediction errors. Furthermore, we weighted the reconstruction losses by 2:1:1 for the employed three layer model.

4. THE NMED-T AND FMA DATASETS

We used the Naturalistic Music EEG Dataset—Tempo (NMED-T) for the evaluations in all presented experiments [3]. NMED-T features EEG recordings from 10 commercially available music pieces, with durations between 270 and 300 seconds, spanning 55 to 150 BPM in various genres. 20 participants were allowed to freely and passively listen to the music, without any additional cognitive load. We used the provided preprocessed version of the EEG data at a sampling rate of 125 Hz. For all presented ERP experiments, we re-referenced the EEG data to the average of all 125 EEG channels and filtered out background noise using a Savitzky-Golay filter before averaging the evoked responses. For network training, we resorted to the "small" partition of the Free Music Archive (FMA) dataset, featuring 8000 songs with 30 seconds duration [43]. We computed magnitude spectrograms for all ten provided audio files of the NMED-T dataset and the FMA audio files before mapping to the mel scale, resulting in mel spectrograms at 125 Hz, equal to the EEG sampling rate. All audio processing steps were done with the librosa library [44]. We tested different mel spectrogram lengths as inputs to the lowest network layer and found lengths between 50 and 150 ms to be the sweet spot with low computation time and without quick overfitting.


5. EXPERIMENTS

For all following experiments, network training was done first on the FMA dataset followed by a evaluation phase using the NMED-T stimuli. After training on the FMA audio, we froze the network weights and processed the NMED-T audio to generate predictions and corresponding prediction errors. For each processed NMED-T audio stimulus we extracted both positive (PPE) and negative (NPE) valued prediction errors. In this context, PPEs refer to areas where the model predictions are lower than the observed threshold, while NPEs refer to predictions that are higher than the actual values. Predictions were computed in a single pass over each song, i.e. without repeated inference of the current musical context. However, such "active learning" or "active inference" schemes could be explored in the future.

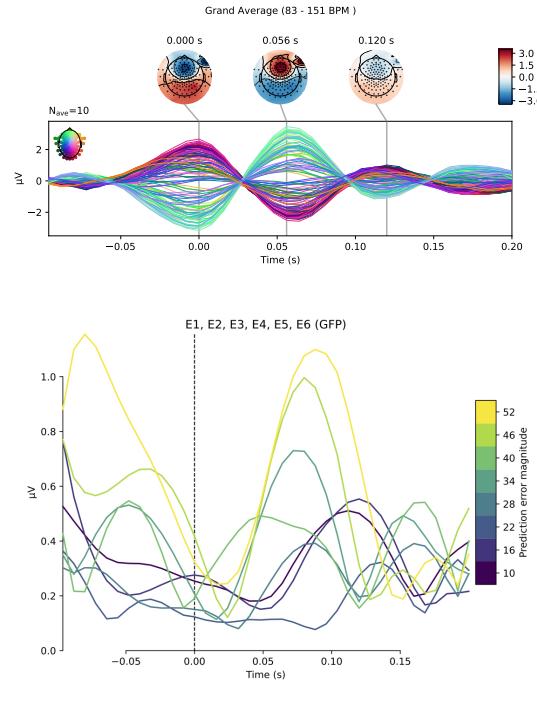
5.1 Deriving segmentation boundaries from prediction errors

In order to inspect the effect of predictive coding at the audio level, we first deactivated the recurrent parts of the lowest layer, forcing the model to express next states as a function of previous observation and the top-down prediction. For model evaluation, we extracted positive and negative prediction errors from each layer of the network. In all layers, we a applied a magnitude threshold to pick peaks from the continuous error response, followed by a peak-picking step that ignores repeated error peaks in a sliding window of fixed size. Both magnitude and window size could be learned by the network itself, leaving

the room for more complex and self-supervised segmentation techniques. All presented experiments use the mean of positive and negative prediction errors, if not further specified. Figure 2 shows two examples for input and predicted audio as well as the corresponding prediction errors and selected peaks. The examples illustrate that autoregressive predictive coding decorrelates large parts of the processed audio in the first layer, by reducing the redundancies in the signal using non-linear weighted predictions based on the past values. This is in line with the spatial and temporal whitening effects described by Rao et al. in the context of center–surround receptive fields in the retina [7]. For the following experiments, we use these sensory predictions to derive segmentation boundaries and explore temporally aligned ERPs in the brain.

Figure 2. Predicted audio and positive and negative prediction errors in the first predictive coding layer for songs with a) 55 and b) 108 BPM. The model generates local predictions about inputs in a sliding window of 50 ms size. This autoregressive and non-linear process removes temporal redundancy in the residual error response. The bottom rows show the thresholded prediction error and picked peaks.

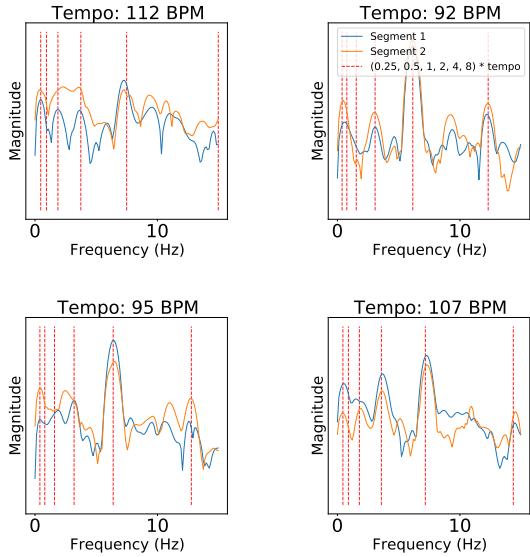
Increasing the weight of the prediction errors in the hidden layer decreased the error magnitudes. This is expected, as the network now learns to include more global temporal context over multiple steps of the lower layer. Ideally, the network learns to predict the rhythmic and timbral structure perfectly and successfully suppresses the prediction error in the first and second layer. If the recurrent parts are

active in the lowest layer, the long-term temporal dependencies can be memorized in the first layer additionally. In our experiments we found that (with a fixed weighting of the prediction errors between layers) deactivating the recurrence in the lowest layer is essential to learning predictive representations in the hidden layers. As visible in Figure 2, the tempo of the song as well as the rhythmic density have influence on the effectiveness of input decorrelation in the lowest layer.


5.2 Grand average ERP

To inspect the possibility to detect ERP events based on the sensory surprise, we extracted the prediction errors from the lowest predictive coding layer and averaged the EEG signal over all trials in all songs and subjects. We were able to derive a total of 242960 trials within 10 songs and 20 subjects using the proposed method. This equates 22140 to 28740 trials per song and between 1108 and 1437 unique event locations per song.

Figure 3 a) shows the grand average ERP for all ten songs in the NMED-T dataset at locations of prediction errors peaks. In comparison to the tempi reported in the orginal NMED-T paper, we sorted the songs between 83 and 151 BPM using beat tracking in the librosa library. The difference between our tempo measures and the ones in the original paper can be explained as being multiples of each other, e.g. 110 BPM being a multiple of 55 BPM. The averaged ERP shows an activity peak for positively correlated channels at the predicted event location, followed by a negative peak around 60 ms after onset. The grand average ERP further shows two smaller peaks around 120 and 170 ms after onset, indicating the presence of surrounding onsets with variable latency. The reduced magnitude of these delayed peaks can be explained by the differences in tempo between songs.Specifically, the difference in peak size between activity close to the predicted onsets and those with greater temporal distance indicates a separation between tempo-independent components (close to the prediction error peak) and attenuated tempo-dependent components. Figure 3 b) shows the grand average ERP in five positively activated channels, sorted by the prediction error magnitude. The magnitude of the first evoked peak after stimulus onset grows proportional with the error magnitude for large error values. For smaller prediction error values, the response shows larger latency. Peaks with similar latency of the evoked activity have magnitudes proportional to the prediction error magnitude. This fits with the assumption that the grand average ERP shows temporally variable peaks induced by differences in tempo.

5.3 Evaluating song-level segmentation with low frequency EEG


Next to inspecting the predicted ERP responses with the local predictions of the input layer, we want to inspect the possibility to segment stimuli on the song level with the model. For this, we repeat the unsupervised training of the previous experiments, but weight the prediction errors in all layers equally after pretraining for 100000 updates.

a)

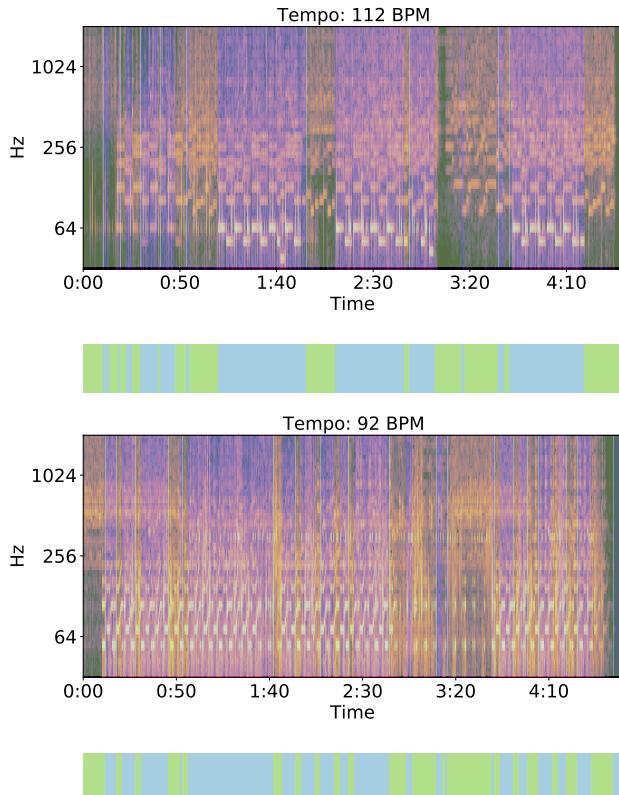
b)


Figure 3. a) Grand average ERP for all songs in the NMED-T dataset at locations of prediction errors peaks generated by the predictive coding network. b) Grand average ERP in five positively correlated channels for trials sorted after the prediction error magnitude of the predictive coding network.

This approach puts more focus on the temporal consistency of the predictions in the hidden layers. Furthermore, we train with multi-step predictions of length 8, i.e. prediction errors are generated with respect to 8 future states at a time. This follows the assumption that both multi-step predictions and increased weighting of the hidden layer prediction errors increase the network's tendency towards more global predictions. In order to evaluate the ability to retrieve meaningful musical structure with the network's predictions, we extracted the timings of prediction errors from the lowest predictive coding layer and used them as starting points of EEG epochs, subsequently averaging the EEG signal over all epochs within each segmented class. Following previous work that illustrates differences in beat processing with SSEPs, we inspect averages of low frequency EEG to detect changes in beat processing or entrainment between the segmented classes derived from prediction errors in the predictive coding network [3]. For this, we use the same epoched data derived from locations computed in the previous experiments but average over all epochs within the bounds of each segmented class.

Here, we want to inspect whether changes in network prediction triggered by peaks in prediction errors show changes that are detectable with SSEPs. To generate binary segmentation, we threshold the prediction error like in the previous steps with a fixed value for each song and switch between segmentation masks when the positive error surpasses the negative error and vice versa. Both

a) SSEPs in low frequency EEG within the segments derived from gated prediction errors of the predictive coding network. Indicated with dashed lines are multiples of the song tempo, ranging from 1 to 16 Hz. Differences between the peaks in the power spectrum of both segments indicate different rhythmic processing between the two segmented classes.

b) Corresponding audio and temporal binary segmentation of two songs derived from gated prediction errors after training the proposed network for unsupervised multi-step prediction. Only the lowest 6 octaves are included for illustration purposes.

Figure 4. Segmented audio and evoked SSEPs in low frequency EEG of the NMED-T dataset.

down-sampling the inputs or increasing to length of multi-step predictions leads to more coarse grained segmentation. We found that using hop lengths up to as much as 16000 successive frames during spectrogram computation were suited to generate song-level segments while simultaneously reducing computation time. Intuitively speaking, the changes in hidden prediction error magnitude reflect the "mid-level" surprise of the network, as the pure sensory surprise is largely minimized in the input layer and the residual errors are further propagated. Future iterations of the model could use learnable error thresholds for improved and self-supervised segmentation. To help visualize the effect of segmentation we reduced spatial EEG dimensionality using Principal Components Analysis (PCA) before averaging the data and analyzed only the first component. Figure 4 a) shows the induced SSEPs in the magnitude of low-frequency EEG for selected songs. Audio and segmentation boundaries for two of these songs are displayed in Figure 4 b). Visible are peaks in the low frequency EEG components within all segmented parts that are aligned with multiples of the song tempo. In most processed songs the noticeable magnitude shifts go along with a stable distribution of the frequencies of evoked peaks, indicating rhythmic differences between the annotated segments which are embedded into the same global tempo.

6. DISCUSSION

This paper explored deep predictive coding for unsupervised audio representation learning inspired by human cognition. We compared the network's prediction errors with evoked potentials in EEG. For this, we related the hierarchical predictions of the model on ten naturalistic musical pieces to onset-aligned evoked potentials captured in EEG. We derived locations for individual musical events from the sensory surprise and inspected steady-state evoked potentials that capture rhythmic differences in the segmented songs. The employed model combines deterministic sequential predictions with probabilistic representations. While the deterministic parts allow to learn regularities over time-scales, the probabilistic elements lessens overfitting and helped shortening training duration. While sensory-level predictions can be employed for local event annotations, the predictions and prediction errors in hidden layers target higher levels of temporal abstraction.

Our results indicate the usefulness of predictive coding for the retrieval of events across the local and global structure of musical works. The model allows to approach audio segmentation jointly with structuring recorded brain activity, forming a basis for retrieval of information about cognitive processes in music perception. This offers an appealing method for researching auditory evoked potentials, as it eases the mapping between stimulus characteristics and connected evoked potentials across time-scales. Future improvements could enhance the capacity of the model, e.g. by allowing the model to segment inputs based on learned error gating.

DECONSTRUCT, ANALYSE, RECONSTRUCT:
HOW TO IMPROVE TEMPO, BEAT, AND DOWNBEAT ESTIMATION

ABSTRACT

In this paper, we undertake a critical assessment of a state-of-the-art deep neural network approach for computational rhythm analysis. Our methodology is to deconstruct this approach, analyse its constituent parts, and then reconstruct it. To this end, we devise a novel multi-task approach for the simultaneous estimation of tempo, beat, and downbeat. In particular, we seek to embed more explicit musical knowledge into the design decisions in building the network. We additionally reflect this outlook when training the network, and include a simple data augmentation strategy to increase the network's exposure to a wider range of tempi, and hence beat and downbeat information. Via an in-depth comparative evaluation, we present state-of-the-art results over all three tasks, with performance increases of up to 6% points over existing systems.

1. INTRODUCTION

A central concept in much of the work on audio beat tracking is the "tactus" – described as the most comfortable foot-tapping rate when unconsciously tapping to a piece of music. As stipulated by London [1, Ch.1] (and references therein), the tactus is essential for our perception of metre. The tactus by itself carries no information concerning the metrical organisation within a piece of music, but it is informative about both local and global tempo. To perceive metre, we require the hierarchical organisation between at least two levels, and ideally three: a level above the tactus which indicates the longer-term grouping of beats into bars (or measures), and a lower level to describe how the beats are sub-divided – whether in *simple* time (divided by two), or *compound* time (divided by three).

In this sense, we can expand the notion of (unmarked) foot-tapping towards "counting" in time to music. While numerous counting systems exist for the teaching of musical rhythm [2], the "traditional" American system is perhaps the most well-known. For two-level counting, we can mark the three beats of the bar of a waltz as follows: **1** 2 3 **1** 2 3 **1**..., where the **1** indicates the first beat of each

bar, the downbeat. Moving to three-level counting, we can count the sub-divisions of a four beat bar into two as: **1** + 2 + 3 + 4 + **1**..., (*one - and - two - and - three - and - four - and*), and the sub-divisions of the same four beat bar into four as: **1** e + a 2 e + a 3 e + a 4 e + a **1**... (*one - "ee" - and - "ah" - two - "ee" - and - "ah" and so on*).

From the perspective of computational rhythm analysis, we can thus make a distinction between approaches which target one metrical level in isolation, as opposed to those which estimate more than one. Among the single-level approaches, the vast most majority fall within the domain of beat-tracking (e.g [3–6]). When the focus of the analysis moves towards downbeats, this almost exclusively relies on the implicit or explicit modelling of another metrical level, either the beat [7], tatum [8], or a contrast between both [9]. One notable outlier is the downbeat prediction approach of Jehan [10] which relies instead on onset-synchronous analysis.

Concerning the modelling of three simultaneous metrical levels, few published approaches exist. Goto [11] presents a real-time system for estimating the quarter-note, half-note, and measure levels, but doesn't address the sub-beat level. Klapuri et al. [12] on the other hand, address the estimation of tatum, beat, and downbeat, with explicit dependencies between the phase of the beat and the tatum, and the period of the beat and downbeat. For a recent review of beat and downbeat estimation, see [13].

Considering the topic of tempo estimation, which, in most instances, seeks to retrieve a single value to describe a global tempo, existing approaches can be split into two categories: those which make their estimate of the tempo based the post-processing of a sequence of beat times (e.g. for a discussion of techniques, see [14]) and those which treat the task as a classification or regression problem and do not require any prior estimate of the beats [15–18].

In this paper, we seek to work from the perspective of leveraging shared connections in musical structure, and address the simultaneous estimation of three highly interconnected properties of musical rhythm: tempo, beat, and downbeat within a single model. In line with much of the recent literature concerning the extraction of musical information from audio signals [19], we adopt a deep learning approach. We depart from our recent multi-task approach [20] for tempo and beat estimation using a temporal convolutional network (TCN), which was shown to provide state-of-the-art results. We undertake a critical assessment of its constituent parts, and on the basis of our

analysis, adapt it in several ways. At the broadest level, we wish to leverage the benefit of modelling a metrical hierarchy (as opposed to just the beat level) by the inclusion of an additional learning task, downbeat estimation. In terms of the structure of the network itself, we adapt the shallowest layers of the network (i.e. those closest to the musical surface) to provide a better model of harmonic musical sounds. In addition, we propose a novel formulation of the TCN architecture which incorporates an additional dilation rate to each layer as a means to embed understanding of integer ratios modelling the metrical structure.

A peculiar aspect of the evaluation in [20] was the ability of the multi-task model to perfectly estimate the tempo of the HJDB dataset [21] when it was included in the training splits, with good, but noticeably lower performance when it was left as a hold-out test set. Given the characteristic fast tempo of *HJDB*, we speculate that the gap in performance arose due to the lack of any similarly fast-tempo music in the training sets. Following this argument, a secondary motivation of this work is to consider how data augmentation can be used in an efficient way to extrapolate information from regions of the training data which are well-covered in terms of tempo annotations to those which are more sparse.

Via a thorough evaluation across the three tasks of tempo, beat, and downbeat estimation, we demonstrate state-of-the-art performance, and draw attention to the ability of TCN-based approaches to leverage shared representations for multi-task analysis of musical audio signals.

The remainder of this paper is structured as follows. In Section 2 we describe our multi-task formulation and data augmentation strategy in detail. In Section 3 we present an ablation study and comparative evaluation against existing reference systems. Finally, in Section 4 we discuss the impact of the contribution and promising areas for future work.

2. APPROACH

Our earlier multi-task approach for tempo and beat estimation [20] was itself an extension of an earlier TCN-based approach for beat tracking [22]. The core component, which is common to both, is a deep neural network (DNN) architecture based on dilated convolutions, most well-known from *WaveNet* [23]. It is quite striking to consider that an architecture designed for the causal generation of raw audio (primarily for speech synthesis), and with its roots in an auto-regressive process, can find application in a problem cast as binary classification through time, i.e. the classification per frame of the presence or absence of a beat. From an alternative perspective, we may view the strength of the TCN in this problem domain as resulting from multiple connections (both forwards and backwards in time) at different time scales, and thus bearing similarity to much earlier work on the cognitively-inspired use of multi-resolution signal processing for beat tracking [24].

For a detailed description of the existing architecture, we refer to the reader to [20, 22]. In brief, the multi-task approach uses a log-magnitude spectrogram with 81 loga-

rithmically spaced frequency bins and a frame rate of 100 frames per second as input. Overlapping spectrogram snippets are passed through 3 convolution and max pooling layers, followed by 11 dilated convolutional layers whose dilation rate increases by a factor of 2 per layer. The so-called "skip connections" between these layers are provided as an auxiliary output of the TCN and are used to generate a prediction of the tempo across a linear range from $0 - 300$ beats per minute (bpm). The main output of the TCN, a beat activation function, is then processed by a dynamic Bayesian network (DBN) [25] to obtain a final sequence of beat estimates.

In spite of the reported high performance of the multi-task approach on a wide range of musical material for both beat and tempo estimation, we believe it is valuable to question the design decisions of this network and consider the ways in which it could be modified to improve performance. Our focus in this paper is on the core of the network, namely the convolutional and max pooling layers together with the TCN. In a coarse sense, we can consider the convolutional and max pooling layers to relate to more surface-level properties of the music and hence local information, i.e. *what are the spectro-temporal properties of the beats?* with the deeper TCN layers oriented more towards their temporal dependency over longer time scales, i.e. *how is the beat and metrical structure organised over the duration of musical pieces?*

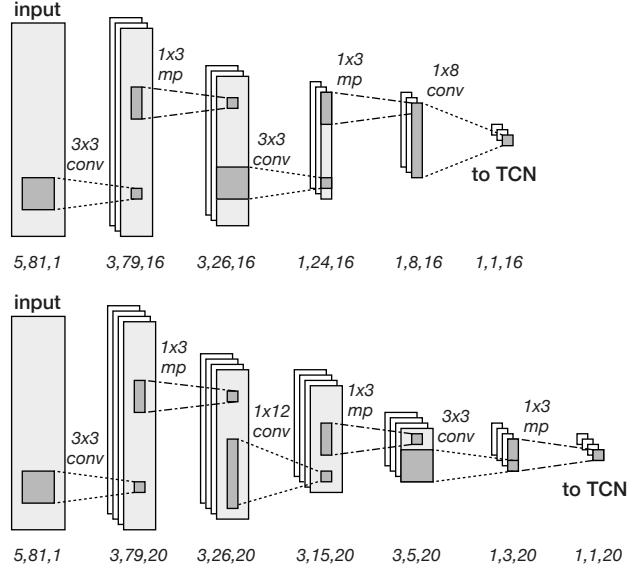
Concerning the first question, a common limitation of beat tracking systems is their ability to reliably detect the beat in music without the presence of drums, as typified, at least in part, by lower reported performance in classical music. Given the high prevalence of rock, pop, jazz, and electronic dance music among existing beat tracking datasets [26], we consider the modelling of harmonic sounds to be important when addressing under-represented musical styles and of crucial importance to reliably detect downbeats in Western music, where harmonic changes often occur at bar boundaries [27]. Regarding the second question, we directly enable the network to learn feature representations which are integer multiplies of each other by deploying multiple concurrent dilated convolutions at each TCN layer, and in so doing embed some implicit hierarchical structure into the model.

In what follows, we describe the specific modifications made to the network. Since the work in this paper explicitly targets the improvement of an existing approach, we allude to performance increases wherever relevant, with detailed results in Section 3.

2.1 Multi-task formulation

Based on the model described above, we add the additional task of downbeat tracking. This can be accomplished in various ways. One option is to model the downbeats and beats jointly as a multi-class problem, i.e. by classifying each input frame to be a beat, a downbeat, or neither. This approach was successfully deployed in [28], but has the downside that it cannot fully leverage the information if a dataset contains only beat or downbeat annotations. Thus

we treat the problem as a multi-label classification problem instead, with the downbeat task treated as a separate binary classification problem with its own output. We model the downbeat output similarly to the beat output as a single *sigmoid* unit which is fed directly from the main TCN output. Whereas the approach in [20] used 16 filters per layer for the multi-task estimation of tempo and beat, with the addition of the downbeat task, we expand the network to include more filters and increase this to 20.

This additional output is then also post-processed with a DBN. Since the beat and downbeat outputs do not define a joint probability density function (i.e. their sum is not guaranteed to be 1 as for multi-class problems), the DBN post-processing used in [28] cannot be applied directly to the combined beat and downbeat activations. Thus the difference of the beat and downbeat activations (limited to positive values) and the downbeat activations are used as state-conditional observations for beats and downbeats, respectively. In Section 3 we refer to this approach as *joint downbeat tracking*.


An alternative approach is to first detect the beats and then in a second inference step to find the downbeats given the set of beat predictions. This approach was chosen in [29] and has the most notable advantage that the large joint state space which is required to model multiple bar lengths and tempi at a frame level resolution can be split into two smaller ones. The first one (tracking the beats) only requires multiple tempi to be modelled at the frame level resolution, whereas the second one operates at beat resolution and is completely tempo invariant, thus requiring only very few states. The downside of this approach is that errors made in beat tracking directly propagate to downbeat tracking. In Section 3 we refer to this approach as *sequential downbeat tracking*.

2.2 Conv layers

Both the original beat tracking paper [22] and the multi-task extension tackling global tempo estimation presented in [20] use the same convolutional block to reduce multiple consecutive STFT frames to a one-dimensional feature vector which is then processed by the TCN. Two groups of alternating 3×3 convolution and 1×3 max-pooling layers were used to reduce overlapping spectrogram windows of size 5×81 (time $\times$ frequency) down to 3×26 and 1×8 before these eight bands (roughly representing one octave each) were combined into a singular value with a 1×8 convolution. This feature representation is closely related to the one used in [12] and was shown to work well.

However, a musically motivated reordering of these layers can have a positive effect on the performance of the model. Convolutional filters covering multiple frequency bins but only a single time step have been shown to concentrate on harmonic and timbral features [30] and proven to work well for multiple tasks, including key estimation [31] and automatic music transcription [32]. Moving the "frequency only" convolution in between the two 3×3 convolutions as shown in Figure 1, enables the network to better capture harmonic content across a wider frequency range

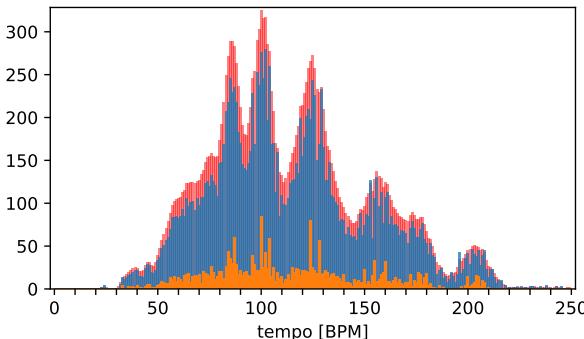
instead of detecting local changes in smaller regions of the spectrogram only and then later aggregating them.


Figure 1: Comparison of the convolution (*conv.*) and max pooling (*mp*) layers. The architecture from [20, 22] (top). Our proposed architecture (bottom). The dimensions of the tensors are shown below each layer.

2.3 TCN layers

From a musical perspective, it is undeniable that discovering downbeats requires more knowledge about the signal than locating beat positions only. Independently of whether this additional knowledge is harmonic or rhythmic in nature, it always requires a longer temporal context. Increasing the temporal context of the TCN by either using larger kernel sizes or adding more layers (with exponentially increasing dilation rates), did not improve any of the tasks under investigation. This observation is not necessarily surprising since the temporal context modelled by the TCN is already about 40 seconds – which should be sufficient to tackle the task of tracking the locations of the downbeats and estimating the length of the bars. Instead, adding a second dilated convolution (with a doubled dilation rate) to each of the TCN layers enables the network to simultaneously model musical properties at various levels which are integer multiples of each other. We discovered that adding a third dilation rate did not further improve performance, but we believe this is very likely an artefact of the data utilised for training, since none of the datasets used have a noticeable number of musical pieces with compound time signatures. The feature maps of the two dilated convolutions are concatenated before spatial dropout [33] and an exponential linear unit (ELU) activation function [34] is applied. In order to keep the output dimensionality of the TCN layer constant, these feature maps are then combined by a 1×1 convolution, which increases the total number of parameters linearly with each TCN layer instead of exponentially.

2.4 Data augmentation

Our approach to data augmentation is both simple and straightforward and similar to the scaling approach applied in [17]. Contrary to other data augmentation strategies, which pre-process the audio signal and manipulate it in various ways (e.g. time stretching, pitch shifting, sample rate conversion to simulate speeding up or slowing down the signal [35, 36]), we do not change the audio signal itself, but instead only change the parameters of the STFT when obtaining a time-frequency representation. To be more precise, we only change the rate at which the overlapping frames of the STFT are obtained from the audio signal by sampling from a normal distribution with 5% standard deviation from the annotated tempo. By changing only the hop size, we obtain spectrograms with varying overlap factors and only the targets have to be adjusted accordingly. Using this data augmentation strategy leads to many more training examples for tempi which are otherwise underrepresented in the data, as can be seen in Figure 2.

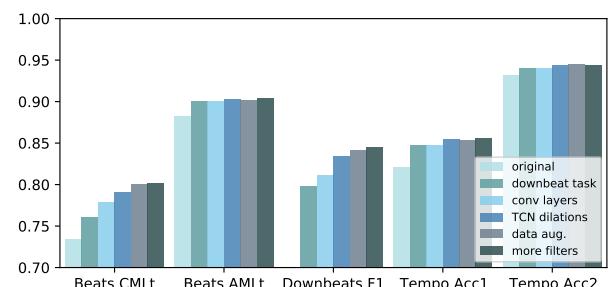
Figure 2: Tempo distribution of original tempo annotations (orange, foreground), after data augmentation (blue) and target widening (red, background).

2.5 Network training

Using data augmentation increases the amount of data the network can learn from. However, this also leads to increased training times when using conventional training procedures. Furthermore, the additional downbeat classification layer, the inclusion of a second dilated convolution and the usage of more filters in each of the TCN layers has a notable impact on the size of the model, which now has $116,302$ trainable parameters compared to $29,901$ of [20].

To this end, we make use of the latest training optimisation strategies, namely *RAdam* [37] and *Lookahead Optimization* [38]. The combination of these two drastically reduces the training time (even accounting for the larger number of weights) simultaneously leading to models being less sensitive to different random initialisations. All remaining hyper-parameters were left unchanged. We found the used learning rate of $2e^{-3}$ and clipping the gradients at a norm of 0.5 a sensible choice, as is training on full sequences with a batch size of 1.

We derive the tempo targets in the same way by computing a smoothed and interpolated histogram on the inter

beat intervals. We apply the same target widening strategy to present the network not only the annotated frame and tempo, but also their direct neighbouring frames and ± 2 BPM values as positive targets, albeit with lower weights of 0.5 and 0.25, respectively.


3. EXPERIMENTS AND RESULTS

We use the same datasets as in [20] with the most recent annotations available. *Beatles* [39], *Cuidado* [40], *Hainsworth* [20, 41], *Simac* [42], *SMC* [26], and *HJDB* [21, 28] are used for training and evaluated in an 8-fold cross validation manner. *ACM Mirum* [43, 44], *GiantSteps* [45, 46], and *GTZAN* [47, 48] are used as test datasets. Predictions for the test datasets are obtained by averaging the predictions of the networks trained for cross validation. To enable future comparisons, we make all annotations as well as the beat, downbeat, and tempo estimates available at the accompanying website. [1]

For evaluation, we use the standard metrics used in the literature. For tempo estimation, we report *Accuracy 1* and *Accuracy 2* scores with a tolerance of $\pm 4\%$ as used in [49]. For beat and downbeat tracking, we use *F-measure* and the continuity based metrics *CMLt* (requires beats being tracked at the annotated metrical level) and *AMLt* (allowing alternative metrical levels, such as double/half and triple/third tempo as well as off-beat) with the tolerances as defined as in [39].

3.1 Ablation study

Before reporting comparative evaluation to other methods, we aim to understand how each of the proposed measures outlined in Section 2 contribute to the final performance of the system.

Figure 3: Impact of the improvements proposed for selected evaluation metrics. Mean values over the complete validation set are given.

From Figure 3 it can be seen that the measures undertaken to improve the original system do not contribute the same to the different tasks and the given evaluation metrics. For example, beat tracking *AMLt* and tempo *Accuracy 2* scores increase only marginally, which is best explained by the fact that the baseline system is already performing at a high level on these tasks. However, since these metrics allow metrical ambiguities, it is impossible

---

[1] `https://github.com/superbock/ISMIR2020`

to determine if the system is considering the correct metrical level in the case of beat tracking or the correct tempo octave. Both *CMLt* and *Accuracy 1* require the reported beat locations and tempo to exactly match the annotations (within the allowed tolerance). These metrics therefore better catch the ability of an algorithm to correctly predict the annotated information.

Concentrating on these metrics, it can be seen that additionally modelling and predicting downbeats has a positive effect on beat tracking and tempo estimation. This effect is then strengthened by the modifications made to the convolutional and TCN layers. Using data augmentation and more filters gives a small additional boost. It should be noted that the positive effect of data augmentation on the generalisation capabilities of the network are mostly visible for the task of tempo estimation if "out of tempo distribution" datasets are used for evaluation. Since the validation set is a randomly chosen subset of the training set (and hence has a very similar tempo distribution), the impact is not fully reflected in Figure 3.

3.2 Tempo estimation

Tempo estimation is the task with the most noticeable overall impact of the proposed refinements. While *Accuracy 2* values have been quite high for many systems among all datasets under consideration, the new system is the only one consistently achieving high *Accuracy 1* values as well (Table 1). The system's ability to model several tasks simultaneously and exploit mutual information relevant to all tasks leads to an increased performance of more than 6% points in *Accuracy 1* over the best results reported so far on certain datasets.

3.3 Beat tracking

Although beat tracking performance of existing systems is already very high, the new system sets new high scores in *CMLt* and even exceeds the very high performance values above 0.9 (on *Ballroom*) by more than 4% points. Other systems achieve such high scores only under the less strict *AMLt* metric, which also permits metrical errors, including double/half, triple/third tempo, and off-beat. This highlights the capability of the system to track beats exactly at the annotated metrical level.

Table 2: Beat tracking results on datasets used for training with 8-fold cross validation (top), and on unseen test data (bottom). ‡ was trained on *Ballroom* data only.

In Table 2 it can also be seen that joint modelling of beats and downbeats (in the DBN) can be beneficial for music with constant meter and steady tempo (e.g. *Ballroom*), whereas it negatively impacts performance for expressive music as contained in *Hainsworth* and *SMC*.

3.4 Downbeat tracking

For the task of downbeat tracking the systems, performance can be clearly separated into two main categories: i) the systems of Durand et al. [8] and Fuentes et al. [9], which explicitly model harmonic features (using chroma features as input for the neural network) and ii) the ones of Böck et al. [28] and ours which learn harmonic features implicitly. Whereas the former show better performance on pop music (e.g. the *Beatles* dataset) where downbeats often coincide with harmonic changes, they perform less well on data where bars are mostly defined based on rhythm.

Ours (joint tracking)	0.672	0.640	0.832

Table 3: Downbeat tracking results on datasets used for training with 8-fold cross validation (top), and on unseen test data (bottom).

Regarding the question of whether *joint downbeat tracking* or *sequential downbeat tracking* is superior, Table 3 shows a consistent advantage for processing beats and downbeats simultaneously. The only exception is the *Beatles* dataset, which contains some music with changing metre. Due to memory constraints, joint downbeat tracking cannot model these metre changes. Modelling them is computationally only feasible with sequential downbeat tracking, which may further benefit from sub-beat modelling, as used in [9].

4. DISCUSSION AND CONCLUSIONS

In this paper we address the multi-task estimation of three inter-related properties of musical metre: tempo, beat, and downbeat. Our approach is somewhat unconventional as we do not propose a new method from scratch, but instead we deconstruct, analyse, and then reconstruct an existing approach as a means to further the state of the art. By pairing our methodology with an ablation study, we are able to directly observe the impact of the implemented changes, and in turn, to observe the cumulative gains in performance. Via our evaluation, it is clear that there is no "magic bullet" among our proposed modifications, yet their combination is clearly effective. Furthermore, we must accept that when the baseline performance is already high, the margin for improvement is somewhat limited.

By close inspection of the performance of our approach in comparison both to the baseline and other existing systems, we consider the main impact of our approach as constituting a "closing of the gap" between stricter and more lenient evaluation metrics across each of the tasks. For tempo estimation, our approach is the first to exceed 0.83 for *Accuracy 1* across three large reference datasets, which are completely unseen to our training scheme. Likewise, when considering the positive impact for beat tracking, we find the clearest improvements in the evaluation metric which enforces tracking at the annotated metrical level. Since the relative improvements under the more lenient metrics are much smaller, we do not believe that our approach has unlocked the means to accurately infer the tempo, beat, or downbeat in extremely challenging musical examples. Reference to the incremental improvements for the *SMC* dataset for beat tracking can immediately attest to this. Indeed, the lack of improvement for this kind of musical material may require the reformulation of the inference techniques used to recover the final outputs, rather than intervention at the point of training the networks. Alternatively, they may require a fundamentally different way in which to present targets to the network which is better able to model temporal uncertainty in the annotations. We consider both of these to be promising areas for future work in order to address more challenging data in a robust way.

Ultimately, we believe the main contribution of our work rests in the increased reliability of the good predictions made by the model across these three tasks. It is well-established within music cognition that the perception of tempo, beat, and metre is ambiguous and varies among listeners; therefore within the MIR community, it is easy to justify the use of "multiple-choice" evaluation methodologies. However, this evaluation practice explicitly masks the fact that for almost any piece of music, at least some of these allowed options will be much less reasonable than others. Thus, in the absence of a multi-level annotation methodology in which the set of allowed annotations are specific to individual pieces of music, the only way to guarantee a high-quality prediction (in an unsupervised way) is to aim to maximise performance under stricter evaluation metrics. The alternative is to perform a subjective assessment of beat and downbeat performance via listening to clicks mixed with the audio signals. Given the large amount of musical material in existing datasets, this remains a daunting prospect. However, by restricting this kind of supervised analysis to the subset of excerpts which are accurate only when allowing for alternative interpretations of the annotations, we may move towards a closer estimate of the true performance of these systems. In addition, this kind of partial subjective evaluation could act as a means to "bootstrap" the specification of alternative hypotheses on a per-excerpt basis.

ABSTRACT

Most commercial music services rely on collaborative filtering to recommend artists and songs. While this method is effective for popular artists with large fanbases, it can present difficulties for recommending novel, lesser known artists due to a relative lack of user preference data. In this paper, we therefore seek to understand how content-based approaches can be used to more effectively recommend songs from these lesser known artists. Specifically, we conduct a user study to answer three questions. Firstly, do most users agree which songs are most acoustically similar? Secondly, is acoustic similarity a good proxy for how an individual might construct a playlist or recommend music to a friend? Thirdly, if so, can we find acoustic features that are related to human judgments of acoustic similarity? To answer these questions, our study asked 117 test subjects to compare two unknown candidate songs relative to a third known reference song. Our findings show that 1) judgments about acoustic similarity are fairly consistent, 2) acoustic similarity is highly correlated with playlist selection and recommendation, but not necessarily personal preference, and 3) we identify a subset of acoustic features from the Spotify Web API that is particularly predictive of human similarity judgments.

1. INTRODUCTION

Suppose you want to recommend a novel artist B to a friend who you know likes some artist A. Which of B's songs should you recommend that they listen to first? As we will argue in the following, the answer to this question involves concepts of acoustic similarity, playlist context, and personal preference as they all relate to the task of music recommendation [18].

The motivation for asking this question comes from an application we are developing called Localify [1] that recommends artists from a listener's hometown based on the listener's favorite artists [7]. While most of these favorite artists will tend to be popular, well-known artists, the vast

[1] https://www.localify.org

majority of local artists are likely to be relatively obscure *long-tail* artists [1, 3, 11]. There is often limited user preference data (listening histories, like/dislike ratings) associated with these long-tail artists and even less associated with their individual songs.

Automatic playlist generation is one of the core components of our locally-focused music recommender system. As we know from recommender systems research, providing the user with a contextual explanation of the recommendation is important because it provides information that is both useful for decision making and for developing trust in the system [13, 21]. We also know from music psychology research that listeners tend to prefer familiar music [6, 15]. To this end, our playlist algorithm creates a list of songs by alternating between a song by a favorite artist and a song by a local artist. This allows the algorithm to balance exploiting familiarity from known artists with exploring novel artists from the local music scene.

Most commercial recommender systems make use of listening histories from a large number of listeners to make accurate recommendations [2]. This technique is referred to as collaborative filtering (CF). CF systems suffer the cold-start problem [19]: little or no historical user preference data exists for new or obscure artists. As a result, a CF-based recommender system cannot recommend these artists with sufficient confidence. An alternative to CF systems are content-based (CB) recommender systems that make use of the audio signal for recommendation.

Although many of the local artists we want to recommend are relatively obscure, we have informally found that our CF system is able to accurately recommend local artists in most cases. However, it tends to do a poor job of recommending relevant songs for many of our obscure local artists. To this end, we have been exploring the suitability of CB recommendation based on acoustic similarity between a given reference song and a set of candidate songs in order to improve our playlist algorithm.

1.1 Research Questions

To better understand the role of acoustic similarity in recommending long-tail artists, we address the following three research questions in this paper:

RQ1 Are human judgments about acoustic similarity consistent across users?

RQ2 Is acoustic similarity a good proxy for how an individual might construct a playlist, recommend music to a friend, or prefer one song over another?

RQ3 If so, what are some of the measurable acoustic properties that correlate with how humans judge acoustic similarity?

The first question acknowledges that music is subjective and people will naturally have differing opinions [5]. However, if there is little or no consistency in how listeners perceive songs and compare them to one another, then modeling music on the basis of acoustic similarity will be unreliable.

While the answer to the second question may seem obvious, many listeners have eclectic tastes and expect some amount of variety, so it is possible that having music that is too acoustically similar could result in homogeneous playlists and boring recommendations. Additionally, listeners bring non-musical context to bear when listening to music. This includes the meaning of the lyrics, the artist's social persona, visual media (album covers, music videos), trust in the source of the recommendation, the listener's emotional state, etc. In addition, an individual's perception of music is influenced by a variety of socio-demographic factors including age, race, ethnicity, gender, social class, family, political beliefs, and values [12]. To this end, it is entirely possible that the acoustic content is only a small part of the equation when it comes to making a successful recommendation [17].

We address the first two questions by asking individuals to choose among two unknown candidate songs (B1 and B2) from an unknown artist B in the context of a third familiar reference song (A1) by a known artist A. Specifically, we ask which one (B1 or B2) is more acoustically similar to A1, which one they would recommend to a friend who likes A1, which one they would include in a playlist after A1, and which one they personally prefer. Throughout this paper, we will refer to a specific set of three songs $\{A1, B1, B2\}$ as a *song tuple*, and we asked a large number of test subjects to each evaluate a subset of 12 total song tuples (see Table 1) based on their genre preferences.

For the third question, there has been a good deal of research within the music information retrieval community that focuses on using digital signal processing and machine learning to estimate acoustic similarity (e.g., MIREX Audio Similarity Task [2], [10,14,22]). We will not advance the state-of-the-art in this paper but rather simply explore how acoustic properties such as estimated tempo, danceability, and valence correlate with a human listener's judgments related to acoustic similarity. For this, we both analyze open-ended responses from listeners and examine correlations between 11 song-level audio features that we obtain from the public Spotify API for each of the songs in our study.

1.2 Related work

Our work is related to other studies that explore how people interact with music recommender systems. One recent study by Lee et al. [13] found that there are many factors, including aesthetic qualities, familiarity, trust in the recommender, and contextualization, that affect whether a person will adopt a music recommendation. This is consistent with our findings that while acoustic similarity is important for music recommendation, other non-content-based information also plays a big role (see Table 2.)

Zhang et al. [23] stress the importance of serendipity and warn about the dangers of self-reinforcing "filter bubbles" when music recommender systems focus too much on optimizing accuracy. Our recommender system embraces these ideas by attempting to introduce novel artists through locally-focused music recommendation. In addition, the design of our survey was influenced by their suggestion that a recommender system should be akin to having a trusted friend recommend music.

Our application also reflects the findings of Jun et al. [8] who suggest that blending songs in a specific order can improve the quality of the playlist. Specifically, we would like to play a familiar song followed by an acoustically similar song by a local artist so that they flow together. The idea is that a user will be more likely accept the local music recommendation if it sounds similar to something they already enjoy.

Finally, we refer the reader to both Lee et al. [13] and Laplante [12] for recent and comprehensive literature reviews on studies related to human-centered music recommendation.

2. METHODOLOGY OF STUDY

In this section, we describe both how we selected the song tuples and how we designed the user study.

2.1 Song Tuple Selection

We began by collecting 12 song tuples of 3 songs each, for a total of 36 songs. We first selected 4 genres (pop, rock, hip hop, and R&B) with 3 tuples assigned to each genre. Each tuple consisted of a song by a popular artist from its genre, as well as two songs by a relatively lesser-known artist from the same genre. We refer to the popular artist and song respectively as the A artist and A1 song, and the lesser-known artist and songs respectively as the B artist and B1 & B2 songs. For example, in one of the song tuples from the pop genre, the A artist is Billie Eilish and the A1 song is *bad guy*, while the B artist is Gabbie Hanna and the B1 & B2 songs are *Honestly* and *Butterflies*.

The A artists were determined by finding popular artists associated with each of our four genres using the Spotify API [3]. The A1 songs were chosen from the most popular tracks for each artist to maximize the likelihood of them being recognized by our study's participants. The B artists were chosen from a large corpus of artists from our own application such that each B artist was listed as being related to artist A according to the Spotify Web API [4]. We also ensured that the B artists and their B1/B2 songs had limited popularity so that they would likely not be familiar to our study's participants to better simulate long-tail music recommendation.

---

[2] https://www.music-ir.org/mirex

[3] https://developer.spotify.com/documentation/web-api/reference/artists/get-artist/

[4] https://developer.spotify.com/documentation/web-api/reference/artists/get-related-artists/

While we generally selected the most popular songs for both the A and the B artists, we skipped over songs in the popularity ranking under the following conditions. For A1 song selection, we skipped over a song if:

1. The song is a cover of a song by another artist
2. The song is actually by another artist where the current artist is only featured
3. The song was very recently released and thus high in popularity but still relatively low in number of streams

For B1/B2 song selection, criteria 1 and 2 were applied as well. In addition, we also skipped over a potential B1/B2 song if it had an excessively high number of streams due to being a "one hit wonder" so as to reduce the likelihood that test subjects would recognize it.

2.2 Survey Design

Our three section study was conducted through an online Qualtrics survey. In the first section, each participant was asked to provide demographic and psychographic data (e.g., age, gender, time spent listening to music daily, preferred streaming services). Additionally, we asked participants for the two genres they were most familiar with from our four genres of pop, rock, hip hop, and R&B.

The second section collected quantitative data regarding the participants' preferences for playlist selection, recommendation to a friend, acoustic similarity, and personal preference. In this section, participants were presented with six song tuples — three song tuples associated with each of their two selected genres — and asked to answer questions regarding each song tuple. The song tuples were shown by genre, with the ordering of the song tuples within each genre as well as the ordering of the genres themselves being randomized. Additionally, within each song tuple, the ordering of the B1 and B2 songs was also randomized for every participant.

For each song tuple, the participants were first asked to listen to clips of the first 30 seconds of the A1 song and the two B1/B2 songs. The length of 30 seconds was chosen firstly to minimize fatigue and restrict the survey to a reasonable length, and secondly to give the user a sufficiently long sample to form a solid impression of the music [20]. Once they had listened to the clips, they were prompted to answer the following questions regarding the two B1/B2 songs:

1. If you were creating a playlist with Song A1 and either B1 or B2, which one would you pick?
2. If you had a friend who likes Song A1 by Artist A and you wanted to introduce them to Artist B, which song would you recommend to them first?
3. Which song is most acoustically similar to Song A1?
4. Which song do you prefer?

In addition to choosing either B1 or B2, participants were also allowed to answer "About the same" if they could not decide. Finally, we also asked participants if they recognized any of the songs or artists presented in the song tuple, for which they could answer "Yes", "No", or "Maybe".

In the third section, participants were asked the following open-ended questions:

1. When deciding to pick specific songs for a playlist, what do you consider to be most important?
2. When deciding songs to recommend to a friend, what do you consider to be most important?
3. When comparing songs in terms of acoustic similarity, what do you consider to be most important?

These three questions were intended to collect qualitative data regarding how participants made their decisions in the second section of the survey.

3. SURVEY DATA

Participants were recruited on a voluntary basis with no compensation via email lists and social media from the authors' academic and social circles, based primarily within the United States. We received responses from 113 participants, with 103 of these considered valid. From these participants, the youngest represented age group was 17 or younger, while the oldest was 61 - 70, with the median age group being 21 - 25. 58.25% of participants identified as male, while 41.75% identified as female. Participants indicated usage of seven different streaming services, with Spotify being by far the most popular. Some participants also indicated usage of older music playback technologies, such as iTunes libraries, CDs, and vinyl records.

3.1 Song Tuple Responses

From the 103 valid responses, we counted a total of 612 song tuple evaluations, with 317 of these considered valid. We considered a song tuple evaluation valid based on the following two criteria. Firstly, the participant must recognize the A1 song and must not recognize the B1 and B2 songs. This is because our set of questions regarding a song tuple were intended to be asked under the assumption that the A1 song was known, and the B1 and B2 songs were both unknown. Secondly, the participant must spend at least 60 seconds evaluating the tuple. We defined 60 seconds per tuple as the threshold at which a participant is considered to have faithfully answered our questions. Based on these criteria, we discarded responses which did not contain any valid tuple evaluations, and we discarded any invalid tuple evaluations from the remaining responses. Each song tuple was evaluated by at least 14 participants, with a mean of 26.4 participants.

3.2 Qualitative Feedback

One author coded the responses to the three open-ended questions from the third section of the survey. Initial categories (e.g., texture content, rhythmic content, context, preference, playlist mix) and subcategories (e.g., energy, tempo, variety) were formed after making a first pass over 95 non-empty responses out of a total of 103 survey responses. Each response was then coded according to these categories and subcategories. The results are found in Table 2.

The main takeaway from our coding exercise is to note that, as expected, acoustic similarity (Q1) is almost entirely related to audio content, while playlist song selection (Q2) and song recommendation (Q3) involve both audio content

Table 1. The 12 song tuples across four genres, consisting of 3 songs per tuple, used in our survey. For each song tuple, the first song listed is the well-known reference song (A1), followed by the more acoustically similar B1/B2 song, and then the less acoustically similar B1/B2 song. The first line for each of our four concepts (acoustic similarity, playlist selection, recommendation, and personal preference) represents the number of participants respectively that selected the first place song / indicated that they were the same / selected second place song based on acoustic similarity. The second line represents the p-value for a binomial hypothesis test in which the null hypothesis assumes that B1/B2 songs are equally likely to be selected by a participant. Song tuples are sorted by these p-values for acoustic similarity. Bold font indicates statistically significant differences at the $\alpha < 0.05$ level. Italics indicate that participants generally preferred the less acoustically similar song.

Genre	Artist	Song	Acoustic Similarity	Playlist Selection	Recommend	Preference
Rock	The Beatles	Here Comes The Sun	45 / 12 / 5	42 / 15 / 5	42 / 15 / 5	31 / 18 / 13

Table 2. Coded responses from 95 participants to questions about acoustic similarity, playlist selection, and music recommendation. The numbers in parenthesis reflect the number responses for each label.

Q1: When comparing songs in terms of **acoustic similarity**, what do you consider to be most important?	
Textural content (71)	Instrumentation (37), Vibe/tone (15), Vocal tone (13), Production/mix (6)
Rhythmic content (65)	Tempo (37), Beat/rhythm (24), Bass line (3), Repetitiveness (1)
Dynamic content (13)	Energy (8), Dynamic range(2), Volume (2), Brightness/intensity (1)
Musicological concepts (8)	Genre/style (4), Mood/expression (4)
Harmonic content (7)	Key (5), Chords (2)
Context (3)	Lyrics (3)

Q2: When deciding to pick specific songs for a **playlist**, what do you consider to be most important?	
Textural content (49)	Vibe/tone (25), Acoustic similarity (18), Instrumentation (5), Vocal tone (3)
Musicological concepts (32)	Mood/expression (19) , Genre/style (12), Time period (1)
Preference (17)	Personal preference (9), Personal mood (6), Catchy (1)
Playlist mix (17)	Flow between songs (10), Variety (7)
Context (13)	Lyrics (7), Theme (6)
Rhythmic content (13)	Tempo (9), Beat (4)
Dynamic content (7)	Energy (7)

Q3: When deciding songs to **recommend** to a friend, what do you consider to be most important?	
Preference (59)	Friend will like (32), Personal preference (16), Interesting to me (5), Catchy (5), Originality (1)
Textural content (30)	Acoustic similarity (20), Vibe/tone (5), Instrumentation (3), Vocal tone (2)
Musicological concepts (11)	Genre/style (11)
Context (6)	Lyrics (3), Meaning (2), Artist background (1)
Rhythmic content (3)	Beat (3)

as well as information that is not directly related to audio content such as personal preference, artist background, and lyrical meaning. That is, while audio similarity is important when creating playlists and recommending music, it is not the only factor that listeners use to make decisions.

4. DISCUSSION OF RESULTS

In this section, we address the three questions that we initially posed using the data that we collected from our user study.

4.1 RQ1: Consistency of Acoustic Similarity Judgments

The first question we explore is the extent to which judgments about acoustic similarity are consistent across many listeners. To do this, we examine how often one of the B1/B2 songs is designated as being more acoustically similar to the A1 song for each of the 12 song tuples. The third column of Table 1 reports the raw counts of how often the *winning* B1/B2 song is designated as being more, equally, or less acoustically similar by our study's participants. We also conducted a binomial hypothesis test where the null hypothesis assumes that both B1/B2 songs are equally similar to the A1 song.

In 9 of the 12 tuples, the similarity judgment was significantly ($\alpha < 0.05$) pointing in one direction [5], suggesting that there was a winner between the B1/B2 songs. The other three tuples showed majorities at or above 64% of the vote. These three tuples were the three R&B tuples that received the fewest number of evaluations, reducing the statistical power of the tests. Overall, the results suggest that listeners are somewhat consistent in their judg-

Table 3. Correlation coefficients for 317 song tuple trials when comparing pairs of acoustic similarity, playlist selection, song recommendation, and personal preference.

	Playlist	Recommend	Pref.
Aco. Similarity	0.716	0.595	0.387
Playlist		0.596	0.386
Recommend			0.116

ment of acoustic similarity even when comparing songs by similar artists.

4.2 RQ2: Relationship between Playlist Selection and Recommendation

To answer our second research question, we look at the correlation between how participants voted for B1 or B2 relative to A with respect to assessing acoustic similarity, song selection for playlist creation, music recommendation, and personal preference. In Table 3, we report the correlation coefficients between pairs of these four concepts. We also conducted a two-tailed hypothesis test for each of these correlation coefficients and found all six to be highly statistically significant, with five p-values less than 0.001 and the p-value for recommendation and preference equal to 0.038.

We see that acoustic similarity is most highly correlated with playlist selection, suggesting that listeners consider acoustic similarity to be important when constructing playlists. This high correlation is also supported by the qualitative feedback (see Table 2) in which *acoustic similarity* is explicitly mentioned as being an important consideration by 18 participants. The participants also mention a large number of acoustic concepts related to texture, rhythm, and dynamics.

---

[5] When applying a Bonferroni correction for multiple hypothesis tests, we observe that 5 of the 12 tuples have p-values less than $\alpha < 0.004$.

We also observe a high level of correlation between acoustic similarity and recommendation. This is consistent with the coded qualitative feedback (see Table 2) in which 20 participants explicitly mention the role of acoustic similarity in music recommendation. However, the slightly lower level of correlation might be attributed to the fact that preference seems to play a greater role in recommendation than acoustic similarity.

Finally, we note a lower level of correlation with personal preference. This is unsurprising since in the previous two cases, we asked participants to make judgments between B1 and B2 relative to the A1 song. It is reasonable that one of the B1/B2 songs would fit more naturally, but that the participant would personally prefer the other B1/B2 song. This, in fact, occurred in 5 of our 12 tuples (see the right most column of Table 1) suggesting that making a recommendation relative to a reference song is different from simply picking preferred songs in isolation.

4.3 RQ3: Acoustic Similarity with Acoustic Features

Here, we explore how a set of song-level content-based features are related to human judgments about acoustic similarity. The specific set of features that we use are obtained using the *Audio Features for a Track* endpoint from the Spotify Web API [6]. These eleven mid-level song features include danceability, energy, key, loudness, mode, speechiness, acousticness, instrumentalness, liveness, valence, and tempo.

Our approach involved conducting a one-tailed paired t-test over the 12 song tuples for each of the 11 audio features. For each tuple, we calculate the magnitude (absolute value) of the difference of an audio feature between the the winning B1/B2 song and the reference track A1, and the magnitude of the difference between the losing B1/B2 song and A1. Here, our alternative hypothesis is that the deviation between the winning B1/B2 song and A1 will be smaller than losing B1/B2 and A1 for a given feature. This would imply that the audio feature encodes information that is used by listeners to assess acoustic similarity.

None of the t-tests for any of the 11 audio features revealed any statistically significant differences at the 0.05 confidence level, suggesting that there is no obvious single audio feature that can be used directly to predict acoustic similarity. However, five features shown in Table 4 have a p-value less than $\alpha < 0.15$, suggesting that these features may be related to acoustic similarity. We should note that our sample size with $n = 12$ tuples is small and, as a result, the power of our hypothesis test was limited. A future study with a larger number of song tuples (i.e., more statistical power) may result in more statistically significant results.

It is interesting to note that two of these features, valence and energy, roughly correspond to the first two dimensions of Russell's classic circumspect model of affect [16] that is frequently used to model mood in emotion [9]. Tempo is a rhythmic audio feature and was explicitly mentioned by a large number of our study's participants as being important for assessing acoustic similarity (see Table 2)

Table 4. Spotify audio features for p-values less than $\alpha < 0.15$.

Acoustic Feature	p-value
valence	0.07
speechiness	0.11
tempo	0.12
liveness	0.13
energy	0.13

as well as for song selection when creating playlists. The other two features, speechiness and liveness, are less typical features that were engineered by researchers first at The Echo Nest [7] and now at Spotify [8] to describe the texture of a song. Taken together, this set of five features reflects song texture, rhythmic properties, and perceived mood, suggesting that acoustic similarity is likely to be multi-faceted.

5. CONCLUSION

In this paper, we have explored the relationships between the concepts of acoustic similarity, song selection for playlist creation, music recommendation, and personal preference. Through our user study, we have found that:

1. There is a degree of consistency among human judgments of acoustic similarity.
2. Acoustic similarity is highly correlated with playlist selection and recommendation, but not personal preference.
3. While certain acoustic features obtained seem to be related to acoustic similarity, additional evidence (i.e., more tuples) is necessary to support this with statistical certainty.

These findings are especially significant for the task of recommending songs by obscure, long-tail artists. They provide empirical support for the usage of content-based recommender systems when lack of user preference data precludes the effective functioning of collaborative filtering-based recommender systems. This can apply to both more general recommendation tasks, as well as specific ones like next-song selection for playlist generation.

Building upon the findings described in this paper, a potential avenue for further investigation would be another user study, in a similar vein to our study, but covering a much wider range of music than the 36 songs included in our study, and perhaps with fewer human evaluations per song tuple. This would allow us to determine with statistical certainty whether specific acoustic features encode information about acoustic similarity, therefore providing insight into what acoustic features should be taken into account when building a content-based recommender system [4]. Ultimately, the findings from this paper combined with additional research will aid in the development of a more effective novel-artist recommender system for Localify and other similar music recommendation services.

DRUMGAN: SYNTHESIS OF DRUM SOUNDS WITH TIMBRAL FEATURE CONDITIONING USING GENERATIVE ADVERSARIAL NETWORKS

ABSTRACT

Synthetic creation of drum sounds (e.g., in drum machines) is commonly performed using analog or digital synthesis, allowing a musician to sculpt the desired timbre modifying various parameters. Typically, such parameters control low-level features of the sound and often have no musical meaning or perceptual correspondence. With the rise of Deep Learning, data-driven processing of audio emerges as an alternative to traditional signal processing. This new paradigm allows controlling the synthesis process through learned high-level features or by conditioning a model on musically relevant information. In this paper, we apply a Generative Adversarial Network to the task of audio synthesis of drum sounds. By conditioning the model on perceptual features computed with a publicly available feature-extractor, intuitive control is gained over the generation process. The experiments are carried out on a large collection of kick, snare, and cymbal sounds. We show that, compared to a specific prior work based on a U-Net architecture, our approach considerably improves the quality of the generated drum samples, and that the conditional input indeed shapes the perceptual characteristics of the sounds. Also, we provide audio examples and release the code used in our experiments. [1]

1. INTRODUCTION

Drum machines are electronic musical instruments that create percussion sounds and allow to arrange them in patterns over time. The sounds produced by some of these machines are created synthetically using analog or digital signal processing. For example, a simple snare drum can be synthesized by generating noise and shaping its amplitude envelope [1] or, a bass drum, by combining low-frequency harmonic sine waves with dense mid-frequency components [2]. The characteristic sound of this synthesis process contributed to the cult status of electronic drum machines in the '80s.

---

[1] https://github.com/SonyCSLParis/DrumGAN

Data-driven processing of audio using Deep Learning (DL) emerged as an alternative to traditional signal processing. This new paradigm allows us to steer the synthesis process by manipulating learned higher-level latent variables, which provide a more intuitive control compared to conventional drum machines and synthesizers. In addition, as DL models can be trained on arbitrary data, comprehensive control over the generation process can be enabled without limiting the sound characteristic to that of a particular synthesis process. For example, Generative Adversarial Networks (GANs) allow to control drum synthesis through their latent input noise [3] and Variational Autoencoders (VAE) can be used to create variations of existing sounds by manipulating their position in a learned timbral space [4]. However, an essential issue when learning latent spaces in an unsupervised manner is the missing interpretability of the learned latent dimensions. This can be a disadvantage in music applications, where comprehensible interaction lies at the core of the creative process. Therefore, it is desirable to develop a system which offers expressive and musically meaningful control over its generated output. A way to achieve this, provided that suitable annotations are available, is to feed higher-level conditioning information to the model. The user can then manipulate this conditioning information in the generation process. Along this line, some works on sound synthesis have incorporated pitch-conditioning [5,6], or categorical semantic tags [7], capturing rather abstract sound characteristics. In the case of drum pattern generation, there are neural-network approaches that can create full drum tracks conditioned on existing musical material [8].

In a recent study [9], a U-Net is applied to neural drum sound synthesis, conditioned on continuous perceptual features describing timbre (e.g., boominess, brightness, depth). These features are computed using the Audio Commons timbre models. [2] Compared to prior work, this *continuous* feature conditioning (instead of using categorical labels) for audio synthesis provides more fine-grained control to a musician. However, this U-Net approach learns a deterministic mapping of the conditioning input information to the synthesized audio. This limits the model's capacity to capture the variance in the data, resulting in a sound quality that does not seem acceptable in a professional music production scenario.

In this paper, we build upon the same idea of conditional generation using continuous perceptual features,

---

[2] https://github.com/AudioCommons/ac-audio-extractor

but instead of a U-Net, we employ a Progressive Growing Wasserstein GAN (PGAN) [10]. Our contribution is two-fold. First, we employ a PGAN on the task of conditional drum sound synthesis. Second, we use an auxiliary regression loss term in the discriminator as a means to control audio generation based on the conditional features. We are not aware of previous work attempting *continuous* sparse conditioning of GANs for musical audio generation. We conduct our experiments on a dataset of a large variety of kick, snare, and cymbal sounds comprising approximately 300k samples. Also, we investigate whether the feature conditioning improves the quality and coherence of the generated audio. For that, we perform an extensive experimental evaluation of our model, both in conditional and unconditional settings. We evaluate our models by comparing the Inception Score (IS), the Fréchet Audio Distance (FAD), and the Kernel Inception Distance (KID). Furthermore, we evaluate the perceptual feature conditioning by testing if changing the value of a specific input feature yields the expected change of the corresponding feature in the generated output. Audio samples of DrumGAN can be found on the accompaniment website (see Section 4).

The paper is organized as follows: In Section 2 we review previous work on audio synthesis, and in Section 3 we describe the experiment setup. Results are presented in Section 4, and we conclude in Section 5.

2. PREVIOUS WORK

Deep Generative modeling is a topic that has gained a lot of interest during the last years. This has been possible partly due to the growing amount of large-scale datasets of different modalities [5, 11] coupled with groundbreaking research on generative neural networks [10, 12–15]. In addition to the methods listed in the introduction focusing on drums sound generation, a number of other studies have applied deep learning methods to address general audio synthesis. Autoregressive models for raw audio have been very influential in the beginning of this line of research, and still achieve state of the art in different audio synthesis tasks [5, 12, 16, 17]. Approaches using Variational Auto-Encoders [13] allow manipulating the audio in latent spaces learnt i) directly from the audio data [4], ii) by imposing musically meaningful priors over the structure of these spaces [7, 18, 19], or iii) by restricting such latent codes to discrete representations [20]. GANs have been extensively applied to synthesis of speech [21] and domain adaptation [22, 23] tasks. The first of its kind applying adversarial learning to the synthesis of musical audio is WaveGAN [3]. This architecture was shown to synthesize audio from a variety of sound sources, including drums, in an unconditional way. Recent improvements in the quality and training stability of GANs [10, 24, 25] resulted in methods that outperform WaveNet baselines on the task of audio synthesis of musical notes using sparse conditioning labels representing the pitch content [6]. A few other works have used GANs with rather strong conditioning on prior information for tasks like Mel-spectrum

inversion [26] or audio domain adaptation [27, 28]. Recently, other promising related research incorporates prior domain-knowledge into the neural network, by embedding differentiable signal processing blocks directly into the architecture [29].

3. EXPERIMENT SETUP

In this Section details are given about the conducted experiment, including the data used, the model architecture and training details, as well as the metrics employed for evaluation.

3.1 Data

In the following, we briefly describe the drum dataset used throughout our experiments, as well as the Audio Commons feature models, with which we extract perceptive features from the dataset.

3.1.1 Dataset

For this work, we make use of an internal, non-publicly available dataset of approximately 300k one-shot audio samples aligned and distributed across a balanced set of kick, snare, and cymbal sounds. The samples originally have a sample rate of 44.1kHz and variable lengths. In order to make the task simpler, each sample is shortened to a duration of one second and down-sampled to a sample rate of 16kHz. For each audio sample, we extract perceptual features with the Audio Commons timbre models (see Section 3.1.2). We perform an 90% / 10% split of the dataset for validation purposes. The model is trained on the real and imaginary components of the Short-Time Fourier Transform (STFT), which has been shown to work well in [30]. We compute the STFT using a window size of 2048 samples and 75% overlapping. The generated spectrograms are then simply inverted back to the signal domain using the inverse STFT.

3.1.2 Audio-Commons Timbre Models

The Audio Commons project [3] implements a collection of perceptual models of features that describe high-level timbral properties of the sound. These features are designed from the study of popular timbre ratings given to a collection of sounds obtained from Freesound [4]. The models are built by combining existing low-level features found in the literature (e.g., spectral centroid, dynamic-range, spectral energy ratios, etc), which correlate with the target properties enumerated below. All features are defined in the range [0-100]. We employ these features as conditioning to the generative model. For more information, we direct the reader to the project deliverable.[3]

- **brightness**: refers to the clarity and amount of high-pitched content in the analyzed sound. It is computed from the spectral centroid and the spectral energy ratio.

---

[3] https://www.audiocommons.org/2018/07/15/audio-commons-audio-extractor.html
[4] https://freesound.org/

- **hardness**: refers to the stiffness or solid nature of the acoustic source that could have produced a sound. It is estimated using a linear regression model on spectral and temporal features extracted from the attack segment of a sound event.

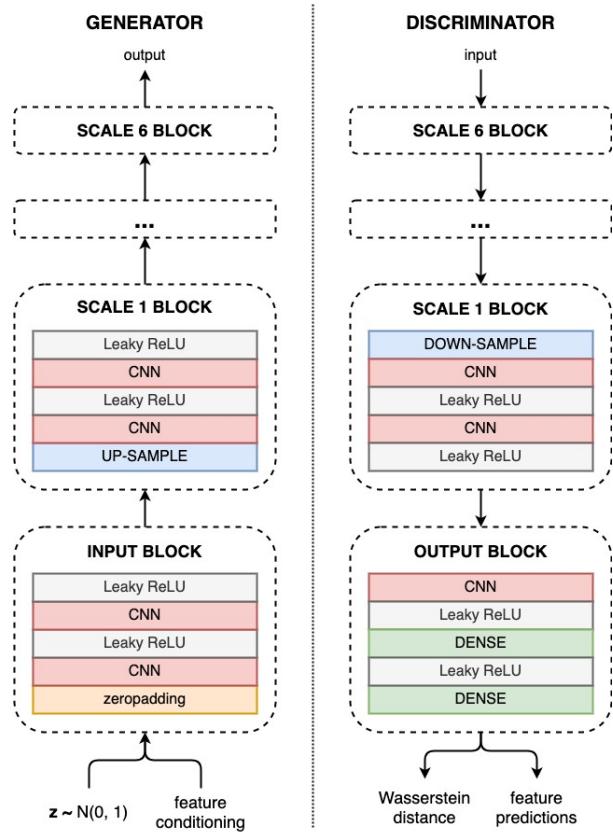
- **depth**: refers to the sensation of perceiving a sound coming from an acoustic source beneath the surface. A linear regression model estimates depth from the spectral centroid of the lower frequencies, the proportion of low frequency energy and the low-frequency limit of the audio excerpt.

- **roughness**: refers to the irregular and uneven sonic texture of a sound. It is estimated from the interaction of peaks and nearby bins within frequency spectral frames. When neighboring frequency components have peaks with similar amplitude, the sound is said to produce a 'rough' sensation.

- **boominess**: refers to a sound with deep and loud resonant components. [5]

- **warmth**: refers to sounds that induce a sensation analogous to that caused by the physical temperature. [5]

- **sharpness**: refers to a sound that might cut if it were to take on physical form. [5]

3.2 Architecture Design and Training Procedure


In the following, we will introduce the architecture and training of DrumGAN, and will briefly describe the baseline model against which DrumGAN is evaluated.

3.2.1 Generative Adversarial Networks

Generative Adversarial Networks (GAN) are a family of training procedures inspired by game theory, in which a generative model competes against a discriminative adversary, that learns to distinguish whether a sample is real or fake [14]. The generative network, or Generator (G), estimates a distribution p_g over the data x by learning a mapping of an input noise p_z to data space as $G_\theta(z)$, where G_θ is a neural network implementing a differentiable function with parameters θ. Inversely, the discriminator $D_\beta(x)$, with parameters β is trained to output a single scalar indicating whether the input comes from the real data p_r or from the generated distribution p_g. Simultaneously, G is trained to produce samples that are identified as real by the discriminator. Competition drives both networks until an equilibrium point is reached and the generated examples are indistinguishable from the original data. For a Wasserstein GAN, as used in our experiments, the training criterion is formally defined as

$$\min_G \max_D \Gamma(D, G) = \frac{1}{N} \sum_i D(x^i) - D(G(z^i)). \quad (1)$$

---

[5] Description of the calculation method for this feature is not available to the authors at current time.

Figure 1. Proposed architecture for DrumGAN (see Section 3.2 for details).

3.2.2 Proposed Architecture

In the proposed architecture, the input to G is a concatenation of the 7 conditioning features c, described in Section 3.1.2, and a random vector z with 128 components sampled from an independent Gaussian distribution. The resulting vector is fed through a stack of convolutional and box up-sampling blocks to generate the output signal $x = G_\theta(z; c)$. In order to turn the 1D input vector into a 4D convolutional input, it is zero-padded in the time- and frequency-dimension (i.e., placed in the middle of the convolutional input with $128 + 7$ convolutional maps). As depicted in Figure 1, the generator's input block performs this zero-padding followed by two convolutional layers with ReLU non-linearity. Each scale block is composed of one box up-sampling step at the input and two convolutional layers with filters of size $(3, 3)$. The number of feature maps decreases from low to high resolution as {256, 128, 128, 128, 64, 32}. Up-sampling of the temporal dimension is just performed after the 3rd scale block. We use a Leaky ReLU as activation functions and apply pixel normalization after every convolutional step (i.e., normalizing the norm over the output maps at each position). The discriminator D is composed of convolutional and down-sampling blocks, mirroring G's configuration. Given a batch of either real or generated STFT audio, D estimates the Wasserstein distance between the real and generated distributions [24], and predicts the perceptual features ac-

companing the input audio in the case of a real batch, or those used for conditioning in the case of generated audio. In order to promote the usage of the conditioning information by G, we add an auxiliary Mean Squared Error (MSE) loss term to the objective function, following a similar approach as in [31]. We use a gradient penalty of 10.0 to satisfy the Lipschitz continuity condition of Wasserstein GANs. The weights are initialized to zero and we apply layer-wise normalization at run-time using He's constant [32] to promote an equalized learning. A mini-batch standard deviation layer before the output block of D encourages G to generate more variety and, therefore, reduce mode collapse [25].

3.2.3 Training Procedure

Training follows the procedure of Progressive Growing of GANs (PGANs), first used for image generation [10], which has been successfully applied to audio synthesis of pitched sounds [6]. In a PGAN, the architecture is built dynamically during training. The process is divided into training iterations that progressively introduce new blocks to both the Generator and the Discriminator, as depicted in Figure 1. While training, a blending parameter α progressively fades in the gradient derived from the new blocks, minimizing possible perturbation effects. The models are trained for 1.1M iterations on batches of 30, 30, 20, 20 12 and 12 samples, respectively for each scale. Each scale is trained during 200k iterations except the last one, which is trained up to 300k iterations. We employ Adam as the optimization method and a learning rate of 0.001 for both networks.

3.2.4 The U-Net Baseline

As mentioned in the introduction, we compare DrumGAN against a previous work tackling the exact same task (i.e., neural synthesis of drums sounds, conditioned on the same perceptual features described in Section 3.1.2), but using a U-Net architecture operating in the time domain [9]. The U-Net model is trained to deterministically map the conditioning features (and an envelope of the same size as the output) to the output. The dataset used thereby consists of 11k drum samples obtained from Freesound[6], which includes kicks, snares, cymbals, and other percussion sounds (referred to as *Freesound drum subset* in the following).

3.3 Evaluation

Assessing the quality of synthesized audio is hard to formalize making the evaluation of generative models for audio a challenging task. In the particular case of GANs, where no explicit likelihood maximization exists, a common evaluation approach is to measure the model's performance in a variety of surrogate tasks [33]. As described in the following, we evaluate our models against a diverse set of metrics that capture distinct aspects of the model's performance.

---

[6] www.freesound.org

3.3.1 Inception Score

The *Inception Score (IS)* [25] penalizes models that generate examples that are not classified into a single class with high confidence, as well as models whose examples belong to only a few of all the possible classes. It is defined as the mean KL divergence between the conditional class probabilities $p(y|x)$, and the marginal distribution $p(y)$ using the class predictions of an Inception classifier (see Eq. 2). We train our Inception Net[7] variant to classify kicks, snares and cymbals, from Mel-scaled magnitude STFT spectrograms using the same train/validation split of 90% / 10%, used throughout our experiments. As additional targets, we also train the model to predict the extracted perceptual features described in Section 3.1.2 (using mean-squared error cost).

$$IS = \exp\big(E_x[KL(p(y|x)||p(y))]\big) \qquad (2)$$

3.3.2 Fréchet Audio Distance (FAD)

The *Fréchet Audio Distance* compares the statistics of real and generated data computed from an embedding layer of a pre-trained VGG-like model[8] [34]. FAD fits a continuous multivariate Gaussian to the output of the embedding layer for real and generated data and the distance between these is calculated as:

$$FAD = ||\mu_r - \mu_g||^2 + tr(\Sigma_r + \Sigma_g - 2\sqrt{\Sigma_r \Sigma_g}) \quad (3)$$

where (μ_r, Σ_r) and (μ_g, Σ_g) are the mean and covariances of the embedding of real and generated data respectively. The lower the FAD, the smaller the distance between distributions of real and generated data. FAD is robust against noise, consistent with human judgments and more sensible to intra-class mode dropping than IS.

3.3.3 Kernel Inception Distance (KID)

The KID measures the dissimilarity between samples drawn independently from real and generated distributions [35]. It is defined as the squared Maximum Mean Discrepancy (MMD) between representations of the last layer of the Inception model (described in Section 3.3.1). A lower MMD means that the generated p_g and real p_r distributions are close to each other. We employ the unbiased estimator of the squared MMD [36] between m samples $x \sim p_r$ and n samples $y \sim p_g$, for some fixed characteristic kernel function k, defined as

$$
\begin{aligned}
MMD^2(X,Y) = \quad & \frac{1}{m(m-1)}\sum_{i\neq j}^{m} k(x_i, x_j) \\
+ \quad & \frac{1}{n(n-1)}\sum_{i\neq j}^{n} k(y_i, y_j) \\
- \quad & \frac{2}{mn}\sum_{i=1}^{m}\sum_{j=1}^{n} k(x_i, y_j).
\end{aligned}
\qquad (4)
$$

Here, we use an inverse multi-quadratic kernel (IMQ) $k(x,y) = 1/(1 + ||x-y||^2/2\gamma^2)$ with $\gamma^2 = 8$ [37], which

---

[7] https://github.com/pytorch/vision/blob/master/torchvision/models/inception.py
[8] https://github.com/google-research/google-research/tree/master/frechet_audio_distance

has a heavy tail and, hence, it is sensitive to outliers. We borrow this metric from the Computer Vision literature and apply it to the audio domain. We train a separate inception model on the FreeSound drum subset used for the U-Net baseline experiments (see Section 3.2.4). This is done to allow comparison of the inception-based metrics with DrumGAN. Since the FreeSound drum subset doesn't contain annotations of the instrument type, we train our variant on just the feature regression task, and restrict our comparison to KID and FAD, as these metrics do not compare class probabilities but embedding distributions.

3.3.4 Feature Coherence

We follow the methodology proposed by [9] for evaluating the feature control coherence. The goal is to assess whether increasing or decreasing a specific feature value of the conditioning input yields the corresponding change of that feature in the synthesized audio. To this end, a specific feature i is set to 0.2 (low), 0.5 (mid), and 0.8 (high), keeping the other features and the input noise fixed. The resulting outputs $x_{\text{low}}^i, x_{\text{mid}}^i, x_{\text{high}}^i$ are then evaluated with the Audio Commons Timbre Models (yielding features fx^i). Then, it is assessed if the feature of interest changed as expected (i.e., $fx_{\text{low}}^i < fx_{\text{mid}}^i < fx_{\text{high}}^i$). More precisely, three conditions are evaluated: E1: $fx_{\text{low}}^i < fx_{\text{high}}^i$, E2: $fx_{\text{mid}}^i < fx_{\text{high}}^i$, and E3: $fx_{\text{low}}^i < fx_{\text{mid}}^i$. We perform these three tests 1000 times for each feature, always with different random input noise and different configurations of the other features (sampled from the evaluation set). The resulting accuracies are reported.

4. RESULTS AND DISCUSSION

In this section, we briefly describe our subjective impression when listening to the model output, and we will give an extended discussion on the quantitative analysis, including the comparison with the baseline U-Net architecture.

4.1 Subjective Evaluation and Generation Tests

The results of the qualitative experiments discussed in this section can be found on the accompaniment website. [9] In general, conditional DrumGAN seems to have better quality than its unconditional counterpart and substantially better than the U-Net baseline (see Section 3.2.4). In the absence of more reliable baselines, we argue that the perceived quality of DrumGAN is comparable to that of previous state-of-the-art work on adversarial audio synthesis of drums [3].

We also perform radial and spherical interpolation experiments (with respect to the Gaussian prior) between random points selected in the latent space of DrumGAN. Both interpolations yield smooth and perceptually linear transitions in the audio domain. We notice that radial interpolation tend to change the percussion type (i.e., kick, snare, cymbal) of the output, while spherical interpolation affects other properties (like within-class timbral characteristics and envelope) of the synthesized audio. This gives a hint on how the latent manifold is structured.

rand feats	2.09	1.36	**0.70**
unconditional	**2.19**	1.07	1.00

Table 1. Results of Inception Score (IS, higher is better), Kernel Inception Distance (KID, lower is better) and Fréchet Audio Distance (FAD, lower is better), scored by DrumGAN under different conditioning settings, against real data and the unconditional baseline. The metrics are computed over 50k samples, except for *val feats*, where 30k samples are used (i.e., the validation set size).

	KID	FAD
real data	0.04	0.00
real feats	1.45	3.09
rand feats	13.94	3.17

Table 2. Results of Kernel Inception Distance (KID) and Fréchet Audio Distance (FAD), scored by the U-Net baseline [9] when conditioning the model on feature configurations from the real data and on randomly sampled features. The metrics are computed over 11k samples (i.e., the Freesound drum subset size).

4.2 Quantitative Results

4.2.1 Scores and Distances

Table 1 shows the DrumGAN results for the Inception Score (IS), the Kernel Inception Distance (KID), and the Fréchet Audio Distance (FAD), as described in Section 3.3. These metrics are calculated on the synthesized drum sounds of the model, based on different conditioning settings. Besides the unconditional setting of DrumGAN (*unconditional*), we use feature configurations from the train set (*train feats*), the valid set (*valid feats*), and features randomly sampled from a uniform distribution (*rand feats*). The IS of DrumGAN samples is close to that of the real data in most settings. This means that the model outputs are clearly assignable to either of the respective percussion-type classes (i.e., low entropy for kick, snare, and cymbal posteriors), and that it doesn't omit any of them (i.e., high entropy for the marginal over all classes). The IS is slightly reduced for random conditioning features, indicating that using uncommon conditioning configurations makes the outputs more ambiguous with respect to specific percussion types. While FAD is a measure for the perceived quality of the individual sounds (measuring co-variances within data instances), the KID reflects if the generated data overall follows the distribution of the real data. Therefore, it is interesting to see that *rand feats* cause outputs which overall do not follow the distribution of the real data (i.e., high KID), but the individual outputs are still plausible percussion samples (i.e., low FAD). This quantitative result is in-line with the perceived quality of

Feature	U-Net			DrumGAN		
	E1	E2	E3	E1	E2	E3
brightness	**0.99**	**0.99**	**1.00**	0.74	0.71	0.70

average	**0.83**	**0.76**	**0.78**	0.76	0.72	0.72

Table 3. Mean accuracies for the feature coherence tests on samples generated with the baseline U-Net [9] and DrumGAN.

the generated samples (see Section 4.1). In the unconditional setting, both KID and FAD are worse, indicating that feature conditioning helps the model to both generate data following the true distribution, overall, as well as in individual samples.

Table 2 shows the evaluation results for the U-Net architecture (see Section 3.2.4). As the train / valid split for the Freesound drum subset (on which the U-Net was trained) is not available to the authors, the U-Net model is tested using the features of the full Freesound drum subset (*real feats*), as well as random features. Also, we do not report the IS for the U-Net architecture, as it was trained on data without percussion-type labels, making it impossible to train the inception model on such targets. As a baseline, all metrics are also evaluated on the real data on which the respective models were trained. While evaluation on the real data is straight-forward for the IS (i.e., just using the original data instead of the generated data to obtain the statistics), both KID and FAD are measures usually *comparing* the statistics between features of real and generated data. Therefore, for the *real data* baseline, we split the real data into two equal parts and compare those with each other in order to obtain KID and FAD. The performance of the U-Net approach on both, KID and FAD is considerably worse than that of DrumGAN. While the KID for *real feats* is still comparable to that of DrumGAN (indicating a distribution similar to that of the real data), the high FAD indicates that the generated samples are not perceptually similar to the real samples. When using random feature combinations this trend is accentuated moderately in the case of FAD, and particularly in the case of the KID, reaching a maximum of almost 14. This is, however, intelligible, as the output of the U-Net depends only on the input features in a deterministic way. Therefore, it is to expect that the distribution over output samples changes fully when fully changing the distribution of the inputs.

4.2.2 Feature Coherence

Table 3 shows the accuracy of the three feature coherence tests explained in Section 3.3.4. Note that, as both models were trained on different data, the figures of the two models are not directly comparable. However, also reporting the figures of the U-Net approach should provide some context on the performance of our proposed model. In ad-

dition, as both works use the same feature extractors and claim that the conditional features are used to shape the same characteristics of the output, we consider the figures from the U-Net approach a useful reference. We can see that for about half the features, the U-Net approach reaches close to 100% accuracy. Referring to the descriptions on how the features are computed it seems that the U-Net approach reaches particularly high accuracies for features which are computed by looking at the global frequency distribution of the audio sample, taking into account spectral centroid and relations between high and low frequencies (e.g., brightness and depth). U-Net performs considerably worse for features which take into account the temporal evolution of the sound (e.g., hardness) or more complex relationships between frequencies (e.g., roughness). While DrumGAN performs worse on average on these tests, the results seem to be more consistent, with less very high, but also less rather low accuracy values (note that the random-guessing baseline is 0.5 for all the tests). The reason for not performing better on average may lie in the fact that DrumGAN is trained in an adversarial fashion, where the dataset distribution is enforced, in addition to obeying the conditioned characteristics. In contrast, in the U-Net approach the model is trained deterministically to map the conditioning features to the output, which makes it easier to satisfy the simpler characteristics, like generating a lot of low- or high-frequency content. However, this deterministic mapping results in a lower audio quality and a worse approximation to the true data distribution, as it can be seen in the KID and FAD figures, described above.

5. CONCLUSIONS AND FUTURE WORK

In this work, we performed percussive sound synthesis using a GAN architecture that enables steering the synthesis process using musically meaningful controls. To this end, we collected a dataset of approximately 300k audio samples containing kicks, snares, and cymbals. We extracted a set of timbral features, describing high-level semantics of the sound, and used these as conditional input to our model. We encouraged the generator to use the conditioning information by performing an auxiliary feature regression task in the discriminator and adding the corresponding MSE loss term to the objective function. In order to assess whether the feature conditioning improves the generative process, we trained a model in a completely unsupervised manner for comparison. We evaluated the models by comparing various metrics, each reflecting different characteristics of the generation process. Additionally, we compared the coherence of the feature control against previous work. Results showed that DrumGAN generates high-quality drum samples and provides meaningful control over the audio generation. The conditioning information was proven useful and enabled the network to better approximate the real distribution of the data. As future work, we will focus on scaling the model to work with audio production standards (e.g., 44.1kHz sample rate, stereo audio), and implement a plugin that can be used in a conventional Digital Audio Workstation (DAW).

ABSTRACT

Unison singing is the name given to an ensemble of singers simultaneously singing the same melody and lyrics. While each individual singer in a unison sings the same principle melody, there are slight timing and pitch deviations between the singers, which, along with the ensemble of timbres, give the listener a perceived sense of "unison". In this paper, we present a study of unison singing in the context of choirs; utilising some recently proposed deep-learning based methodologies, we analyse the fundamental frequency (F0) distribution of the individual singers in recordings of unison mixtures. Based on the analysis, we propose a system for synthesising a unison signal from an *a cappella* input and a single voice prototype representative of a unison mixture. We use subjective listening tests to evaluate perceptual factors of our proposed system for synthesis, including quality, adherence to the melody as well the degree of perceived unison.

1. INTRODUCTION

Throughout history, singing has been an important cultural activity for humans, serving for propagation of beliefs and ideas amongst the masses as well as for social entertainment. The social aspect led to gatherings of people singing in a group, which evolved into polyphonic ensemble singing with multiple voices singing counterpoint melodies in complex harmonies. A group of people singing in such an ensemble is commonly termed as a choir and the focus of our study is on one setting of such choirs consisting of four voices known as Soprano, Alto, Tenor and Bass (SATB). Each voice within an SATB ensemble has its own function and melodic range in the whole. SATB is one of the most widely studied, documented, and practiced forms of choirs with numerous dedicated conservatories across Europe, highlighting the cultural importance of the art form. Within each of the SATB voices, it is common to have multiple singers of similar

vocal range singing the same melody simultaneously, in a form known as unison singing. While all the singers in a unison sing the same melody, it is impossible for a group of two or more people to perfectly synchronize and sing the exact same pitch line. Each singer has their own natural micro-deviations, both in terms of timing and pitch, from the prescribed score and their own distinct timbre. The combination of micro-deviations and the ensemble of timbres leads to the perception of unison, wherein several singers are perceived to be singing a single pitch contour [1], and is the main focus of our study.

Pitch and fundamental frequency (F0) are related but not equivalent terms. While the F0 generally refers to the physical frequency of vibrations of the vocal folds for a singing voice signal, pitch refers to an abstract perceptual concept which has been found to be closely correlated to the F0. Frequency is usually measured in Hertz, representing the number of cycles of a periodic signal per second, whereas pitch is described in terms of perceptual units like *cents*. The cent is a unit defined on a logarithmic scale, as a measure of the ratio between the frequency in Hertz and a base frequency, commonly chosen to be $440\,\mathrm{Hz}$, as shown in Equation 1.

$$f_{cents} = 1200 \cdot log_2 \frac{f_{hertz}}{440} \qquad (1)$$

Thus defined, the cent is correlated to the perceptually relevant musical unit of an equally tempered semitone. Specifically, one semitone spans $100\,\mathrm{cents}$. Examined individually, the pitch of the singers in a unison can be represented by the F0 of each individual singer's vocal signal, this can be tested by synthesising a time-varying sinusoid with the frequency of the signal. However, when the individual signals are added the resultant pitch is not merely the sum of F0 value, and the methodology of synthesising a sum of sinusoids as with single singers fails to produce the same perceptual result due to physical phenomena such as beating, among others. Past studies have utilized artificial unison mixes created by the use of a vowel only singing voice synthesizer to study the perception of a single pitch contour in a unison [1]. Other areas of past research related to unison singing include single voice to unison synthesis models, based on creating voice clones with variations in the input [2, 3]. Fuelled by the deep learning revolution, singing voice synthesizers have evolved over the

last few years, allowing us to take a step further both into exploring the perception of unison and into effective solo voice to unison synthesis. We build on the work done by Ternström [1] by leveraging recently proposed synthesis methodologies to synthesize a single voice prototype representing the melodic and linguistic content of a unison mixture. This allows use to further test the hypothesis of a single F0 contour representative of the perceived pitch of a unison via subjective listening tests. We also verify the author's findings by analysing a set of real recordings of unison singing. In addition, we propose a methodology combining previous research and recently developed techniques to synthesize a unison mixture from a single voice input. We follow the basic methodology used by Schnell et al. [2] to create voice clones with variations in three aspects; pitch, timing and timbre, and use perceptual evaluation tests to evaluate the effect of each of these parameters on the perception of the sense of a unison.

The rest of the paper is structured as follows. Section 2 discusses previous works pertinent to our study. We then present the analysis of the choir recordings in Section 3, including a description of the dataset of choir recordings, the methodology used for the analysis and the results of the analysis. The synthesis methodology we use for synthesizing voice clones and the single voice prototype of the unison mixture is described in Section 4. Section 4.3 presents the perceptual evaluation methodology used and the results of the perceptual tests. Finally, we present a discussion on our findings in the analysis of the choir and the perceptual evaluation of the synthesis in Section 6.

2. RELATED WORK

We divide the description of related works into three sections: past studies into the analysis of the perception of unison, previous works on synthesising unison mixtures from choirs and recently proposed deep-learning based methodologies what we will use for analysis and synthesis.

2.1 Analysis Of Unison Perception

The perception of pitch dispersion has previously been studied in [1], wherein the author used synthesized singing voice stimuli to investigate the preferences of expert listeners in unisons. In the study, pitch dispersion is defined as the bandwidth of the fundamental frequency and its harmonic partials across individual singers in a unison. It is suggested that this dispersion is related to the *flutter*—small variations in F0 that are too fast to be perceived as pitch variations. The concept of pitch *scatter* is presented in the study as the standard deviation over voices in the mean F0: the average F0 computed over the duration of each tone of a song. The study concludes that a *scatter* of 0 cents–5 cents was preferred by the participants while a *scatter* of 5 cents–14 cents was seen as the limit of tolerance before dissonance was reported. In addition, the author also highlights several differences between solo and ensemble singing. For instance, a single performer produces tones with well-defined properties: pitch, timing,

loudness, timbre, while an ensemble of performers produces sounds with statistical distributions of each of these properties.

A similar method for modelling *scatter* in choir sections was presented by Cuesta et al. [4] using small windows to compute the standard deviation between individual F0s in the unison. This study used real recordings of choral singing instead of synthesised stimuli, presenting a mathematical model for dispersion rather than a perceptual evaluation. For the dataset used in the research, F0 (or pitch) dispersion was found to be in the range of 20 cents–30 cents for all SATB voice sections, being slightly larger in the Bass.

Another recent study focused on the analysis of F0 in vocal music is work by Weiss et al. [5], where the authors proposed an approach to measure intonation quality of choir recordings. They create an ideal 12-tone equal temperament grid, and then calculate the deviation of each F0 and its partials to their theoretical position in the grid. The overall deviation is computed as a weighted sum of each partial's deviation. This method enables the analysis of the overall intonation of a full choir recording, but does not account for the deviations within sections of the choir.

2.2 Unison Synthesis

Signal processing techniques have previously been utilised to synthesize choir unison by adding several clones of a monophonic *a cappella* signal with uncorrelated pitch, timing, and timbre deviations. Most particularly, Pitch Synchronous Overlap Add (PSOLA) methods [2] have been exploited as an analysis-synthesis framework to decompose the vocal signal into a set of constituent waveforms representing successive pitch periods of the signal. Pitch and timing deviations are added to the vocal signal using time stretching and pitch shifting techniques to create voice clones, which are combined to form the output unison signal.

Other proposed methodologies for creating a unison output from an *a cappella* signal include morphing the spectral and pitch components of the vowels of the input signal as in [3]. The methodology's effectiveness is constrained to low tempo inputs . Random modulation of beating partials to create a choral effect [6] has also been used.

2.3 Deep Learning For Analysis and Synthesis

For our work, we build on the work done in [1] and [4], modelling the perceptual pitch contour of a unison mixture as a single F0 contour. To this end, we use a recently proposed Convolutional Representation for Pitch Estimation (CREPE) methodology [7] for extracting F0 contours from real world recordings of individual singers in a choir setting as well the F0 contour of unison mixture created by combining the individual voices. This methodology uses a series of convolutional operations on the waveform of the input signal and outputs a probability distribution over a discrete representation of the underlying F0 contour of the signal across a series of time-frames.

To synthesize the single voice prototype representing a unison mixture output and the voice clones for creating a unison mixture from a single voice input, we adapt the methodology proposed by Chandna et al. [8], which allows for the re-synthesis of a solo single voice from a musical mixture input via the underlying linguistic features. This methodology builds on the idea of re-synthesizing a vocal signal from a musical mixture by estimating the parameters of a vocoder synthesizer [9] and uses an encoder built of a bank of bi-directional long short-term memory (LSTM) recurrent neural networks (RNNs) to estimate a continuous representation of the underlying linguistic features present in the input mixture signal. The continuous representation is singer-independent and language agnostic, and was initially proposed for zero-shot voice conversion via an autoencoder network [10]. The linguistic features can then be used to generate the spectral envelope of the vocal signal in the mixture, providing the singer identity. The authors of [8] proposed two decoders for this process, a Singer Dependent Network (SDN) which takes the singer identity as a one-hot vector, and a Singer Independent Network (SIN) which intrinsically learns the singer identity from the given input. The spectral envelope is then combined with the F0, extracted via an external algorithm, to synthesize the vocal signal. While the original framework was proposed for extracting a singing voice from a pop/rock musical mixture, we adapt the SDN network for synthesising a unison mixture from an *a cappella* input and the SIN network for synthesizing an *a cappella* singing voice from a unison mixture. The adaptations we apply are described in Section 4. The SIN and SDN models [8] were trained on a proprietary dataset with 12 hours of data comprising 205 songs by 45 male and female singers, and we have obtained a copy of the trained model with permission from the relevant authorities for our study.

3. ANALYSIS OF CHOIR RECORDINGS

We analyse the variations between individual singers in a unison in terms of variance in pitch and timing. Below, we present the dataset that we use in our analysis, followed by the methodology used for analysis, and finally the results of our analysis.

3.1 Datasets

We analyse the Choral Singing Dataset (CSD) [4], which includes monophonic recordings of 3 choral pieces: *Niño Dios d'Amor Herido*, written by Francisco Guerrero, *Locus Iste*, written by Anton Bruckner, and *El Rossinyol*, a Catalan popular song. There are 16 different singers for each song with 4 singers for each of the four parts; Soprano, Alto, Tenor and Bass. The dataset also includes manually corrected F0 annotations for each track.

3.2 Analysis Methodology

To analyse inter-singer variance in **pitch**, the first step is the extraction of an F0 contour from a unison mixture of singers. We aim to study the behavior of a monophonic

F0 extractor in such cases, assuming that we have a sufficiently balanced unison performance, where the contribution of each singer is similar in terms of volume and energy. To this end, we use CREPE [7] to extract the fundamental frequency of the unison mixture created by summing and normalizing all corresponding individual singers in each vocal part of the recordings. This is termed as $EstF0_U$.

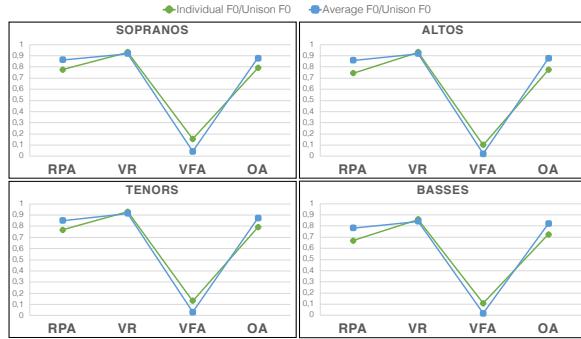
We then measure the resemblance of the estimated $EstF0_U$ to each of the manually annotated F0 tracks and to the mean $F0_m$ [1] . We use standard evaluation metrics for melody extraction including *Raw Pitch Accuracy (RPA), Overall Accuracy (OA), Voicing Recall (VR)* and *Voicing False Alarm (VFA)* between the $EstF0_U$, the average the mean $F0_m$, and each individual singer curve, $GTF0_i$ [2]

Once we have verified the accuracy of the extraction system, we build a statistical model for the individual contours in the unison, as suggested by [1]. In our model, the framewise F0 of an individual singer, $F0_i$, can be represented as a distribution of values around the mean $F0_m$ with a deviation of F_{devi}, as shown in Equation 2

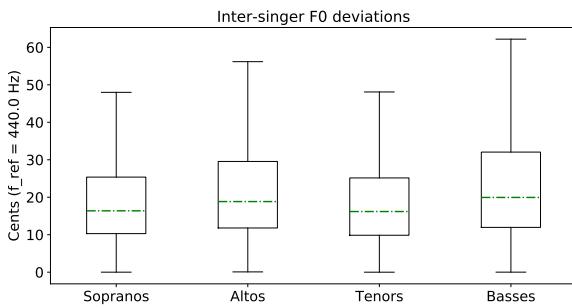
$$F0_i = F0_M + F_{devi} \qquad (2)$$

This equation also allows us to define the $F0_{i+1}$ of a singer in terms of the $F0_i$ of another singer in the unison as

$$F0_{i+1} = F0_m + F_{devi+1}$$
$$F0_{i+1} - F0_i = F_{devi+1} - F_{devi}$$
$$F0_{i+1} = F0_i + F_{devi+1} - F_{devi}$$
$$F0_{i+1} = F0_i + \Delta F0_s \qquad (3)$$

Where we define $\Delta F0_s$ as the inter-singer deviation, represented by Equation 4. For each pair of singers in the unison, we compute the frame-wise difference between the corresponding F0 contours in cents. For this calculation, only frames with positive F0 values, also known as *voiced* frames, were considered. We average these inter-singer deviations across time and songs, and obtain a single value for each group, i.e., SATB.


$$\Delta F0_s = \frac{\displaystyle\sum_{i=1}^{n} \sum_{j=i+1}^{n} \left| F0_i - F0_j \right|}{\binom{n}{2}} \qquad (4)$$

where the sub-index s indicates the choir section, $s \in [S, A, T, B]$, and n is the number of singers. In our use case, $n = 4$.


To study **timing** deviations, we focus in the transitions from *voiced* to *unvoiced*, and vice-versa—where singers are not entirely in sync. We call these regions *transition regions*, where some of the singers in the mixture are voiced

---

[1] Note that the average F0 value has to be adjusted for timing differences between the individual singers. To this end, we define the average to be zero (unvoiced frame) if and only if all individual values for that frame are zero. for all other cases, the average is calculated only accounting for the non-zero values.

[2] We use the `mir_eval` library [11] for this evaluation, and we use a pitch tolerance of 30 cents

Figure 1. Resemblance of the estimated unison $EstF0_U$ estimation to each individual $GTF0_i$ contour (green) and the average (blue) using pitch evaluation metrics averaged across each choir section.

Figure 2. Inter-singer deviations in cents averaged across the whole dataset for each choir section. Deviations are calculated using Equation 4.

and others are unvoiced, with a positive or zero F0. We measure the length of all the transition regions in every unison from the CSD, and then average across choir sections.

3.3 Analysis Results

A summary of the results of the comparison between the fundamental frequency extracted by CREPE, $EstF0_U$, and the manually corrected fundamental frequency, $GTF0_i$ is illustrated in Figure 1, along with a comparison with the mean, $F0_m$. We observe that all sections follow the same pattern with similar metric values, and the unison F0 estimated by CREPE, $EstF0_U$, is closer to the average $F0_m$, than to the individual contours. In addition, all metrics improve when we compare the average F0 curve to the extracted F0 contour from the unison: RPA, VR and OA are higher in the blue plots, while VFA is lower. We can thus use the pitch estimated by CREPE, $EstF0_U$, as a representative of the mean single pitch contour perceived in a unison mixture [1].

The calculated $\Delta F0_s$ is shown in Figure 2. We observe an inter-singer deviation in the range of $0\,\text{cents}$–$50\,\text{cents}$, with a mean of around $20\,\text{cents}$. This value, representing the inter-singer deviation in the unison mixtures, is comparable to the pitch dispersion studied by Cuesta et al. [4]. While the methodology for modelling is different, these re-

Section	Average Timing Deviation $\pm$ Standard Deviation
Soprano	0.134 ± 0.039 sec
Alto	0.093 ± 0.0024 sec
Tenor	0.100 ± 0.021 sec
Bass	0.124 ± 0.021 sec

Table 1. Timing deviations averaged across the CSD. These values measure the time span in which all singers in the unison transition from voiced to unvoiced, and vice-versa, averaged across all transitions in each song.

sults are in accordance with their reported per-section pitch dispersion: larger in the bass section, smaller in the sopranos, and very similar for altos and tenors.

Table 1 shows the results of the timing analysis. We observe an average timing deviation of $0.1\,\text{s}$ between the voices in the unison for all parts of the choir.

4. SYNTHESIS METHODOLOGY

We present two synthesis models, Solo To Unison (STU) to synthesize voice clones for creating a unison mixture from a single voice input, and Unison to Solo (UTS) for synthesizing single voice prototype representing the melodic and linguistic content of a unison mixture input [3]. Similar to the work presented by Schnell et al [2], we decompose the input signal into the F0, harmonic spectral envelope, and aperiodicity envelope. However, instead of using Pitch Synchronous Overlap Add (PSOLA) methods, we utilize the WORLD vocoder [12], which has been shown to be an effective vocoding system for singing voice synthesis [13, 14, 14]. Similar to [14], we use truncated frequency warping in the cepstral domain [15] to reduce the dimensions of the harmonic components from 1024 to 60 log Mel-Frequency Spectral Coefficients (MFSCs) with an all-pole filter with warping coefficient $\alpha = 0.45$. In addition, we use bandwise aperiodic analysis to reduce the dimensionality of aperiodic features to 4. For the rest of this paper, we refer to these 64 features together as the spectral envelope.

4.1 Unison to Solo (UTS)

As shown in Figure 3, we first perform a short-time Fourier transform (STFT) to extract a spectrogram from the input waveform. The magnitude part of the spectrogram is passed through the encoder proposed in [8] to extract a continuous representation of the linguistic features present in the unison mixture input. The linguistic features are decoded via the SIN network [8] to generate the spectral envelope for vocal synthesis. This envelope is combined

---

[3] Audio examples are provided as complementary material at `https://pc2752.github.io/unison_analysis_synthesis_examples/` and the source code with the trained models are available at `https://github.com/MTG/content_choral_separation`

with the pitch contour output from CREPE [7], $F0_U$ to synthesise the single voice prototype representing the unison mixture input.

4.2 Solo to Unison (STU)

The analysis part of the STU case follows a similar methodology, as we extract the linguistic features and the $EstF0_i$ contour from the input *a cappella* voice signal. To create voice clones with pitch and timing deviations, we add randomly sampled noise from a normal distribution with a mean of 0 and a variable standard deviation, termed as std. This represents the inter-singer deviation, $\Delta F0_s$, and allows us to model the $F0_{i+1}$ of the clone as per Equation 3. Timing deviations are added by shifting the voiced portions of the input signal or the portions between tow blocks of silence of more than $80\,\text{ms}$ by a variable amount, randomly sampled from a normal distribution of mean 0 and standard deviation ts. The values of std and ts are based on our analysis of the Choral Singing Dataset presented in Section 3.3

Finally, for variations in timbre, we generate the spectral envelope of a variable number singers, ns, of the same gender as the input using the SDN network proposed in [8]. This is based on our analysis presented in Section 3.3. There was no overlap between singers in the set used for training the synthesis model and the singers in the Choral Singing Dataset used for evaluation. The various voice clones are added together and normalized in amplitude to produce the final unison output. We evaluate various combinations of std, ts, and ns on their impact of the perception of unison.

4.3 Perceptual Evaluation Methodology

We used subjective listening tests with low and high anchors, as modified versions of the MUSHRA-methodology [16] to evaluate subjective criteria of the synthesis produced by our analysis synthesis framework.

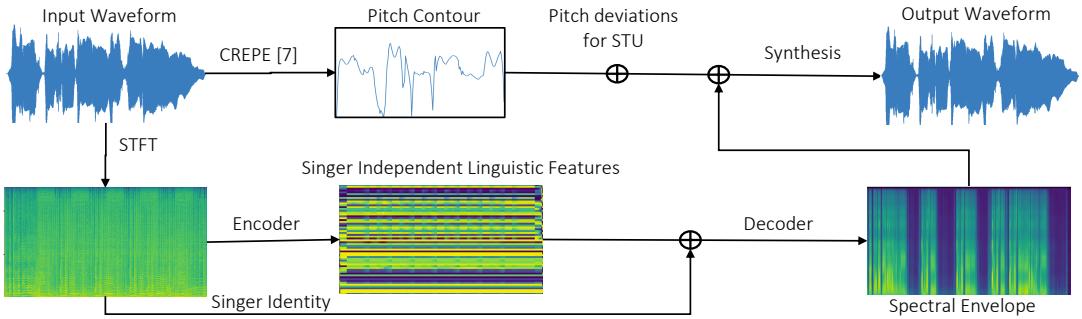
While there are several aspects that could be evaluated, we focused on three keys aspects: adherence to melody, perception of unison, and audio quality. For each aspect, the participants were presented with 4 questions, one for each part of the SATB choir, and were asked to rate the test cases in the question on a continuous scale of 1–5 with respect to a presented reference. The test case and references provided pertained to the the same section of the song and were between $7\,\text{s}$–$10\,\text{s}$ each. The parameters used for these tests are described below for each aspect.

4.3.1 Adherence to melody and lyrics

For this aspect, we wanted to see the similarity of the perceived pitch contour of the output for both the UTS and STU cases to that of a ground truth unison mixture. To this end, the reference provided to the participant was a ground truth unison sample made by summing the corresponding four individual singers of a part to form a unison mixture. This reference is referred to as *REFU*. The participants were asked to rate test samples which included the single voice prototype of the unison as output by the UTS

system, referred to as *UTS*. In addition, we evaluated the output of STU with a pitch deviation with parameter std set to $50\,\text{cents}$, the acceptable limit of pitch deviations, as shown by our analysis in Section 3.3 and suggested by [1]. Four singers were used for generating this test case, with parameter ns set to 4, and it is referred to as *STU_PS*. We also evaluated the output of the UTS system with both pitch and timing deviations with parameter ts set to $40\,\text{ms}$. While our analysis in Section 3.3 suggests that higher values of ts could have been used, we found that increasing the value beyond $40\,\text{ms}$ leads to a unacceptable level of degradation in output quality. We refer to this test case as *STU_PTS*. We also provided a lower anchor of a sample of the same length from another vocal part.

4.3.2 Perception of unison

Unison is a loosely defined perceptual aspect, the cognition of which we aim to study here. For this, we provide a reference of a ground truth unison sample created in the same manner as described above, *REFU*. Given this, participants were asked to rate outputs from the STU system based on their similarity to the reference in terms of the perception of unison. In addition to the *STU_PTS* and *STU_PS* cases with pitch, timing and timbre variance, we also tested the case for just timing and singer variation, referred to as *STU_TS* and a case with just pitch and timing deviations, referred to as *STU_PT*, timbral changes were not done for the voice clones used for creating this test case. The *a cappella* sample of a single singer singing the same example as the reference was provided as a lower anchor.


4.3.3 Audio Quality

Audio quality is another subjective measure that is well defined in literature but not easily understood by non-expert participants. For the evaluation, we set an upper limit of audio quality to the resynthesis of a single voice recording with the WORLD vocoder *REFS* and a lower limit to the resynthesis of a unison mixture with the same *RESSYN-THU*. The test cases provided to the participants were the same as those provided for the adherence to melody case, except that the lower anchor was changed.

4.4 Perceptual Evaluation Results

There were 17 participants in our evaluation, of which 10 had prior musical training. To account for inter-participant variance in subjective evaluation, the opinion score for each question was normalized over ratings for the reference and the lower anchor before calculating the mean opinion scores (MOS) and the standard deviations in opinion scores, presented in Table 2.

The subjective nature of the perceptual aspects evaluated must be taken into account for the evaluation and the mean opinion scores are indicative of preferences rather than absolute measures of quantity. It can be observed that the perceived adherence to melody for the prototypical *a cappella* voice synthesized by the UTS model has higher preference than the STU models, although a high variance

Figure 3. The synthesis framework. The magnitude part of the spectrogram of the input is passed through the encoder from [8] to extract linguistic content. For the UTS case, this is passed to the decoder along with a learned embedding to the SIN decoder [8] to generate the spectral envelope. For STU, the linguistic features are passed to the SDN decoder along with a one-hot vector of the same gender as the input. F0 is extracted from the input waveform via CREPE [7]. Both the envelope and the F0 are used to synthesize the output voice. For the STU case, timing deviations are further added before summing with the input and normalizing.

Test Case	Adherence To Melody	Unison Perception	Audio Quality
UTS	3.6 ± 0.93		2.1 ± 0.65
STU_PS	3.3 ± 0.83	2.6 ± 0.85	2.8 ± 0.45
STU_PTS	2.9 ± 1.14	3.2 ± 0.96	3.1 ± 0.63
STU_TS		2.3 ± 1.11	
STU_PT		3.0 ± 1.23	

Table 2. Mean Opinion Score (MOS) $\pm$ Standard Deviation for the perceptual listening tests across the test cases provided. The models shown corresdond to the Unison to Solo (UTS) model, the Solo to Unison with pitch, timing and singer variations, indicated by the addition of the letters P,T and S as suffixes to the abbreviation, respectively. The scores for each question were normalized by the responses to the upper and lower limits for the responses defined in section 4.3.

is observed in the ratings for the same. The unison perception evaluation shows that the variations in either timing or pitch alone are not as preferred as variations in both aspects together. Timbre variations do not have as significant an effect on perception of unison as variances in timing and pitch. The evaluation of audio quality shows room for improvement in the synthesis of the voice signals. This can partly be attributed to the use of the WORLD vocoder [12] and we believe that this can be improved on in the future using recently proposed neural synthesis techniques.

5. CONCLUSIONS

We have presented an analysis of the Choral Singing Dataset, building on the work presented in [1]. In accordance with the analysis done by [4], we observe deviation in the range of $0\,\text{cents}$–$50\,\text{cents}$ between the F0 contours of the individual singers in the unison mixtures in the dataset. We further note an timing deviation of $0.1\,\text{s}$ between singers in unison in the dataset.

We then used this analysis along with recently proposed deep-learning based methodologies to present a synthesis system for a unison mixture from a single voice input and a single voice prototype synthesis representing the melodic and linguistic content of a unison mixture input. Based on these systems, we were able to conduct a perceptual evaluation of the unison, further supporting the claim of [1] that the a mixture of different voices singing in unison is perceived to have a single pitch. In addition, we found that pitch and timing deviations together are important for the perception of the unison, and that variations in either aspect alone is insufficient for such. However, timbre variations were not found to be as relevant.

We present this work as the first step into the analysis of an under-explored research area, hoping to fuel further discussion on the topic. While interesting from an academic standpoint, the systems we present also have several commercial applications such as creating a unison choral effect to be used in music production as well as for transposition and transcription, in conjunction with the work presented in [17]. We also plan to incorporate the presented work with [18], for complete source separation for choral recordings.

ABSTRACT

Open-source software libraries for audio/music analysis and feature extraction have a significant impact on the development of Audio Signal Processing and Music Information Retrieval (MIR) systems. Despite the abundance of such tools on the native computing platforms, there is a lack of an extensive and easy-to-use reference library for audio feature extraction on the Web. In this paper, we present *Essentia.js*, an open-source JavaScript (JS) library for audio and music analysis on both web clients and JS-based servers. Along with the Web Audio API, it can be used for efficient and robust real-time audio feature extraction on the web browsers. *Essentia.js* is modular, lightweight, and easy-to-use, deploy, maintain and integrate into the existing plethora of JS libraries and Web technologies. It is powered by a WebAssembly back-end of the Essentia C++ library, which facilitates a JS interface to a wide range of low-level and high-level audio features. It also provides a higher-level JS API and add-on MIR utility modules along with extensive documentation, usage examples, and tutorials. We benchmark the proposed library on two popular web browsers, Node.js engine, and Android devices, comparing it to the native performance of Essentia and Meyda JS library.

1. INTRODUCTION

The Web has become one of the most used computing platforms with billions of web pages served daily, and JS being an essential part of building modern web applications. Using HTML, CSS, and JS, developers can make dynamic, interactive, and responsive web pages by implementing custom client-side scripts. At the same time, the developers can also use cross-platform run-time engines like Node.js [1] to write server-side code in JS. The flexibility of using JS on both server and client ends of web

---

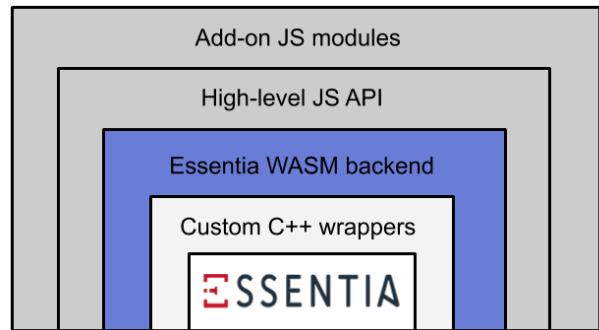
[1] https://nodejs.org

applications arguably makes it one of the most used computer programming languages in the recent years [2]. JS is also widely used as an entry-level programming language by the thinkers from design, art, computer graphics, architecture, and spaces in between where audio processing and analysis can be relevant.

With the adoption of both HTML5 and the W3C Web Audio API specifications [14], modern web browsers are capable of audio processing, synthesis, and analysis without any third-party dependencies on proprietary software. This allows developers to move most of the audio processing code from the server to the client and can provide better scalability and deployment, considering that the web-client has computational resources for the required processing. Web Audio API provides a JS interface to various predefined nodes for audio processing, synthesis, and analysis. Even though the provided capabilities are limited, the API includes the *ScriptProcessorNode* for developers to add custom JS code for audio processing. [2] The design of this node has been criticized by the audio developer community since it runs the JS audio processing code on the main UI thread, which can result in unreliable performance and audio glitching [15]. As an alternative, *AudioWorklet* [10] has been introduced to mitigate this design issue to a great extent by allowing running custom audio processing code on a dedicated audio thread. It also allows bi-directional communication between the audio thread and the control thread of Web Audio API asynchronously using the web message ports.

Despite all of these recent developments of Web Audio technologies, the Audio Signal Processing and MIR communities still lack reliable and modular software tools and libraries that could be easily used for building audio and music analysis applications for web browsers and JS run-time engines. To the best of our knowledge, Meyda [11] and JS-Xtract [18] are the few available JS libraries that are ready-to-use and have implementations of a limited set of MIR audio features. [3] The lack of more extensive alternatives is not surprising, given that writing a new JS audio analysis library from scratch would require a lot of effort. Also, JS code for audio processing are prone to performance issues due to the *just-in-time* (JIT) compilation and garbage collection overhead, which can be critical for

---

[2] https://www.w3.org/TR/webaudio/#scriptprocessornode


[3] As of May 2020, Meyda only has 20 MIR algorithms.

real-time audio and music analysis tasks. Due to these reasons, researchers and developers often rely on server-side audio processing solutions using the existing native MIR tools for writing the required web applications.

Over the last two decades, the existing software tools for audio analysis have been mostly written in C/C++, Java and Python and delivered as standalone applications, host application plug-ins, or as software library packages. Software libraries with a Python API, such as Essentia [7], Librosa [23], Madmom [6], Yaafe [22] and Aubio [8], have been especially popular within the MIR community due to rapid prototyping and rich environment for scientific computations. Meanwhile, the libraries with a native C/C++ back-end offered faster analysis [24] and were often required for writing industrial audio applications. Various web applications for audio processing and analysis have been developed using these tools. Spotify API [4] (formerly Echonest), Freesound API [13] and AcousticBrainz [25] are examples of web services providing precomputed audio features to the end users via a REST API. Besides, numerous web applications were built for aiding tasks such as crowd sourcing audio annotations [9, 12], audio listening tests [19, 26] and music education platforms [1, 21] to mention a few. All these services manage their audio analysis on the server, which may require a significant effort and resources to scale to many users.

With the recent arrival of WebAssembly (WASM) support on most of the modern web browsers [16], one can safely port the existing C/C++ audio processing and analysis code into the Web Audio ecosystem using compiler toolchains such as Emscripten. [5] WASM is a low-level assembly-like language with a compact binary format that runs with near-native performances on modern web browsers or any WebAssembly-based stacks without compromising security, portability and load time. WASM code was found to be comparatively faster than JS code [17] and generates no garbage from the code and can run within *AudioWorkletProcessor*. [6] This makes it an ideal solution to the problems that were previously hindering us from building efficient and reliable JS MIR libraries for the web platform [20]. However, taking full advantage of all these features can be challenging because it requires understanding concurrent programming wrapped with several JS APIs and dealing with cross-compilation and linking of the native code. Even for experienced developers, compiling native code to WASM targets, generating JS bindings, and integrating them in a regular JS processing code pipeline can be cumbersome. Hence, it is essential that an ideal JS MIR software library should encapsulate and abstract all these steps and be packaged as a compact build which is easy-to-use and extendable using a high-level JS API. Besides the JS API, the potential users might also need utility tools that are often required while building MIR-based projects, such as plotting audio features on an HTML page, ready-to-use feature extractors, and possible integration with web-based

Figure 1: Overview of the *Essentia.js* library in terms of its abstraction levels.

machine learning frameworks.

In [24], the authors evaluated a wide range of MIR software libraries in terms of *coverage*, *effort*, *presentation*, *time-lag* and found Essentia [7] [7] to be an overall best performer with respect to these criteria. Essentia is an open-source library for audio and music analysis released under the AGPLv3 license providing a wide range of optimized algorithms (over 250 algorithms) that are successfully used in various academic and industrial large-scale applications. Essentia includes both low-level and high-level audio features, along with some ready-to-use features extractors. And, it provides an object-oriented interface to fine tune each algorithm in detail. Given all these advantages and that the code repository is consistently maintained by its developers, it is a good potential choice for porting into WASM target for the web platform.

In this paper, we present *Essentia.js*, an open-source JS library for audio and music analysis on the web, released under the AGPLv3 license. It allows building audio analysis and MIR applications for web browsers and JS engines such as Node.js. It provides straightforward integration with the latest W3C Web Audio API specification allowing efficient real-time audio feature extraction on the web browsers. Web applications written using the proposed library can also be cross-compiled to native targets such as for PCs, smartphones, and IoT devices using the JS frameworks like Electron [8] and React Native. [9]

The rest of the paper is organized as follows. Section 2 outlines the design choices, software architecture and various components of *Essentia.js*. An overview of potential use-cases and usage examples are detailed in Section 3. A detailed benchmarking of *Essentia.js* across and against various platforms and alternative JS libraries can found in Section 4. Finally, we conclude in Section 5.

2. ESSENTIA.JS

Essentia.js is much more than just JS bindings to the Essentia C++ library. It was developed with coherent design and functional objectives that are necessary for building an efficient and easy-to-use MIR library for the Web. In this

section, we discuss our design choices, the architecture, and various components of *Essentia.js*. Figure 1 shows an overview of these components.

2.1 Design and Functionality

We chose the following goals and design decisions for developing the library:

- **User-friendly API and utility tools**. The Web is a ubiquitous computing platform, and an ideal JS MIR library should provide a simple, user-friendly API while being highly configurable for advanced use cases. *Essentia.js* ships with a simple JS API and add-on utility modules with a fast learning curve for new users. The main JS API is composed of a singleton class with methods implementing most of the functionality (each method is an algorithm in Essentia). These methods are automatically generated from the upstream C++ code and documentation using code templates and scripting as described in Sections 2.2 and 2.3. We also provide add-on modules with helper classes for feature extraction and visualisation that can be used for rapid prototyping of web applications. A quick preview of the JS API can be seen in Listing 2.

- **Modularity and extensibility**. Just like Essentia itself, the *Essentia.js* codebase is modular by design. It contains a large amount of configurable algorithms that can be arranged into the desired audio processing chains. The add-on utility modules shipped with the library leverage this functionality to build custom feature extractors.

- **Web standards compliance.**Web browsers provide a standard set of tools for loading and processing audio files using the HTML5 Audio element [10] and the Web Audio API. *Essentia.js* rely on these standard features for loading audio files or for streaming real-time audio from various device sources. It also provides seamless integration with the latest tools in the Web Audio ecosystem such as AudioWorklets, Web Workers, [11] WASM and *SharedArrayBuffer*. In addition, JS conforms to the ECMAScript specification [12] and it is evolving fast with new features added to the language every year. For backward and forward compatibility of our JS code, we wrote our JS API using Typescript (Section 2.3).

- **Lightweight and few dependencies**. It is important for a JS library to be lightweight since the load times of JS code can directly impact the UI/UX and performance of web applications. This includes having fewer dependencies, which also makes the library much more maintainable. Taking this into account, *Essentia WASM backend* is built without any third-party software dependencies of the Essentia library except for Kiss FFT. [13] It includes

the majority of the algorithms in Essentia, [14] while the few excluded algorithms can be still integrated into the WASM backend by compiling and linking with the required third-party dependencies using our build tools (Section 2.5). Besides, all the JS code in the library is passed through a code compression process to achieve lightweight builds for the web browsers. With all these efforts we were able to achieve builds of *Essentia.js*, including the WASM backend and the JS API, as small as 2.5MB approximately. We also provide tools for custom lightweight builds of the library that only include a subset of the selected algorithms to further reduce the build size (Section 2.5).

- **Reproducibility**. Using the WASM backend of Essentia ensures identical analysis results across various devices and native platforms on which Essentia has been previously extensively used and tested. Remarkably, *Essentia.js* allows reproducing a large amount of existing code and research based on Essentia as well as, to a certain extent, other libraries. In particular, it is possible to use *Essentia.js* to reproduce common input audio representations for the existing machine learning models, enabling their usage in web applications.

- **Easy installation**. *Essentia.js* is easy to install and integrate with new or existing web projects. It is available both as a package on NPM [15] and as static builds on our public GitHub repository. In addition, we also provide continuous delivery network (CDN) through open source web services.

- **Extensive documentation**. We provide a complete API reference together with the instructions to get started, tutorials, and interactive web application examples. [16] The documentation is built automatically using JS-doc [17] and the algorithm reference is generated from the upstream Essentia C++ documentation using Python scripts.

2.2 Essentia WASM backend

As already mentioned, the core of the library is powered by the *Essentia WASM backend*. It contains a lightweight WASM build of Essentia C++ library along with custom JS bindings for using it in JS. This backend is generated in multiple steps.

Firstly, the Essentia C++ library is compiled to LLVM assembly [18] using Emscripten. Emscripten [28] is a LLVM to JS compiler which provides a wide range of tools for compiling the C/C++ code-base or the intermediate LLVM builds into various targets such as *asm.js* [19] and WASM. Secondly, we need a custom C++ interface in order to generate the corresponding JS bindings which would allow us access the algorithms in Essentia on the JS side. We used

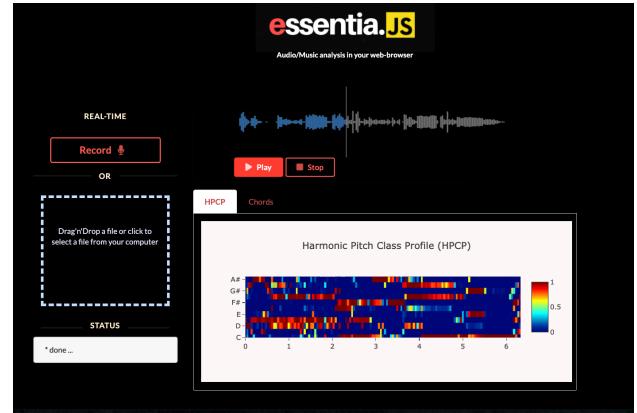
[11] https://w3c.github.io/workers/
[12] http://ecma-international.org/ecma-262
[13] https://github.com/mborgerding/kissfft

[14] As of May 2020, over 200 algorithms are supported.
[15] https://www.npmjs.com
[16] https://mtg.github.io/essentia.js
[17] https://jsdoc.app
[18] https://llvm.org
[19] http://asmjs.org

Embind [4] for generating this C++ interface that binds Essentia native code to JS.

Writing custom JS bindings for all Essentia algorithms can be tedious considering their large amount. Hence, we created Python scripts to automate the generation of the required C++ code for the C++ wrapper from the upstream library Python bindings. Using this scripts, it is possible to configure which algorithms to include in the bindings by their name and category. Therefore, it is possible to create extremely lightweight builds of the library with only a few specific algorithms required for a particular application. The *Essentia WASM backend* is built by compiling the generated wrapper C++ code and linking with the precompiled Essentia LLVM using Emscripten.

Essentia WASM backend provides compact WASM binary files along with the JS bindings to over 200 Essentia algorithms. We provide these binaries and a JS glue code for both asynchronous and synchronous import of Essentia WASM backend, covering a wide range of use cases. The build for asynchronous import can be instantly loaded into a HTML page. The synchronous-import build supports the new ES6 style class imports characteristic of the modern JS libraries. This build can be also seamlessly integrated with AudioWorklet and Web Workers for better performance demanding web applications.


2.3 High-level JS API

Even though it is possible to use the *Essentia WASM backend* with its bindings directly, they have limitations due to the specifics of using *Embind* with Essentia: a user needs to manually specify all parameter values for the algorithms because the default values are not supported. This is cumbersome and to solve this issue we developed a high-level JS API written using Typescript [5]. Typescript is a typed superset of JS that can be compiled to various ECMA targets of JS. In addition, this gives us the benefit of having a typed JS API which can provide better exception handling. Again we used custom Python scripts and code templates to automatically generate the Typescript wrapper in a similar way to the C++ wrapper for the WASM backend. The high-level JS API of *Essentia.js* provides a singleton class *Essentia* with all the algorithms and helper functions encapsulated as its methods All the algorithm methods are configurable similarly to the Essentia's C++/Python API itself. Listing 1, shows an example of using the high-level API of *Essentia.js*.

2.4 Add-on utility modules

Essentia.js is shipped with a few add-on modules to facilitate common MIR tasks. These add-on modules are written entirely in Typescript using the *Essentia.js* high-level JS API. Currently, we provide two add-on modules:

- **essentia.js-extractor** contains predefined feature extractors for common MIR tasks, computing BPM, beat positions, pitch, predominant melody, key, chords, chroma features, MFCC, etc. Each extractor implements the entire processing chain starting from audio input and outputs the resulting track-level or frame-level features. These extractors are configurable as well.

Figure 2: Screenshot of a example web application that use *Essentia.js* and its add-on modules.

- **essentia.js-plot** provides helper functions for visualization of MIR features, allowing both real-time and offline plotting in a given HTML element. It uses the *Plotly.js* data visualization library, which has a design layout and functionalities much alike of Matplotlib, [20] and is easily configurable. Currently, we provide object-oriented classes for plotting basic MIR features like melody/pitch contours, spectrograms, chroma, MFCC, etc. The module is functionally similar to the *display* module in Librosa [23].

A full reference of the modules can be found in the documentation of the library. Both modules can be easily extended with more functionalities as per the demands of the user community.

2.5 Build and packaging tools

We provide tools for custom builds and packaging of *Essentia.js* for the developers and the end-level users:

- **Command-line interface (CLI)**. We provide CLI for building *Essentia.js* using some customised shell scripts.

- **Docker**. We provide a Docker image with static builds of Essentia with Emscripten and other development dependencies required for building *Essentia.js*.

- **Web application**. We also host a website for building custom *Essentia.js* online. [21] It allows users to select specific set algorithms and build settings.

The official *Essentia.js* builds are bundled using Rollup [22] and then packaged and hosted using NPM.

3. GETTING STARTED

In this section, we outline several usage examples and application scenarios for getting started with *Essentia.js*.

The library can be imported into a web application using the following methods:

- **HTML <script> tag**. The most simple way to use *Essentia.js* is by using it with the HTML *<script>* tag.

---

[20] https://matplotlib.org
[21] https://mtg.github.io/essentia.js-builder
[22] https://rollupjs.org

- **NPM**. *Essentia.js* can be also installed from NPM using the command `npm install essentia.js`.

- **ES6 class imports**. *Essentia.js* can be imported using the ES6 class style imports in JS. This allows to integrate the library into any modern JS framework. Listing 1 shows an example of using ES6 style imports for an offline feature extraction task.

- **CDN**. We also provide CDN links for instantly serving *Essentia.js* online using free third-party web services such as Jsdelivr [23] and Unpkg. [24]

There are a lot of potential web applications that can be built with *Essentia.js*. The library provides algorithms for typical sound and music analysis tasks, including spectral, tonal, and rhythmic characterization. In particular, it is suitable for onset detection, beat tracking and tempo estimation, melody extraction, key and chord estimation, sound and music classification, cover song similarity, loudness metering, and audio problems detection among others. Figure 2 shows the screenshot of an example web application that we include with the library. Below we outline some of the common application use cases of the library. We provide an extensive collection of analysis examples on our website. [25]

3.1 Offline feature extraction

Many MIR use cases rely on an offline audio analysis and feature extraction. Listing 1 shows a simple JS example of using the library for offline analysis of pitch and onsets. For features computed on overlapping frames, *Essentia.js* provides the *FrameGenerator* method similarly to Essentia's Python API. Frames generated by this method can be used as an input to other algorithms in the processing chain. The offline feature extraction can be run inside a Web Worker to improve the efficiency in performance-demanding web applications.

3.2 Real-time feature extraction

Essentia.js can be used for efficient real-time audio/music analysis in web browsers along with the Web Audio API. This can be done by using the *ScriptProcessorNode* or the newly introduced *AudioWorklet* in the Web Audio API:

- **ScriptProcessorNode** allows users to provide custom JS code for audio feature extraction in its `onprocess` callback. Even though the *ScriptProcessorNode* is deprecated according to the current W3C Web Audio API specifications, it is still widely used by the developers because of its cross-browser support.

- **AudioWorklet** design pattern [10] allows users to write high-performance real-time audio analysis on a dedicated audio thread. Users can write custom analysis code by extending the *AudioWorkletProcessor* and further abstract it as a node in the Web Audio API graph

```javascript
// Imports Essentia WASM backend
import {EssentiaWASM} from 'essentia-wasm.module.js';
// Imports Essentia.js core API
import Essentia from 'essentia.js-core.es.js';

// Creates Essentia.js instance
const essentia = new Essentia(EssentiaWASM);

// Instance of Web Audio API AudioContext
const audioContext = new AudioContext();
// URL of an audio file
let audioURL = "https://freesound.org/data/previews
    /328/328857_230356-lq.mp3";

// Decode audio file as Float32 typed array
const audioData = await essentia.
    getAudioChannelDataFromURL(audioURL, audioContext,
    0); // audioContext, channel number

// Convert audioData array into vector
const audioVector = essentia.arrayToVector(audioData);

// Onset detection with SuperFluxExtractor algorithm
let bt = essentia.SuperFluxExtractor(audioVector);
console.log(bt.onsets);

// Pitch estimation with PitchYinProbabilistic
    algorithm
let pyIn = essentia.PitchYinProbabilistic(audioVector,
    4096, 256); // frameSize, hopSize

console.log(pyIn.pitch);

// Shutdown Essentia.js instance and free memory
essentia.shutdown();
essentia.delete();
```

Listing 1: A simple example of offline audio feature extraction using *Essentia.js* via ES6 style imports.

using *AudioWorkletNode*. [26] Currently, the only limitation is that it is only supports in the latest Firefox and Chromium-based web browsers.

3.3 Machine learning applications

In the recent years, machine learning (ML) techniques, especially deep learning have been widely used in a wide range of MIR tasks. With the support of WebGL and WASM, modern web browsers are also capable of running ML applications. *Essentia.js* can be easily integrated with popular JS ML frameworks such as *TensorFlow.js* [27] and *Onnx.js* [27] for training and inference. Pre-trained audio ML models using features computed with Essentia as an input (e.g., mel-spectrograms, Constant-Q transform, or chroma) can be easily ported and used for inference in web browsers. In particular, Essentia now ships with a collection of pre-trained TensorFlow models for music audio tagging and classification [3]. These models can be run for inference using *Essentia.js* and *TensorFlow.js* libraries. Our *essentia.js-extractor* add-on module provides a mel-spectrogram extractor for computing the inputs to these models.

4. BENCHMARK

We tested the performance of *Essentia.js* in terms of the analysis time for common MIR audio features on various

(a) *Essentia.js*

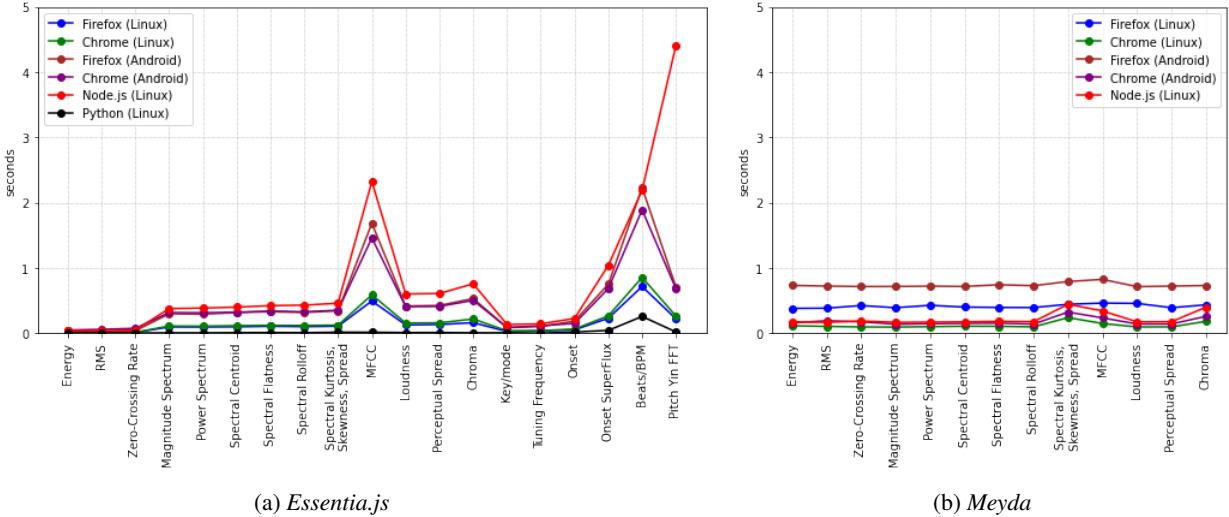
(b) *Meyda*


Figure 3: Average analysis times (in seconds) for common audio features on a 5-second music clip. "Python (Linux)" corresponds to the analysis baseline using native Essentia with Python bindings.

platforms, and compared it to the native Essentia library. In addition, we measured the analysis times for features available in *Meyda* and compared them to their *Essentia.js* counterparts. To this end, we built a set of test suites using the JS library *benchmark.js* and implemented the equivalent features using both libraries. In our benchmark we measure the time it takes for the entire processing chain to compute a feature given a 5-second audio segment as an input. The code used by *Essentia.js* is equivalent to the one for *Essentia* used in Python. The benchmarking of Python implementation was done using the library *pytest* with the *benchmark extension*. We provide the code and website to reproduce these experiments online. [28]

The results are reported in Figure 3. They include tests on five different environments:

- Linux with Chrome 84.0.4147.89 run with disabled extensions.

- Linux with Firefox 78.0.2 in private browsing mode.

- Android 9 (LineageOS 16) with Chrome 84.0.4147.89 in incognito mode.

- Android 9 (LineageOS 16) with Firefox Nightly 200727 06:00

- Linux with Node.js v.13.13.0.

The Linux computer used for all runs is a 2017 DELL XPS-15 with a 2.80GHz x 8 Intel Core i7-7700HQ processor, 16GB of RAM and Ubuntu 19.04 as OS. The mobile phone is a Xiaomi Redmi Note 7 Pro with a Snapdragon Octa-core 1.7 GHz processor and 6GB RAM. All the tests were done with the same 5 seconds audio file.

As we can see from Figure 3, the results shows that the performance of *Essentia.js* algorithms were considerably slower when running on Node.js and Firefox and Chrome on Android compared to Firefox and Chrome on Linux. Interestingly, Node.js performed worse than Firefox and

Chrome on Android, which was not expected. This is probably because different vendors have slightly different implementations of WASM support in their platforms or due to some other reasons yet to be found. In addition, WASM is a relatively new technology in active development. [29] Many proposals for improving its performance such as SIMD optimizations and multi-thread support are under way. We also aim to do detailed benchmarking of real-time use cases and using the Web Audio API Audio Worklets in our future work.

5. CONCLUSIONS

We have presented *Essentia.js*, an open-source JavaScript library for music/audio analysis on the Web. It is based on the Essentia C++ library which is commonly used in MIR, ported to JS via WASM, and compatible with the latest technologies in the Web Audio ecosystem. To the best of our knowledge, this is the most comprehensive library for audio analysis and MIR, which can be run on web browsers as well as JS server applications. We hope that the library will contribute to the creation of new online music technology tools in educational, industrial, and creative contexts. The source code of the library is publicly available in our Github repository. [30] Everyone is encouraged to contribute to the library.

In our future work, we will focus on improving the performance of the library along with expanding the add-on modules, particularly on providing pre-trained audio ML models for audio analysis, classification, and synthesis on the web client. We also aim to develop interesting web applications that go beyond typical MIR tasks to attract and build a diverse user community. The detailed information about the library is available at the official web page. [31] It contains the complete documentation, usage examples and tutorials needed for one to get started.

ON THE CHARACTERIZATION OF
EXPRESSIVE PERFORMANCE IN CLASSICAL MUSIC:
FIRST RESULTS OF THE *CON ESPRESSIONE* GAME

ABSTRACT

A piece of music can be expressively performed, or interpreted, in a variety of ways. With the help of an online questionnaire, the *Con Espressione* Game, we collected some 1,500 descriptions of expressive character relating to 45 performances of 9 excerpts from classical piano pieces, played by different famous pianists. More specifically, listeners were asked to describe, using freely chosen words (preferably: adjectives), how they perceive the expressive character of the different performances. In this paper, we offer a first account of this new data resource for expressive performance research, and provide an exploratory analysis, addressing three main questions: (1) how similarly do different listeners describe a performance of a piece? (2) what are the main dimensions (or axes) for expressive character emerging from this?; and (3) how do measurable parameters of a performance (e.g., tempo, dynamics) and mid- and high-level features that can be predicted by machine learning models (e.g., articulation, arousal) relate to these expressive dimensions? The dataset that we publish along with this paper was enriched by adding hand-corrected score-to-performance alignments, as well as descriptive audio features such as tempo and dynamics curves.

1. INTRODUCTION

In the Western classical music tradition, music exists at an interplay of creative intentions of composer, performers and listeners. Composers encode their ideas using written notation (i.e., musical scores), and performers bring these ideas to life, guided by the expression markings, performance traditions, and their own creative imagination. Each performance can sound very different from the next.

Much of the research on musical expression has focused on what pieces express through attributes of their musical structure [1–3]. There has been much focus on the expression of *emotion* in particular (e.g., [4–8]); however, a comprehensive description of the expressive character of a performance includes additional, not specifically emotion-related aspects. The aim of this research is to find the dimensions of musical expression that can be attributed to a performance, as perceived and described in natural language by listeners.

Within the classical music tradition, there is already a practice of assigning verbal descriptors to aspects of musical expression. For example, instructions related to expressive character are sometimes marked on the score by the composer with a fixed set of (mostly) Italian terms (e.g., *Allegro*, *dolce*). Many of those terms describe emotions, but they describe a wide range of other aspects as well, including movement analogies and metaphors (e.g., free, flowing) [9].

Using an online questionnaire, the *Con Espressione* Game (CEG), which is part of the research project of the same name [10], we collected verbal descriptors of expressive performances. In this paper we present first results on three main questions: (1) can we observe any consistency in the way listeners perceive and describe *expressive character*?; (2) can we identify main descriptive dimensions along which these characterizations can be organized?; and (3) how are these dimensions related to measurable qualities (or parameters) from audio recordings, or to performance information extracted from these?

The rest of this paper is structured as follows: Section 2 points to some related work. Section 3 describes the CEG and the collected data. We continue the paper with individual sections addressing the three main questions we want to study: Section 4 presents results on how similar/consistent the characterizations of the participants are, Section 5 focuses on analyzing the main descriptive dimensions. Section 6 presents results relating performance and audio features to the expressive dimensions. Section 7 discusses the results of these experiments. Finally, Section 8 concludes the paper.

2. RELATED WORK

In this section we provide a few pointers to related work on research on music emotion and expressive performance, and on characterizing musical expression. A full overview is beyond the scope of this paper.

From a musicological and philosophical viewpoint, the study of musical expression has focused on music as in composition [1,2], although there is a trend in recent times to include and recognize both the role of the performer and the role of the listener. Some recent papers have focused on developing mid-level features that capture qualities of musical recordings that relate to perceptual aspects of the music [11, 12] . For an overview of literature on emotion in music, we refer the reader to [3] and [13].

Computational models of expressive performance are a means to study principles of performance in quantitative terms. In Western classical music, much of this work has focused on establishing relationships between structural aspects of a musical score and quantifiable aspects of a performance such as expressive timing and dynamics. At the intersection of research on music emotion and computational models of performance is the study of the relation between performance parameters (timing, dynamics) and emotion [4–8]. For an overview of computational modeling of music performance, we refer the reader to [14].

Particularly relevant to the current study are adjective lists for describing musical expressiveness, including the seminal work by Hevner [15] and its more recent updates [16, 17]. Hevner identified several clusters of adjectives that describe musical expression. Many of these clusters relate to emotions, and include aspects such as *'happy'* and *'sad'*. Schaerlaeken et al. [18] conducted a large study to investigate the use of metaphors for describing Western classical music. They propose the Geneva Musical Metaphors Scale (GEMMES), which comprises 5 metaphorical scales including aspects like *flow, movement, force, interior* and *wandering*. The focus of their study was on characterization of different pieces of music, rather than on description of the character of different expressive performances. A related study [9] presents a perception-based clustering of expressive musical terms (i.e., performance directives such as *catabile* and *leggiero*), relating these terms to locations in Russell's arousal–valence space [19]. Murari et al. [20] study of listeners' characterization of music using non-verbal sensory scales.

3. THE *CON ESPRESSIONE* GAME

We collected our data through a Web-based questionnaire ("CEG"), where participants listened to several performances of each of 9 classical piano pieces. They were then asked to describe the performance in free text (preferably adjectives, as many as they liked), concentrating on the performative aspects and not on the piece itself. The target phenomenon thus is what we would call the *expressive character* of performances. Users could also select their favorite performance of each piece. Upfront, a few general questions were asked regarding their level of mu-

Figure 1. A word cloud of the terms in the dataset.

sical education, how often they listen to classical music, and whether they play the piano. The order of pieces and performances was randomized. Users could stop at any time.

3.1 Pieces and Responses

The CEG contains 45 performances of 9 excerpts (see Table 2). [1] The length of the excerpts was between 27 seconds and 188 seconds. The CEG was launched on the 3rd of April 2018. The questionnaire was filled out by 194 participants, out of which 88% had some kind of music education – on average 11.7 years; 179 participants answered in English, 12 in German and three in each of Russian, Spanish and Italian. On average, participants listened to the performances of 4.5 out of 9 pieces, 27 participants listened to all the 45 excerpts.

3.2 Meta-data and Annotations

We enriched the dataset by adding score-to-performance alignments for all performances in the dataset, as well as descriptive performance features. The alignments were produced by manually annotating the position of the beats in the audio files using Sonic Visualiser [21]. The scores were encoded manually and exported in MusicXML format following publicly available editions. [2] From these alignments we compute performance features such as tempo and loudness curves (see Section 6.1). The dataset is available online. [3]

4. HOW SIMILARLY DO LISTENERS DESCRIBE A PERFORMANCE OF A PIECE?

Probably the first question that arises concerns the similarity of the descriptions in the dataset, i.e., whether there are

Table 1. Performances used in the *Con Espressione* Game.

commonalities in the way listeners describe and like performances. In this section we present a series of analyses that provide different perspectives on the data.

4.1 Frequency and Distribution of Terms

Users provided 1,515 individual descriptions for a total of 3,166 terms, of which 1,415 (approx. 45%) are unique. Figure 1 shows a word cloud of the terms appearing in the dataset. Taken all answers together, each performance was described using at least 47 and at most 114 terms. The average number of terms per piece varies between 60.3 for Liszt's *Bagatelle sans tonalité* and 98.4 for Bach's *Prelude in C*. Each performance is characterized by at least 44 and at most 91 unique terms. The average number of unique terms per piece varies between 51.0 for Liszt's Bagatelle and 78.4 for Bach's Prelude.

The terms *'dynamic'*, *'expressive'*, *'fast'*, *'like'*, *'loud'*, *'mechanical'*, *'slow'*, and *'soft'* appear in at least one performance of every piece. 420 terms appear more than once and, coincidentally, also for different performances. Only 40 terms appear in more than ten performances. The most frequently used terms *across performances* are *'dynamic'*, *'expressive'*, and *'soft'*, which appear in at least 22 performances. In increasing order of occurrence, the terms *'playful'*, *'boring'*, *'dynamic'*, *'mechanical'*, *'slow'*, *'soft'*, *'expressive'*, and *'fast'* are used at least 40 times, with this last term being the most used with 64 occurrences.

4.2 Complexity of the Descriptions

An interesting question is whether there is a relation between listeners' musical backgrounds and the complexity of their answers. In particular, we are interested in determining whether listeners with more musical experience with Western classical music describe performances of this kind of music in a more complex language. As a measure of the complexity of the descriptions we use the Dale-Chall readability score [22], a measure that takes into account the number and commonality of words (defined as words that would be familiar to American students) in a weighted sum. Intuitively, we can understand this measure as a way of combining the length (i.e., number of terms) of the answer and the use of specialized vocabulary (such as musical terms). A larger score means a more complex answer. To test whether listeners with more musical training describe performances in a more complex language, we conduct a linear regression (years of musical training

vs. answer complexity). This analysis reveals a positive correlation that we assessed for statistical significance using a one-tailed Wald test (Pearson's $r = 0.27$, $W = 2.32$, $p = 0.01$, $R^2 = 0.07$), which suggests a small effect. We also test whether listeners that often *listen* to classical music describe performances in more complex terms, and find a small, non-significant correlation. These results present weak evidence supporting the idea that listeners with more musical experience describe the expressive character in more complex ways.

4.3 Listeners' Preferences

To determine how similar the preferences of the listeners are, i.e., if they like (or dislike) similar performances we compute a χ^2-test for each piece to determine if there are clear preferred performances, or if all performances of the same piece are equally liked. There are only three pieces that reject the null hypothesis (the frequency of preferred performances is flat) at a level $\alpha = 0.01$, namely the performance of Bach's piece by Richter; and the performances of the two excerpts of Schumann's Arabeske (in this case, the preferred performances were both by Vorraber). Two additional pieces reject the null hypothesis at level $\alpha = 0.05$: Schumann's Kreisleriana performed by Brendel and Mozart's piece by Pires. Both Gould's performances and the deadpan MIDI performances (for both Bach and Mozart) were the least preferred for this piece. It is important to emphasize that this analysis only indicates the presence of preferred performances; it does not identify what the preferred performance is.

4.4 Semantic Similarity of the Descriptions

We use Li et al.'s [23] method for estimating the semantic similarity of short sentences, to compute the pairwise similarity between descriptions of performances. Similarity between individual terms is estimated as the semantic distance between words in WordNet [24], and the overall sentence similarity is weighted with corpus statistics. Intuitively, this method quantifies the overlap in terms (and very directly related synonyms of these terms) between the answers of the participants. The average similarity of the descriptions of a performance of a piece by the same pianist (i.e., *intra-performance*) is 16%, the average similarity of descriptions of a performance and the descriptions of other performances of the same piece by different pianists (i.e., *inter-performance*) is 15%; and the average similarity

of descriptions of a performance and performances of other pieces (i.e., *inter-piece*, excluding performances of the same piece by other pianists) is 15%. To test whether the differences between these groups are significant, we performed a one-way ANOVA ($F(132, 2) = 9.8$, $p < 0.001$, $\eta^2 = 0.13$), which suggests a medium-small effect. We use t-tests with Bonferroni correction to test the pairwise differences (3 tests, $\alpha = .02$). These tests suggest that the average intra-performance similarity is larger than both the average inter-performance (one-tailed $t(88) = 3.4$, $p < 0.001$, Cohen's $d = .76$) and inter-piece similarity (one-tailed $t(88) = 3.6$, $p < 0.001$, Cohen's $d = .71$). The difference between the inter-performance and inter-piece similarities is not statistically significant (two-tailed $t(88) = 0.0$, $p = 0.99$, Cohen's $d = 0.0$). These results suggest that listeners describe a performance of a piece in more similar terms than they describe other performances of the same piece by different pianists. A possible explanation for the fact that there is little variation in how listeners describe performances of different pieces could be that listeners have a limited vocabulary with which to distinguish the difference in expressive character.

5. WHAT ARE THE MAIN DIMENSIONS FOR EXPRESSIVE CHARACTER?

Most of the terms in Hevner's adjective checklist [15], as well as the main five dimensions of expressive performance markings identified by Sulem et al. [9] and main factors of the GEMMES [18] are present in listeners' responses. However, the characterizations go beyond the aforementioned clusters in at least three aspects: many terms are non-emotional, technical, or disapproving. Non-emotional terms are e.g., those that are hard to unambiguously place in the arousal–valence space (unlike Hevner's or Sulem et al.'s clusters) such as *'clean'*, *'metallic'* or *'[t]his is Glenn Gould, obviously'*. Technical terms include terms that describe playing techniques such as *'legato'*, *'staccato'*, or more generally *'fast'*, *'loud'*, and *'mechanical'*. Disapproving terms include descriptions with negative connotations such as *'boring'*, *'sterile'*, or *'robotic'*.

Regarding automated analysis, characterization of expressive performance is not a common case in natural language processing (NLP). Also, the meanings of many terms in the context of expressive performance are slightly different from their common usage. Preliminary tests indicate that learned occurrence-based semantics on related or general topic corpora largely fail to represent more than superficial similarity for this dataset.

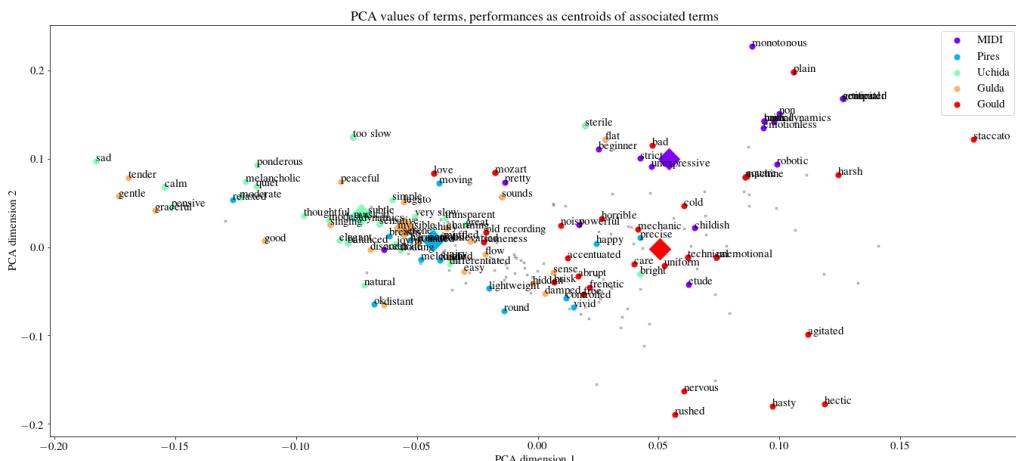
In order to identify the main dimensions of terms, we compute a principal component analysis (PCA) on the occurrence matrix of the dataset. The data is preprocessed in several steps: answers in other languages are translated to English and terms are stemmed. A term is omitted if (1) it shows up less than three times in the dataset (its contribution to the global variance is minimal) or (2) it is used for all interpretations of the same piece (its piecewise entropy is zero; for instance, a participant wrote *'i love mozart'* (sic) for all performances of the Mozart piece).

Table 2 shows the terms that have the strongest loading on the dimensions in the above PCA. Dimension 1 carries intuitive meaning: its extremes reach from *'hectic'* and *'agitated'* to *'gentle'* and *'calm'*. The other three dimensions are harder to connect to a clear semantic dimension. Note for instance the terms *'cold'* and *'warm'*; both influence dimension 4 strongly in the same direction. Figure 2 displays the terms used to describe Mozart's Sonata in the space spanned by the dimensions 1 and 2. The performances themselves are embedded in the space as the centroid of their respective terms. Three clusters emerge, with the deadpan MIDI and Glenn Gould clearly sticking out, and Mitsuko Uchida slightly more towards the *'calm'* and *'sad'* end of Dim.1 (an impression confirmed by listening).

6. HOW DO MEASURABLE/COMPUTABLE PERFORMANCE FEATURES RELATE TO THE EXPRESSIVE CHARACTER DIMENSIONS?

In this section we study whether there is a systematic relationship between the expressive character dimensions described in Section 5 and measurable or computed performance qualities that can be extracted directly from the audio files or from the score-to-performance alignments. In the rest of this article, we refer to these measurable or computed performance qualities as *performance features*.

6.1 Description of Performance Features

6.1.1 Performance Parameters


We consider two performance parameters, tempo and dynamics curves, to relate to the expressive dimensions described above. The tempo curves are extracted directly from the hand-corrected score-to-performance alignments by computing the inter-beat intervals. For computing loudness we use the loudness curve computed from the MIR Toolbox [25] using a perceptually weighted smoothing of the signal energy. For inter- and intra-piece comparisons, we calculate the average value, standard deviation, kurtosis and skewness of these curves. Average tempo/dynamics provides an indicator of how fast/loud a performance is, the standard deviation quantifies the tempo/loudness deviations, kurtosis provides a measure of how extreme these deviations are, and skewness indicates how asymmetric the tempo/loudness values are (e.g., whether the piece is regularly faster or slower than the average tempo).

6.1.2 Mid-level Features

Mid-level features are perceptual qualities of music such as articulation, rhythmic clarity and modality that describe overall properties of musical excerpts and are intuitively clear to listeners [11]. We extract the seven mid-level features described in [12], using the deep convolutional network architecture from [26] (the A2Mid variant, specifically). The 7 mid-level features are *melodiousness*, *articulation*, *rhythmic complexity*, *rhythmic stability*, *dissonance*, *tonal stability*, and *minorness* (see [12] for a detailed description of the features). We train our model on the mid-level features dataset [12], which contains 5000

| Dimension 1 | | | | Dimension 2 | | | |
positive loading		negative loading		positive loading		negative loading	
hectic	0.17	sad	-0.20	rushed	0.22	hard	-0.19
staccato	0.15	gentle	-0.18	nervous	0.20	stumbling	-0.18
hasty	0.15	tender	-0.18	too fast	0.17	staccato	-0.17
agitated	0.14	calm	-0.16	bit	0.16	ponderous	-0.14
irregular	0.14	graceful	-0.16	hasty	0.15	monotonous	-0.13
Dimension 3				**Dimension 4**			
positive loading		negative loading		positive loading		negative loading	
monotonous	0.22	heavy	-0.14	ok	0.24	cold	-0.15
bad	0.17	graceful	-0.13	happy	0.21	warm	-0.14
warm	0.16	smooth	-0.12	joyful	0.19	floating	-0.14
peaceful	0.16	ponderous	-0.12	free	0.15	blurred	-0.14
beautiful	0.15	soaring	-0.10	breathy	0.14	mysterious	-0.13

Table 2. Terms with strongest loadings for each expressive character dimension.

Figure 2. A visualization of the first two dimensions recovered by the PCA. Dots represent terms used in the CEG. Colored terms from characterizations of Mozart's Sonata K 545, grey terms from other pieces. The terms are colored according to the performance they characterize.

audio snippets of 15 seconds each, and use the trained model to predict the mid-level features of the piano performances without any fine-tuning, as there is too little data for a supervised fine-tuning step. To improve the validity of the transfer, we incorporate unsupervised domain adaptation [27] during the training phase. Since the pieces in the CEG are piano performances, we use a separate private collection of non-annotated piano music as the data source for domain adaptation. We observe more variation in the mid-level predictions between the performances while using a domain-adapted model than a non-domain-adapted one, which indicates that it is a useful step in the pipeline.

6.1.3 High-level Features

As high-level emotion-related descriptors, we choose the common *arousal* and *valence* dimensions [19, 28] and aim to predict these from the audio recordings, to then relate them to the expressive character dimensions. We train a dynamic arousal-valence prediction network using the DEAM dataset [29]. We tested a VGG-like model, similar to the one described in Section 6.1.2, and we observed that when the network is pre-trained on the mid-level dataset

and extended with a multi-layer GRU-RNN (Gated Recurrent Unit Recurrent Neural Network) that is trained on the DEAM dataset, we get the best results. To improve the results further, we use the recently released receptive-field regularized ResNet [30] for the pre-training phase, since it appears to give better results for short audio snippets than the VGG-like variant. The inputs to our network are Mel-spectrograms and we process 2-second segments of the spectrogram with 0.5-second hops. As in the case of the expressive performances, in order to compare the predicted arousal and valence curves for inter- and intra-piece comparisons, we compute average, standard deviation, kurtosis and skewness of these curves for each performance of each piece.

6.2 Analysis with Multiple Linear Regression

To study the relation between the performance parameters and mid- and high- level features to the expressive character dimensions described in Section 5 we use multiple linear regression (MLR) analysis. In this analysis, the *dependent variables* are each of the expressive character dimensions (Dimensions 1 to 4) and the *independent vari-*

Dimension 1		Dimension 2		Dimension 3		Dimension 4	
PP ($R^2 = 0.24$)		PP ($R^2 = 0.18$)		PP ($R^2 = 0.26$)		PP ($R^2 = 0.24$)	
loudness avg	0.51^{***}	loudness sk	0.45^{**}	loudness std	-0.53^{**}	beat period k	-0.34^{*}
						loudness std	-0.44^{*}
MF ($R^2 = 0.39$)		MF ($R^2 = 0.00$)		MF ($R^2 = 0.00$)		MF ($R^2 = 0.29$)	
rhythmic complexity	-0.74^{*}	minorness	0.15	articulation	-0.15	rhythmic complexity	0.52^{*}
tonal stability	-0.94^{**}					tonal stability	0.84^{***}
articulation	0.46^{*}						
HF ($R^2 = 0.22$)		HF ($R^2 = 0.00$)		HF ($R^2 = 0.36$)		HF ($R^2 = 0.09$)	
valence sk	0.48^{**}	valence avg	0.14	valence k	0.42^{**}	valence k	-0.33^{*}
				arousal avg	-1.24^{***}		
				valence std	0.27^{*}		
				valence avg	-0.82^{*}		

Table 3. Multiple Linear Regression Analysis. PP, MF and HF refer to performance parameters, mid- and high- level features, respectively. avg, std, k and sk denote average, standard deviation, kurtosis and skewness. The values are the regression coefficients (indicating the contribution of that feature to the model). R^2 is the adjusted coefficient of determination for the whole model. *, **, and *** indicate statistical significance at levels $\alpha = .05, .01$ and $\alpha < .001$, respectively.

ables are the performance features described above. We carry out $4 \times 3 = 12$ MLRs for each expressive character dimension (4 in total) and subset of performance features (expressive parameters, mid- and high-level features). Each of these regressions investigates whether each subset of performance features (expressive parameters, mid-/high-level) can significantly predict the position of the pieces in the expressive character dimensions. The position of each piece in the 4D expressive character space is computed as the centroid of all of its terms in this space. For each of these MLRs we perform a variable selection using the Zheng-Loh method [31]. The results are summarized in Table 3. The MLR results indicate that the expressive parameters are significant predictors of all 4 expressive character dimensions, with medium effect sizes (R^2). Mid-level features are only significant predictors of Dimensions 1 and 4. High-level features are only significant for Dimensions 1 and 3. Thus, Dimension 1 (the *'gentle'/'calm'* vs. *'hectic'/'agitated'* axis, see Section 5) seems systematically related to our performance features at all three levels, which further corroborates its significance.

7. DISCUSSION

In Section 4.2 we observed a small positive relationship between the complexity of verbal descriptions and listeners' musical training. We expect that stronger evidence of a relationship would emerge if musical training were better controlled for (our sample had few listeners with < 5 years of training) and the complexity measure were further developed to account for specialized musical terms. Our analysis of listeners' preferred performances in Section 4.3 revealed that the deadpan performances and performances by Glenn Gould were least well-liked. Prior research has suggested that listeners prefer quantitatively average expressive performances [32], which might explain partially the lack of enthusiasm for Gould's idiosyncratic playing.

The results in Sections 4.4 and 5 suggest that listeners tend to describe performances of the same piece similarly, although there is some variability (e.g., a performance can

be described both as *'beautiful'* or *'bad'* by different listeners; cf. both *'cold'* and *'warm'* being negatively correlated with Dimension 4). An important issue is that NLP methods for assessing similarity between the descriptions are not really suitable for analyzing performance descriptions, where each term is loaded with complex meaning [4] as well as many cross-domain mappings (e.g., metaphors).

The results in Section 6.2 reveal relationships between performance features and expressive dimensions that conform to musical intuition, with the effects being most pronounced for expressive character Dimension 1 (which is also the one that we find easiest to interpret, see table 2). For instance, the analysis suggests that louder performances or performances with large outliers in the valence curve would be perceived as more irregular and agitated, while softer performances or performances without large outliers in valence would be perceived as calm or graceful.

8. CONCLUSIONS AND FUTURE WORK

This paper has introduced the CEG dataset and presented some exploratory analysis addressing three main questions related to inter-listener agreement, main emerging description dimensions, and relations between user characterizations and measurable performance parameters.

Future work will focus on a more in-depth analysis of the question of semantic similarity. As discussed in Section 5, the description of expressive character includes many nuances that are not well suited to be analyzed with generic NLP methods, given how loaded with meaning certain terms are. We plan to investigate methods like *pile sorting* [33] with expert musicians to devise a meaningful semantic clustering of the terms. Furthermore, we plan to collect more human annotations (e.g., mid- and high-level features) as a basis for a more systematic comparison.

---

[4] For example, the performance of the Mozart piece by Austrian-trained Japanese pianist Mitsuko Uchida was described by a participant as 'Russian pianist'. To understand this description, it is necessary to have the concept of the Russian School of performance.

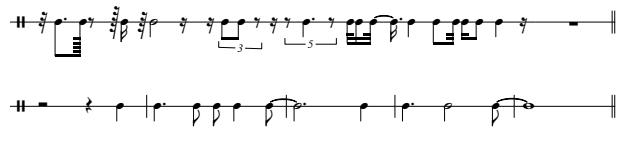
TOWARDS A FORMALIZATION OF MUSICAL RHYTHM

Martin Rohrmeier


Digital and Cognitive Musicology Lab, École Polytechnique Fédérale de Lausanne

`martin.rohrmeier@epfl.ch`

ABSTRACT

Temporality lies at the very heart of music, and the play with rhythmic and metrical structures constitutes a major device across musical styles and genres. Rhythmic and metrical structure are closely intertwined, particularly in the tonal idiom. While there have been many approaches for modeling musical tempo, beat and meter and their inference, musical rhythm and its complexity have been comparably less explored and formally modeled. The model formulates a generative grammar of symbolic rhythmic musical structure and its internal recursive substructure. The approach characterizes rhythmic groups in alignment with meter in terms of the recursive subdivision of temporal units, as well as dependencies established by recursive operations such as preparation and different kinds of shifting (such as anticipation and delay). The model is formulated in terms of an abstract context-free grammar and applies for monophonic rhythms and harmonic rhythm.

1. INTRODUCTION

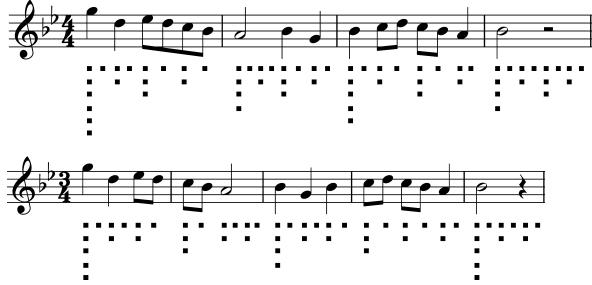
Temporality lies at the very heart of music, and the play with rhythmic and metrical structures constitutes a major device across musical styles and genres. However, there is comparably less research on rhythm itself than on other temporal structures of music. For instance, there is a lot of work on modeling beat and beat inference [1–3], tempo estimation [4] as well metrical structure [5] and its inference [6–10]. There has been major theoretical work differentiating between grouping and meter [11], and between rhythm and meter [5, 12]. In comparison, there is less formalization work on musical rhythm [13–15], and some major studies such as the GTTM [11] or [5] avoid a formal characterization of musical rhythm. The purpose of this theoretical paper is to address this gap and to provide a generative model of musical rhythm in terms of an abstract context-free grammar that generates rhythmic structure in alignment with metrical structure.


Figure 1: Two different series of onsets and durations.

2. MOTIVATION

Rhythm is commonly thought of as a series of onsets and durations of musical events. While duration patterns are essential for musical rhythm, the core idea of the model is to capture that rhythmic structures, especially those in tonal music, are more than (fully) freely placed onsets over time and that the concept of rhythm involves different kinds of dependencies that are constituted between its musical events. To illustrate this point, Figure 1 displays two different series of onsets and durations. Only the lower one looks like a plausible candidate for a rhythm from a tonal piece of music. There are several points underpinning this distinction. In essence, it is argued that rhythm is understood involving an *interpretation* in terms of hierarchical dependencies of temporal events and their assignment to the metrical grid, which result in a surface projection of patterns of onsets and durations.

One central point is that the rhythmic Gestalt is fundamentally defined by its relation to metrical structure; rhythm cannot be separated from a metrical interpretation. This point is illustrated by Figure 2. Both rhythms have the identical sequence of onsets and durations, but different metrical structures associated with them, and this results in both rhythms sounding very different. In particular, the ways in which events are linked to weak and strong metrical beats and also their underlying meter have a major impact on the interpretation of a given pattern of durations.

A second major point lies in the fact that we characterize rhythmic structures in terms of an *interpretation* by event dependencies and transformations. For instance, certain events lead to other events; we understand a certain event or group of events as an upbeat to (or preparation of) another event; and we understand certain events as subdivisions of longer units (such as triplets). Furthermore, when we speak about syncopation, anticipation, or delay, it means that certain events occur earlier or later, implying that there is an (underlying) position where these events would have been expected normally before the transformation (shift) [13, 16]. Rhythmic events are also recognized as grouped.

Figure 2: The alignment with metrical structure may yield two very different rhythmic interpretations for the same pattern of onsets and durations.

Generally, it is useful to distinguish different levels of musical time [17–20]. Rhythmic structure, in the aspect that is modeled here, lives in *idealized* time. The metrical grid presumes an underlying isochronic beat, and rhythmic patterns are related by simple integer ratios in relation to the grid and the beat. The rhythmic structure at this symbolic level in relation to the symbolic beat is different from the level of tempo variation, expressive timing, swing, groove, performance errors and other subsymbolic variations of timing.

In sum, we generally conceive of rhythms as structured both in terms of an associated metrical structure as well as in terms of event dependencies such as the ones mentioned. In contrast, events occurring with purely random onsets and durations (like the first example in Figure 1) sound erratic—which in turn means that they have no *interpretation* in terms of the dependencies outlined. It is the purpose of the proposed model to express the various rhythmic dependencies at the deep structure that give rise to the patterns of event onsets and durations observed at the surface.

One common observation in rhythmic structure is that events may reach into the timespan of other events. This is particularly common with preparations before an event, anticipations or syncopations that may enter during the timespan of the directly preceding event. This may cause the preceding event to be shortened, which we refer to as *time stealing* when it is discussed below.

2.1 Related literature

Numerous approaches have addressed rhythmic and metrical structure in music [5, 21]. While there are several research directions in terms of rhythmic corpus studies [22–27] and mathematical analyses [28–30], there is less research proposing formal theoretical frameworks generating rhythmic structure. Differentiating metrical structure from grouping, the GTTM [11] laid a foundation for the understanding of meter that is still in place today. Several endeavors have been devoted to implementing the GTTM in a computational way [31, 32].

Several computational approaches to rhythm have proposed sequential models such as Markov models, HMMs or other graphical models [33, 34]. More recently various hierarchical approaches and probabilistic grammars have been used for rhythmic inference and transcription problems [15,35–37]. These approaches are essentially built on recursive subdivision (split). [14] proposed an algorithmic model of rhythm using transformations of syncopation, figural, and density (split) based on the transformation vector proposed by [13]. From the perspective of mathematical music theory, rhythmic structure has also been modeled in terms of subdivision of a graph [38].

The present model extends previous approaches [14,15, 39] by characterizing an overarching abstract context-free grammar of recursive rhythmic dependencies. It is based on five abstract operations of splits, preparations, and shifts using a tripartite representation of rhythmic categories, and models rhythmic conflicts using the concept of *time stealing*. As a grammar-based generalized model of rhythm, it can be naturally integrated with syntactic models of harmony [39–48] for modeling harmonic rhythm.

3. THE FORMALISM

3.1 Metrical structure

Metrical structure has been famously modeled by [11] with a recursive grid of metrical weights and a notation adopted from metrical phonology in linguistics [49–53]. Examples of the metrical grid are shown in Figures 2 and 3. In the grid, each level m is characterized by a multiple (2 or 3) of the period of the subordinate level $m - 1$ and an offset. Generally, the subdivision for regular meters is binary or ternary [5]; for irregular meters the formalization would need to be extended to combinations of twos and threes (e.g. $\frac{7}{8} = \frac{3}{8} + \frac{2}{8} + \frac{2}{8}$).

The metrical grid can be characterized as follows for regular meters: the beat level is marked with m_0 and the beginning of the segment or piece is indicated by the index 0, and locations are indicated in reference to m_0. Each higher metrical level i is characterized by the tuple (π_i, o_i), the regularity $\pi_i \in \{2, 3\} \cdot \pi_{i-1}$, and the offset $o_i := o_{i-1} + a\pi_{i-1}, with a \in \mathbb{N}_0$, $o_0 = 0$ and $\pi_0 = 1$. This ensures that higher levels can only subselect beats established in all lower metrical levels. Metrical levels below the beat ($i < 0$) are characterized in the same way with $\pi_i \in \{\frac{1}{2}, \frac{1}{3}\} \cdot \pi_{i+1}$, and the offset $o_i = 0$. Accordingly, a metrical grid M is fully defined by the list (or series) of all tuples $M := (\pi_i, o_i)$. The metrical grid is potentially infinite in duration and has an arbitrary number of metrical levels i. Most commonly, almost all values of π are 2, except for the levels 1 and 2 in ternary meters.

The metrical weight at position t is characterized as:

$$W_{M:=(\pi_i, o_i)}(t) = \sum_i \left(1 - sign(\mid t - o_i \mid \mod \pi_i)\right) \ (1)$$

where the $1 - sign(\cdot)$ function is used to compute 1 for a position falling on the metrical grid and 0 otherwise. Furthermore, a subsegment of a metrical grid M is characterized by $M_{[a,b]}$, where a and b denote the beginning and end locactions of the open or closed subsegment interval.

3.2 Generative rhythm

The formalism is modeled employing abstract context-free grammars [47]. The grammar consists of four parts: $\mathcal{G} = (C, \Sigma, P, C_0)$, non-terminal rhythmic categories C, terminal symbols Σ, production rules P, and, in this case, a set of start symbols $C_0 \subseteq C$. All sets C, Σ, C_0 are infinite.

A rhythmic category consists of a tuple (t, m): a timespan t and the metrical grid m associated with the timespan. The timespan represents a formalization of the rhythmic time interval (which is going to be generatively subdivided). It is itself a triple $[a : b : c]$ that combines three parts: a downbeat part of a duration b, also called the *body* of t, and an initial offset (upbeat) of duration a, and final offset (coda) of duration c. Durations are defined in beats ($\in \mathbb{Q}$) including fractions of beats, such as $\frac{1}{8}$. The offset parts can be positive or negative. If positive, a time segment is added to the core length of b; if negative, b is shortened by that amount. The total duration of t is $a + b + c$. While in practice, a and c are each mostly no longer than $\frac{b}{2}$, it is avoided to postulate such a restriction theoretically rather than empirically. However, $-b < a < b$, $-b < c < b$, and $a + c <= b$ are required.

The set of surface symbols Σ consists of musical events that are characterized by pairs (l, m) of event durations $l \in \mathbb{Q}, l \leq b$ in beats with associated metrical weights $m \in \mathbb{Q}$. The separate modeling of the event length in addition to the timespan is important because a realized event may in turn occupy a shorter duration than its timespan (e.g. a quarternote in a half-note timespan, or a staccato note). This makes it possible to model the type of rests that can occur in this case. Since the focus in this paper is about the rhythmic grammar, other features of the musical event (like pitch) will be left out of account.

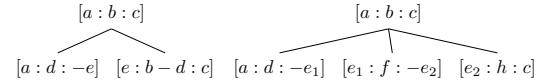
The set of start symbols $C_0 \subseteq C$ consists of rhythmic categories that do not have a coda offset:

$$C_0 = \{k \mid k = (t = [a : b : c], m) \in C \wedge c = 0\} \quad (2)$$

Because the symbol space is infinite, rules do not constitute rewrite operations over symbols (as in classical context-free grammars), but as rewrite functions. The set of generative production rules P is characterized as

$$P \subseteq \{r \mid r : C \to (C \uplus \Sigma)^*\}, \quad (3)$$

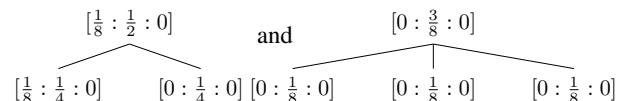
where the rules are functions that map sets of categories onto sets of categories or surface symbols, establishing an abstraction over different paramaterized instantiations of analogous rules.

The set of core rules constitutes the heart of the generative formalism. For the generation of rhythmic structure, five main rules are assumed: *split*, *prepare*, *(c-split)*, *anticipate*, and *delay*.


Split rule. The main rule of the formalism is *split*, which subdivides the body of the rhythmic category, while the outer upbeat and coda parts remain identical. The split can induce *timestealing* such that a timespan protrudes into

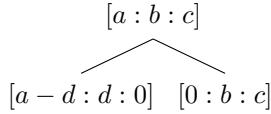
an adjacent one by an upbeat or coda of length e. Note that it does not result in an update of the length of the timespan body b, but of its upbeat or coda part. This maintains the core durations at the deep structure. Split can subdivide a timespan into two or three parts; other subdivisions, such as four or five, etc., require multiple split operations.

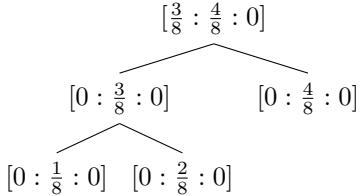
$$
\begin{aligned}
&([a : b : c], m_0) \longrightarrow ([a : d : -e], m_1)\,([e : b - d : c], m_2) \\
&\quad \mid 0 < d < b, m_1 = m_{0[0, a+d-e[}, m_2 = m_{0[a+d-e, a+b+c]}
\end{aligned}
\quad (4)
$$

$$
\begin{aligned}
&([a : b : c], m_0) \longrightarrow \\
&([a : d : -e_1], m_1)\,([e_1 : f : -e_2], m_2)\,([e_2 : h : c], m_3) \\
&\quad \mid d + f + h = b, \quad m_1 = m_{0[0, a+d-e_1[}, \\
&m_2 = m_{0[a+d-e_1, a+d+f-e_2[}, m_3 = m_{0[a+d+f-e_2, a+b+c]}
\end{aligned}
\quad (5)
$$


The working of these rules may be visualized by the subtrees they produce (ignoring the metrical assignment):

It is further assumed that the majority of these split operations divide the body of the timespan equally ($d = f = \frac{b}{2}$, for even b) or into simple integer ratios. The actual instantiation of these splits in practice is, however, not a matter that should be decided a-priori at the level of the formalism. Note, for instance, that an unequal subdivision like 3:1 in the context of a long note and an upbeat to the next bar, is not required since such cases are rather expressed with the upbeat (u-split) rule that is explained next.

Also note that for categories where the metrical accent lies at the beginning of the body, it is sufficient to metrically characterize the split segments by the metrical weight at the downbeat (onset) of the body. The notation $m = u \oplus v$ is used to denote the weight of the downbeat in terms of the metrical level u generated by the split operation plus the metrical weight v inherited from the parent node in the tree. Figure 3 and 4 illustrate this notation.


As an example, a halfnote split into two quarter-notes or dotted quarter-note split into three eighth-notes would be expressed like this:


Prepare (U-Split) rule. The second core rule models upbeat structures. It takes the upbeat part of the timespan of a rhythmic category and generates an own rhythmic category from it:

$$
\begin{aligned}
&([a : b : c], m_0) \longrightarrow ([a - d : d : 0], m_1)([0 : b : c], m_2) \\
&\quad \mid 0 < d \leq a, m_1 = m_{0[0, a[}, m_2 = m_{0[a, b+c]}
\end{aligned}
\quad (6)
$$

The corresponding tree fragment looks like this:

$$[a:b:c]$$
$$[a-d:d:0] \quad [0:b:c]$$

For example, a half-note that is prepared by a combined upbeat of an eighth and a quarternote would be expressed as follows:

$$\left[\tfrac{3}{8}:\tfrac{4}{8}:0\right]$$
$$\left[0:\tfrac{3}{8}:0\right] \qquad \left[0:\tfrac{4}{8}:0\right]$$
$$\left[0:\tfrac{1}{8}:0\right] \quad \left[0:\tfrac{2}{8}:0\right]$$

One may postulate a corresponding counterpart to the upbeat split in the *prepare* rule; this rule (*c-split*) would instantiate a rhythmic category from the coda-part of a given rhythmic category. While it is unclear if such a rule would indeed be required for tonal rhythm (i.e. a phenomenon of "post-paration" as opposite to "pre-paration"), still the rule is listed even though it may be dropped from the formalism (or be found to not occur empirically):

$$([a:b:c], m_0) \longrightarrow ([a:b:0], m_1)\,([c-d:d:0], m_2)$$
$$\mid 0 < d \le c, m_1 = m_{0[0,a+b[}, m_2 = m_{0[a+b,a+b+c]} \quad (7)$$

Shift rules. Two further rhythmic phenomena do not relate to subdivision but to the shift of events, such as in the context of syncopations. In these cases, a rhythmic category c may be shifted to occur early or late. The corresponding rules are *anticipate (e-shift)* and *delay (l-shift)*. These rules are unary rules that transform a rhythmic category rather than creating a new one.

$$\text{e-shift: } ([a:b:c], m_0) \longrightarrow ([0:b:a+c], m_0) \quad (8)$$

$$\text{l-shift: } ([a:b:c], m_0) \longrightarrow ([a+c:b:0], m_0) \quad (9)$$

Surface rules. Finally, from the set of recursive generated rhythmic subdivisions and transformations a rhythmic surface will be generated. If events are shortened by *timestealing*, the lengths of the core are updated (by the first two rules). In order to ensure that all upbeat parts and codas have been instantiated either with events or shifts, surface symbols can only be generated for categories that have an empty upbeat and coda part. Once generated, surface symbols cannot reenter the generative process.

$$([a:b:c], m) \longrightarrow ([0:b+a:c], m) \text{ for } a < 0 \quad (10)$$
$$([a:b:c], m) \longrightarrow ([a:b+c:0], m) \text{ for } c < 0 \quad (11)$$
```
surface:
```
$$([0:b:0], m) \longrightarrow (b, W_m(0)) \quad (12)$$
$$([0:b:0], m) \longrightarrow (l, W_{m_{[0,l[}}(0))(\epsilon, b-l, W_{m_{[l,b]}}(0)) \quad$$
$$\mid 0 < l \le b \quad (13)$$

In other words, the surface rule yields the rhythmic surface duration $l = b$ or $l \le b$ as well as its metrical weight

m. If the event is shorter than its timespan b, the surface rule also creates a rest event ϵ that fills up the remaining space, so that the subsequent events are not affected by the shortening.

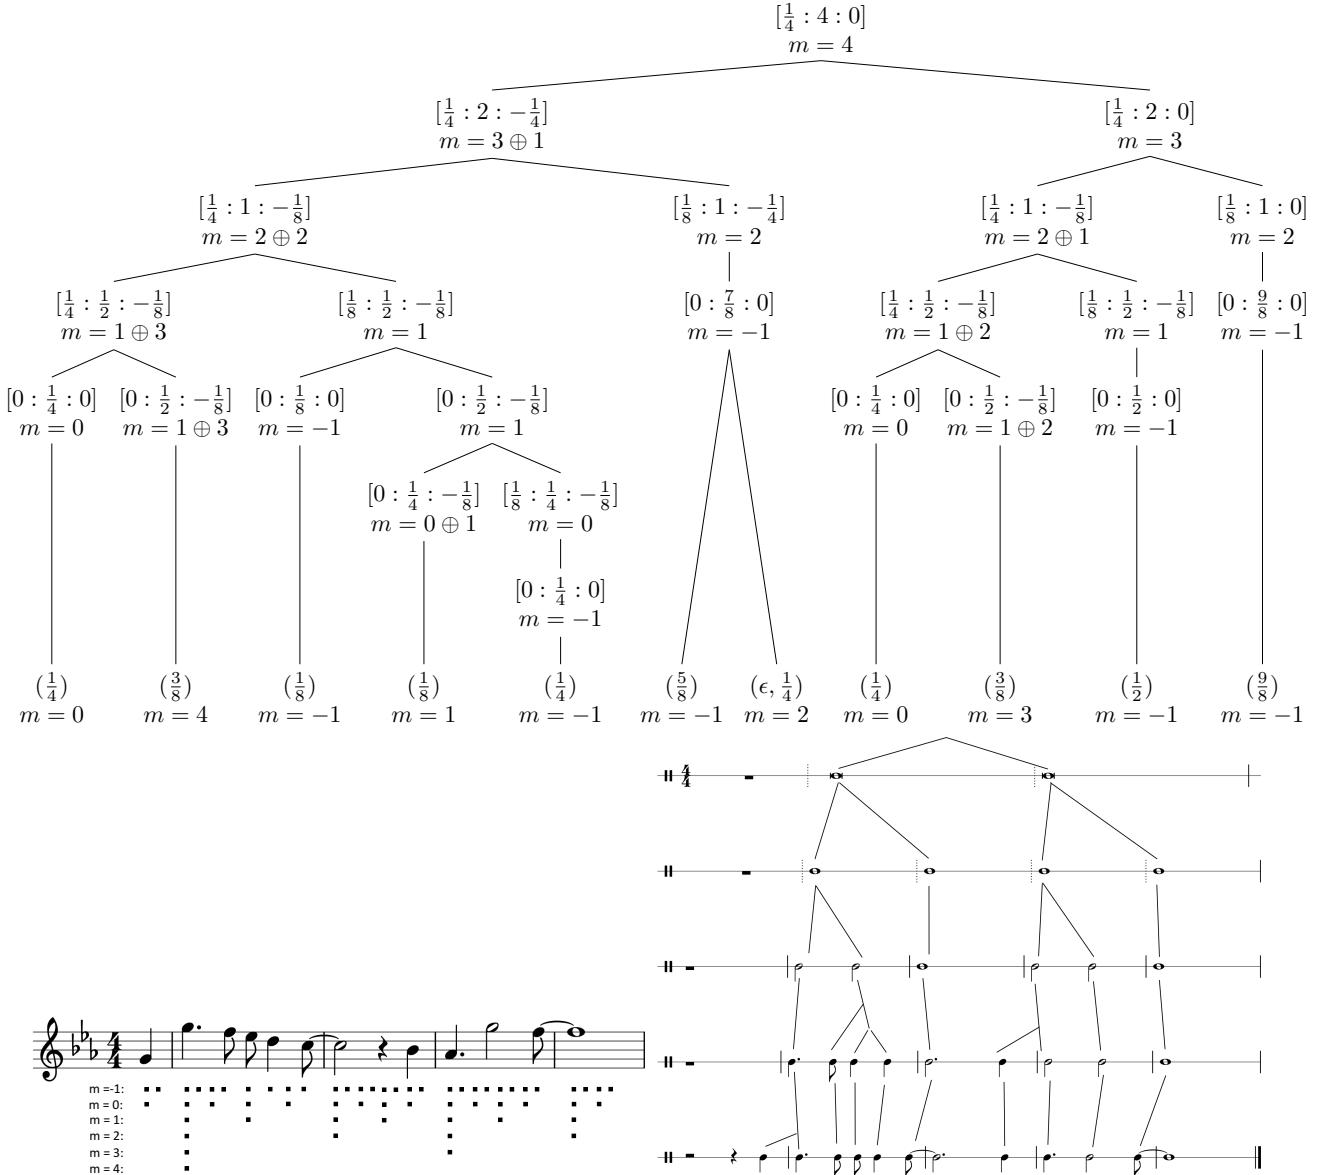
The surface rule is designed in such a way that all lengths of all surface events add up to the full length of the entire musical segment from the start symbol:

$$\sum l_i = a + b \quad \text{for } c_0 = [a:b:0] \in C_0 \quad (14)$$

An illustrative example of this sum can be reconstructed from the surface-note durations in Figure 3 and 4.

4. EXAMPLES

4.1 Melodic rhythm

A first detailed analysis is carried out on the first two bars of the jazz standard "Blue Bossa". The tree analysis based on the generative model is displayed in Figure 3 together with a corresponding analysis that visualizes the recursive rhythmic subdivisions and shifts of the same generation using musical score lines. All durations are encoded following common music notation, i.e. $\frac{1}{2}$ refers to a half-note, 1 to a whole note, or $\frac{3}{8}$ to a dotted quarter-note; $\frac{1}{4}$ refers to the quarter-note beat level. The figure characterizes the metrical (sub)grids of each category employing the $m = u \oplus v$ notation.


Several observations can be made based on the figure. All of the applications of *split* illustrate that timespans may be subdivided with equal subdivision of the core, yet resulting in unequal timespan durations based on time-stealing effects encoded in the upbeat and coda parts of the timespan category. The derivation of the sixth note provides an example where an event at the metrical whole-note level is syncopated by an eighth note and at the surface instantiated shorter than its timespan resulting in the surface generation of an additional rest.

Further, the first, third, and seventh note may be understood as upbeats to the subsequent events. The second halves of measures 1 and 3 have syncopations in which the shifted events reach into the timespan of the previous events, causing the notes on beats 3 and 1, respectively, to be shortened by one eighth note.

4.2 Harmonic rhythm

The formalism proposed has a different application in the modeling of harmonic rhythm. For instance, this concerns modeling the harmonic-rhythmic structure as it is contained in leadsheets. A major difference between the previous case of melodic rhythm is that harmonic rhythm in leadsheets may well employ (harmonic) upbeats, yet no rhythmic shifts in the sense of syncopation, anticipation or delay; also time overlaps that involve the timespan coda have not been observed. A computational version of this (sub)model has been proposed in [39].

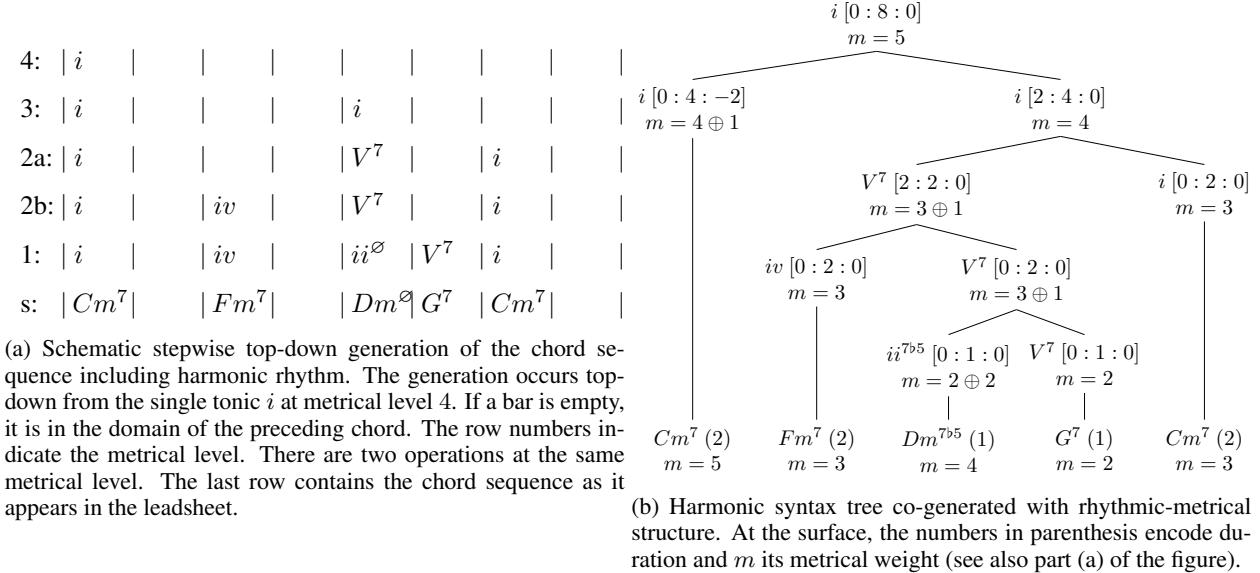
Figure 4 shows an example analysis of the first 8 bars of the harmonic phrase of "Blue Bossa". The tree analysis displays the harmonic syntactic dependencies following [47, 54, 55] in conjunction with the harmonic rhythm


Figure 3: A rhythmic analysis of the first four bars of the melody of the Jazz standard "Blue Bossa".

and the metrical levels. This requires a product grammar as defined by [39] for the formulation of the coordination between harmonic and rhythmic structures—which is an application of the formalism as proposed here. The tonic i at the highest level is equally split into two tonic timespans at level 3. When the preparing dominant V^7 is inserted, it causes to take up half of the space of the timespan of i and causes i to appear later. When iv is introduced preparing V^7 it is introduced at the same metrical level (level 2) and reaches into the time domain of the initial i (time-stealing). By analogy, the introduction of $ii^\varnothing$ takes up the half of the V^7 time domain. Accordingly, the analysis reveals that the metrical domains of the chords in the hierarchical analysis are not identical with the position where the chords occur on the surface. Figure 4 (a) displays the stepwise joint derivation of harmonic syntactic dependencies and harmonic rhythm.

5. DISCUSSION

The contribution of this paper is to characterize the recursive internal structure of musical rhythms using a formal grammar. This goes beyond the GTTM, which does not propose a model of rhythm, and further argues that the inference of the hierarchical rhythmic deep structure is central to music cognition. Because of the joint representation of rhythmic and metrical structure in the model, a parser of the proposed abstract grammar of musical rhythm instantiates rhythmic interpretation and metrical inference at the same time.

In this formalism, the concept of *timestealing* is proposed. It is modeled at the highest metrical level it affects, and the split operation already sets up the timespans for subsequent preparation or shift operations in the upbeat or coda parts of the timespan category. This modeling ensures that all operations remain context-free and could be implemented and parsed efficiently with a parser of abstract

4: | i | | | | | | | |

context-free grammars. This would not be guaranteed if the upbeat feature would only be instantiated at the upbeat or shift operation, for instance. If such an upbeat would reach across a border at a different metrical level the information to adapt the coda part of the adjacent subtree would have to perculate through the tree in a context-sensitive fashion, thus resulting in a model of much higher computational complexity. Such an instance could, for example, be observed in the syncopation of the sixth note in Figure 3. The eighth note syncopation of a note at the whole-note level results in a shift of the corresponding right neighbor at the quarternote level, accordingly the information would have to traverse one node up and four nodes down the tree to reach the right node. Further, a generation of upbeats and shifts without timespan reservation may result in the generation of impossible structures if both sides expand in a unrestricted context-free fashion.

Because of the hierarchical modeling of shifts of timespans, it is not necessary to include "hacks" such as binding-over of events as in musical notation (as in the long notes C and F in Figure 3) since the logic of syncopation can be modeled directly. With the formalism and the upbeat feature it is further possible to model the rhythmic displacement of an entire group of events, such as the syncopation of four quarternotes by an eighth note.

The tripartite representation of a timespan with upbeat, core, and coda parts makes it possible to maintain the simple split ratios at the deep structure. It also models the normalized locations where syncopations originated, as well as the overarching timespan that a deeper event dominates even though it may only occur at a different surface position (such as the tonic or dominant symbols in Figure 4). Maintaining simpler deep structure relations aggregates of similar rules, which establishes theoretical parsimony and facilitates probabilistic modeling and inference.

In the presented model rhythmic structure is generated in alignment with meter. It is possible to devise a variant

of the model such that metrical structure is *co-generated* jointly with rhythm rather than having it defined with the start category. The additive $m = u \oplus v$ characterization as used in Figure 3 and 4 defines metrical weight with a current metrical level and a part inherited from the parent. Split, prepare and shift rules can be redefined in such a way that they recursively generate each successive metrical level. While such an approach has advantages for complex and irregular rhythms, it would require additional constraints to ensure metrical consistency across independent context-free subtrees.

The proposed formalism models the generation of a single rhythmic sequence. For musical structures with multiple streams or voices, additional parallel trees can be instantiated which need to fulfill the constraint that their derived metrical structures are aligned. Moreover, complex (non-Western) rhythms and meters can be modeled with an extended model of meter that allows for non-isochronous or additive subdivisions [5]. Application of a computational implementation of the model would be measures of rhythmic complexity based on the derivation tree as well as rhythmic similarity based on largest embeddable common subtrees as for instance employed in [43].

The fact that rhythmic relations instantiate upbeats and splits is closely related to the core syntactic principles of preparation and prolongation [54]. This is corroborated by the fact that harmonic syntax and rhythm are found to be highly correlated in computational modeling [39].

Finally, there is also a close relation between such recursive rhythm and grouping; in fact, the higher order rhythmic categories reflect or *constitute* the grouping structure, refining the concept from the GTTM [11]. Crucially, it has not been argued that this model holds for all rhythms found in musical practice. Rather, the formalism models rhythmic interpretability based on the deep structural rhythmic dependencies outlined; while music is highly flexible, certain complex rhythms (Figure 1) may not be interpretable.

Paper Session 5

PRACTICAL EVALUATION OF REPEATED RECOMMENDATIONS IN PERSONALIZED MUSIC DISCOVERY

Brian Manolovitz

m.ogihara@miami.edu

ABSTRACT

Studies have shown that repeated exposures to novel songs cause an increase in a person's memory and liking. These studies are commonly verified through self-reporting emotion-based surveys. This paper proposes the "retention rate" as an additional parameter for evaluation, which examines the rate at which the listener revisits the novel items. The authors hypothesize that when a person listens to novel (i.e., both unfamiliar and interesting) pieces of music, the retention rate will be proportional to the number of times the discovery engine suggests the pieces to her, as long as they remain novel. The authors have tested the hypothesis through a six-week human-subject experiment which simulates a real-world listening environment and a follow-up survey. During the experiment period, each subject received, through Discover Weekly in Spotify, suggestions for novel songs up to three times and provided evaluation. One month after the evaluation experiment, the human-subjects answered whether they had revisited the novel songs. Through the analysis of the response and survey data, the researchers conclude that the more times a listener is exposed to a song during the discovery process, the more likely she is to return to the song.

1. INTRODUCTION

The arrival of online music streaming services, such as Spotify[1] and Apple Music[2], has greatly changed the way people listen to music. They allow their users to make dynamic selections of music from vast libraries and thus provide an improved exposure outlet for musicians. By adopting a music streaming service, listeners are far more likely to broaden their tastes and explore songs and artists appearing in the long tail of the popularity distribution [3]. The instant accessibility to a myriad of songs through streaming platforms addresses the long-tail problem [13], where most listening data corresponds to few songs and the vast majority of songs have very little listening data, especially through use of collaborative filtering (CF). CF is a technique that finds a group of users whose tastes and activities show substantial similarity to each other and makes recommendations based upon what the other members of the group liked. The more people in the group who enjoy a piece, the more likely that the system recommends it, which gives rise to a recommendation bias towards popular songs, though other techniques can help correct this issue.

Personalized music discovery tools, such as Spotify's Discover Weekly playlist, aim at recommending music independent of user groups. They utilize the personal listening history of a user and try to suggest new and interesting songs specific to her interests. These "serendipitous recommendations" [9] are useful for extracting music from the long tail, which would otherwise be difficult for the user to find. They make use of content-based filtering techniques, which determine song similarity through the audio features and are a potential solution to the popularity contest that tends to be created by collaborative filtering methods.

However, even when presented with novel songs, the onus is on the user to remember to revisit them, usually by saving them or adding them to a playlist. The goal of the user during the experience of a new piece may not be to record what she liked for future relistening, but instead, she may want to listen to something in the background [4]. As a result, some songs may disappear not only from the memory of the user but also from her song collection, despite that the listener enjoyed them on first listen. These songs in oblivion create missed opportunities to expand both the listening repertoire of the user and the audience of the artist. The goal of this study is to show that when repeating recommendations during the music discovery process, the listeners are significantly more likely to revisit the discovered songs. This addresses the long-tail problem by focusing on data saturation, rather than item selection, in order to help items break out of the long tail.

Missed opportunities also arise when a user has a neutral or uncertain initial response to a song and discards it, since subsequent listens may have yielded a more favorable response. The music domain has the somewhat unique characteristic that users are expected to revisit songs many times. Studies have shown that repeated listens to a piece of music cause an initial increase in liking, which subsides with satiation. Simultaneously,

[1] www.spotify.com
[2] www.apple.com/apple-music

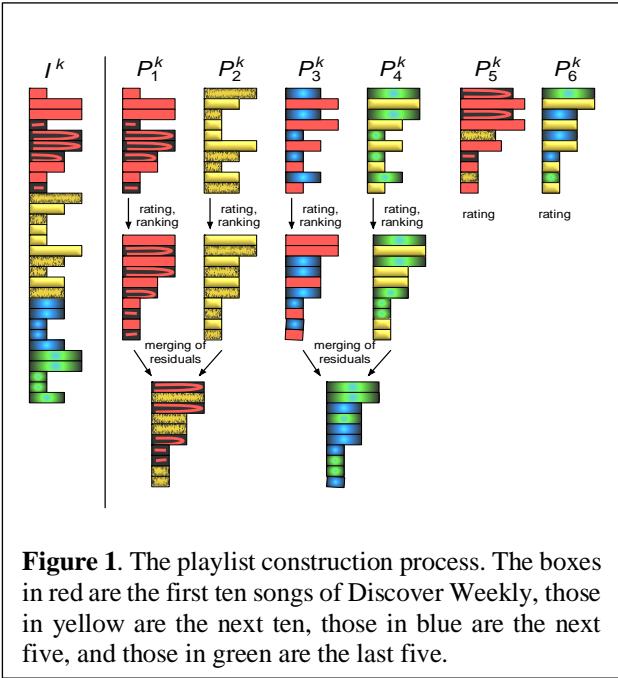
memory steadily increases throughout [7,11,14,15]. This is not an issue in the typical radio format for music discovery, where songs are presented many times upon their release, ensuring listeners will become familiar. Though streaming services have adopted the radio format to an extent [5], this study should provide justification for expanding its use in the music discovery tools.

In the present paper, the authors studied whether repeated recommendations of novel songs cause users to return to the songs later. A six-week human-subject experiment with a follow-up survey was conducted, which simulated a real-world listening environment. During the experiment period, the subjects were provided, through Discover Weekly in Spotify, suggestions for novel songs. Each novel song appeared no more than three times during the experiment. Each subject provided her response to each song on the list. One month after the conclusion of the six-week experiment, the human-subjects answered whether they had revisited the novel songs. Although it is typical to evaluate the effects of repeated recommendations with respect to a person's familiarity and preference to the songs, this study will introduce two additional factors, retention rate and forgetting rate, which allow the standard listening behaviors of the subjects to dictate the results. This paper will describe the details of the experiment and present the analysis of the data that was collected.

2. RELATED WORKS

When examining research on novelty and the effects of repeated recommendations, it is essential to trace everything back to [1], where Berlyne coined the inverted-U theory for collative variables. This theory postulates that as a collative variable (i.e., familiarity, complexity) increases, a person's liking increases to a point, then decreases, creating an inverted-U shape. Chmiel and Schubert [2] examined the validity of this theory throughout the past several decades of research. They found that, in general, the theory holds in the results of the studies they surveyed. It is, therefore, safe to assume that the first time a person listens to a song will not be their most enjoyed listening experience. Vargas and Castells [16] point out that flaws exist in evaluating novel recommendations solely based on the accuracy of the selected songs. They offer an alternative strategy that accounts for the ranking of the chosen items and their relevance to the user.

The problem of recommending long-tail items is a popular topic in the current recommendation systems research. Park [12] proposed an adaptive clustering method that clusters items based on their popularity but chose only the data objects in the long tail for clustering. This method performed better than prior approaches, both in terms of performance and the system's ability to recommend long-tail items. Wang et. al [17] utilized the users' experience level to control the extent to which long-tail items are recommended, finding that more experienced users were more open to the items in the long tail. [6] adapts the diversification of recommendation lists based on the perceived preferences of the user towards diversity and penalizes the inclusion of popular items while increasing accuracy. Using a multi-objective simulated

annealing process, the resulting recommendation lists performed very well, compared to existing methods. Finally, [10] extended an existing tripartite graph approach for long-tail recommendations by expanding full genres, allowing more connections between items and genres. The results showed an increase in diversity and recall scores over existing methods.


Several studies exist to test the effects of repeated listens on liking and familiarity [7,11,14,15]. All have a result stating that both factors typically increase after the first listen. Hargreaves [7] found that when novel songs were repeated in weekly intervals, rather than in one continuous setting, familiarity ratings plateaued as in the inverted-U shape, but the "like" ratings remained constant in both cases. In [14], Szpunar et al. tested the effects of repeated listens during focused versus unfocused listening on memory and liking. They found that inattentive (or passive) listeners exhibited a slow and steady increase in liking and memory with repeated listens, whereas attentive listeners showed an inverted-U shape for both.

Similarly, in [11], Madison and Schiolde utilized a series of user listening experiments to conclude that familiarity increases liking regardless of the complexity of the music, and that familiarity is the most critical indicator of enjoyment. Van den Bosch et. al [15] conducted experiments involving psychophysiological scans that measured electrodermal activity. They connected self-reports on liking of music with these emotional responses. They found that as the unfamiliar songs were repeated, the emotional measurements became more closely related to the self-reported liking ratings.

Ward et al. [18] tested the effects of familiarity on music choice by asking subjects to rate songs in terms of familiarity and preference. After the initial rating, the songs were paired the songs up, one familiar and one unfamiliar, and asked the subjects which they would rather hear. They found that the subjects tended to select the songs with which they were more familiar, regardless of their liking ratings, leading them to conclude that people prefer to hear familiar music despite claiming they would like to hear more novel songs. Alternatively, their results indicate a greater need to boost familiarity during the discovery process, so that novel songs are more likely to be revisited.

3. PROBLEM OVERVIEW

Automatic personalized music discovery systems can make serendipitous recommendations to their users based on their listening histories. One example of these systems is Spotify's Discover Weekly, which provides users with a 30-song playlist of new and interesting songs based on their listening histories. Since the playlist is refreshed every Monday, the users will need to remember to revisit the songs they enjoy, usually by saving them or adding them to a playlist. If the users forget to do this, or if they prefer to listen to new music in the background [4], there will be missed opportunities to broaden the listener's repertoire, since songs the users enjoyed or may have

Figure 1. The playlist construction process. The boxes in red are the first ten songs of Discover Weekly, those in yellow are the next ten, those in blue are the next five, and those in green are the last five.

grown to enjoy never entered their listening rotation. We are proposing an improvement to the personalized music discovery approach, where the novel recommendations are repeated at least once to boost familiarity and increase the likelihood of the users revisiting the songs in the future. The first and main question of this research is as follows:

RQ1. Is the likelihood for a user to revisit a liked song proportional to the number of times that the song is presented to the user?

To answer this question, we introduce *retention rate*, R, as an evaluation metric. Let N be the set of songs a person listens to for the first time, and let r be the number of songs in N that person listens to more than once, $R = r / |N|$.

As shown in previous research [7,11,14,15], repeated listens of a novel song will typically lead to an initial increase in preference, followed by a decrease once the listener is satiated. The phenomenon is in line with the inverted-U theory for familiarity and preference [1,2]. Although the number of listens will need to be sufficiently large to see this pattern, we should still expect an increase in preference over the initial listening experiences. Therefore, the second research question is as follows:

RQ2. Does the preference toward the unfamiliar songs increase with repeated presentations?

Properly answering these questions will require a real-world listening simulation, where subjects are as free as possible to listen to the music and report on their behaviors. Since this approach utilizes actual listening activities for evaluation, it will yield more practical results than the usual feelings-based self-reports.

4. EXPERIMENT SETUP

To answer the two research questions, 19 Spotify users (15 female) were recruited to participate in a 6-week music listening study. This study was designed to simulate real-

world listening behavior, allowing the subjects to listen freely and report on their activity. To begin, the subjects were each asked to provide their most recent 30-song Discover Weekly playlist (570 total songs) without first listening to it. Let I^k represent this playlist for user k, such that I_n^k represents the nth song from the initial discovery playlist for user k. Every week, on Monday, subject k is provided with a link to a 10-song playlist, P_w^k, where w is the current week number. They were asked to listen to the playlist once, then fill out a survey before any further listens. No restrictions or requirements were placed on the setting or device of the listening. The only suggestion given to the subjects was to treat the listening as they would their normal music discovery. The survey asked the subjects to evaluate the entire playlist in terms of both their enjoyment and its effectiveness for discovery, both on a 5-point Likert scale. Additionally, they were asked to place each of the individual songs into one of three categories: "Like it," "Not sure yet/Neutral," or "Don't like it."

4.1 Playlist Construction

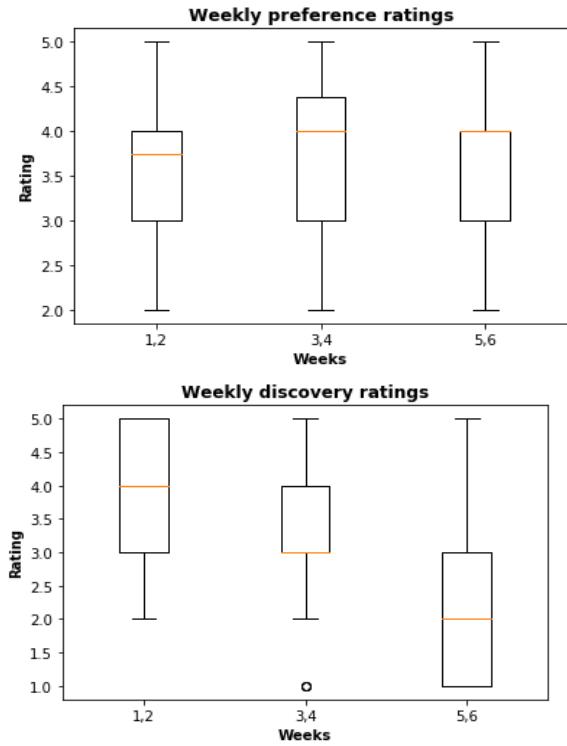
Let us describe in detail the playlist construction process (see Figure 1). Since the duration of the experiment is six weeks and we make weekly playlists, there are six playlists for subject k: P_1^k, ..., P_6^k. The six playlists contain ten songs each. Recall that the subject k disclosed the 30 songs in her Discover Weekly list, I^k, without listening to any of the songs in it. appearing in the Discovery Weekly. Since the selection in the Discover Weekly playlists ensures that the user has never listened to the song before using Spotify, we generated the playlists under the assumption that each subject had not heard any of the 30 songs in her list before. We constructed the six ten-song lists dynamically as follows:

- P_1^k and P_2^k contained songs $[I_1^k : I_{10}^k]$ and $[I_{11}^k : I_{20}^k]$, respectively, in the same order they appeared in I.
- P_3^k and P_4^k contained songs $[I_{21}^k : I_{25}^k]$ and $[I_{26}^k : I_{30}^k]$, respectively, as well as five songs repeated from P_1^k and P_2^k, respectively. It is necessary to control for the subjects' song ratings when deciding which songs to repeat. Practical implementations would simply repeat the songs the users seemed to enjoy most (saved, liked, did not skip, etc.), but the retention rate must be independent of preference in this experiment; otherwise it would be impossible to claim that it is correlated with repetition. We chose the five repeats in P_3^k and those in P_4^k to preserve the proportion of the initial ratings (Like = Not sure/Neutral = Dislike). These ratings are unknown ahead of time due to the nature of the experiment, and so we used the subject's ratings from weeks 1 and 2 for balancing the ratings. We first sorted the ten songs in P_1^k and the ten in P_2^k in the decreasing order of rating (in the case of ties, the order from I^k was preserved). We then assigned the songs at odd numbered positions in the ranking (i.e., 1, 3, 5, 7, and 9) from the first list to P_3^k. Similarly, we assigned the five songs from the second list at odd numbered positions to P_4^k. After determining the ten-song sets from which to build P_3^k and P_4^k, we fixed the order in

which the ten songs appeared. We increased the perception of diversity by placing the repeated songs and new songs alternatingly in these playlists, following the idea from [8].

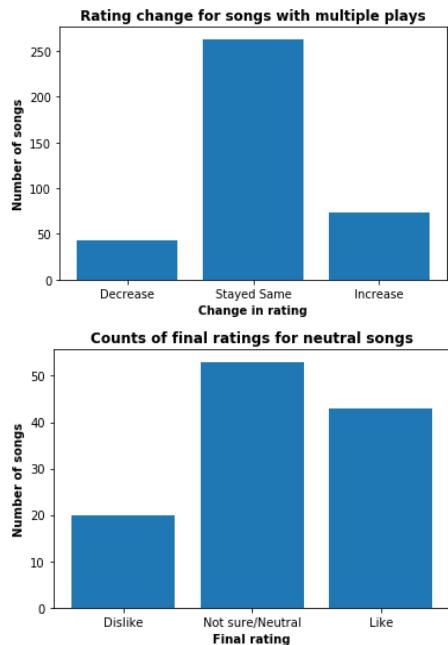
- In P_5^k and P_6^k, we kept the repeats from P_1^k and P_2^k, that we used in P_3^k and P_4^k, respectively. We selected the remaining songs as follows:
  - For P_5^k, the five remaining songs are those from P_1^k and P_2^k that we did not use in P_3^k and P_4^k (i.e., those with even numbered ranks after sorting in the decreasing order of rating). We merged the two ranked lists of five remaining songs and selected five at those at odd numbered positions in the merged list.
  - P_6^k is constructed in the same manner, but the source of the five repeats are the five non-repeats each from P_3^k and P_4^k. Again, we sorted the ten songs in the decreasing order of rating and then selected those at odd numbered positions.
- In the end, 10 songs were presented 3 times, 10 were presented twice, and the remaining 10 were only presented once and were used as a baseline.

4.2 Surveys and Evaluation Process

After the 6-week music listening portion of the experiment, the subjects were asked to complete a survey containing general questions about their music listening habits, as well as a final evaluation of the songs in I, which was simply a 5-point Likert scale rating of their likelihood to revisit the songs in the future. They were asked to fill out this portion without listening to the songs again, relying solely on their memory of the song based on name and artist. If the subject could not remember the song, they were asked to respond with an asterisk instead of a rating. Since the weekly surveys asked the subjects to place the song name and artist into one of the three fields, they were required to think critically about the song, and therefore, should be expected to remember this information. The analysis will refer to the *forgetting rate*, which refers to the percentage of forgotten songs with respect to some characteristic, such as initial rating or the number of presentations of the song. Finally, if the subjects had heard the song prior to the experiment, they were asked to leave the field blank, and that song would be omitted from the results.


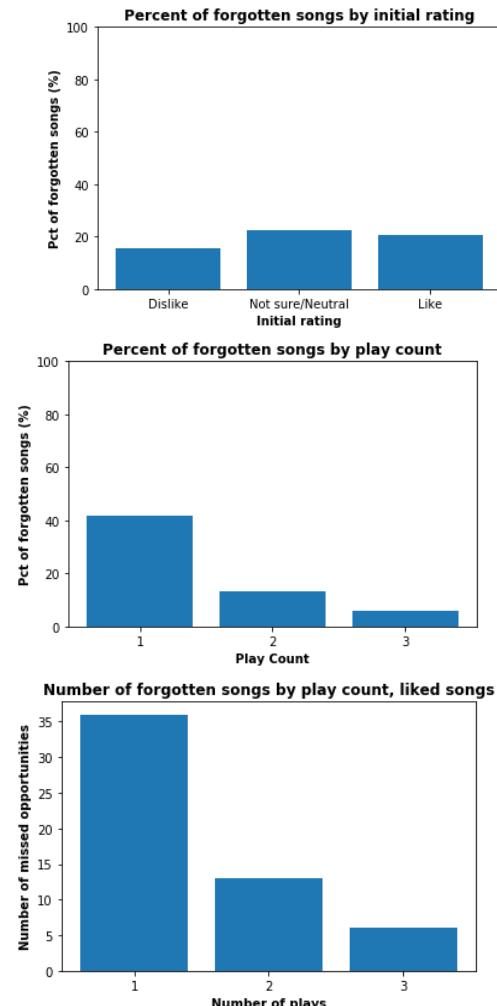
One month after the end of the experiment, the subjects received a follow-up survey asking them to indicate whether they had chosen to listen to each song in I during the month since the experiment. We evaluate the *retention rate*, R, with respect to the number of times the songs were presented, R^x as well as with respect to the subjects' ratings of the songs.

5. RESULTS AND DISCUSSION

The study utilized Spotify's Discovery Weekly playlist to provide serendipitous recommendations to the subjects based on their listening histories on the system, which meant some of the songs were not entirely new to the subjects. This is because Spotify is not the only music listening platform the subjects use, and we rectify it by omitting previously heard songs from the results analysis (26 out of 570 – less than 0.5%). It is also worth noting that the limited number of subjects restricts the generalizability of these results, but this being a multi-week study made finding subjects difficult.


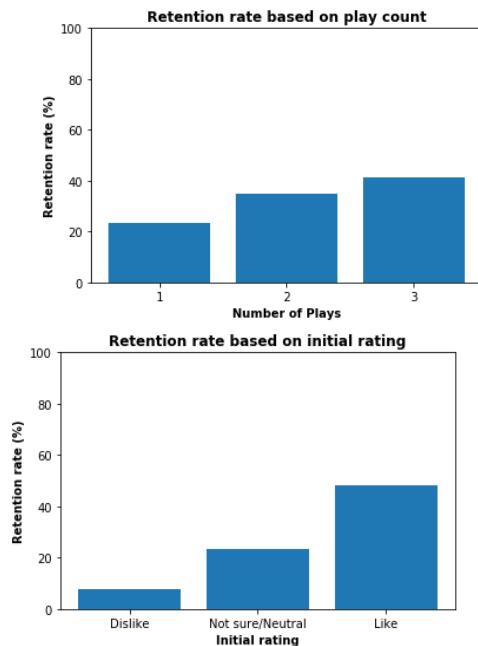
The weekly preference and discovery ratings were grouped by their composition as mentioned in Section 4, and their results are shown in Figure 2. The preference ratings were basically constant across each group, with means as follows: weeks 1-2 = 3.57, weeks 3-4 = 3.75, and weeks 5-6 = 3.67. The discovery ratings unsurprisingly declined in weeks where fewer new songs were presented, with means as follows: weeks 1-2 = 3.88, weeks 3-4 = 3.12, and weeks 5-6 = 2.41. It is worth noting, however, that an even split between new and repeated songs is likely not ideal in a real-world setting, but determining the optimal split was outside of the scope of this research.

Figure 2. Boxplots of the weekly preference (top) and discovery (bottom) ratings for all subjects, grouped based on the composition of the playlists (unfamiliar vs. familiar).

Figure 3 shows the number of songs whose rating changed, either positively or negatively, after the first listen, as well as the counts of the final ratings for "neutral" songs with more than one presentation. Though it was most common for the rating to remain the same, when it changed, it increased almost twice as often as it decreased. Of all songs with more than one play, 43 of them showed a decrease in rating and 73 showed an increase, though 263 retained their initial rating. Isolating the 116 songs with an initial rating of "neutral," we see that 43 of them (37%) had a final rating of "like," versus 20 (17%) whose rating decreased to "dislike" and 53 (46%) that remained at "neutral." Therefore, there is a potential for missed


opportunities with a "neutral" song, since the initial listen may not entice the listener to revisit the song, whereas subsequent listens are likely to yield a more favorable response. We can answer RQ2 by saying that it is more likely for a person's preference toward an unfamiliar song will increase with repeated listens, but most of the time their feelings will remain constant. A rating scale with finer granularity would have answered this question more effectively.

Figure 3. The rating changes of all songs (top) and neutral songs (bottom) with more than one presentation during the study.

Figure 4 illustrates the forgetting rate with respect to play count and initial rating. It also takes an isolated look at the songs with an initial "like" rating. In total, 105 of the 544 songs (19.3%) were forgotten. Two one-tailed paired samples z-tests were performed, comparing the forgetting rate between songs with 1 and 2 plays, as well as 2 and 3 plays, $z(343) = 5.88$, $p < 0.00001$ and $z(342) = 2.38$, $p < 0.01$, respectively. The forgetting rate decreases significantly as the number of plays increases, which should be reciprocated with a higher retention rate, though any subjects who saved the songs for later would be less reliant on their memory. In terms of liking, two additional one-tailed paired samples z-tests were conducted to compare the difference between the forgetting rates for songs with an initial rating of "dislike" versus "neutral," $z(250) = 1.38$, $p < 0.1$ and "neutral" versus "like," $z(423) = 0.44$, $p < 0.33$. In both cases, we found no significant differences on the forgetting rates, which indicates a lack of connection between preference and memory. Looking at the forgetting rate of the liked songs, we can see another potential for missed opportunities, as the songs with only one presentation are significantly more likely to be forgotten, $z(182) = 4.21$, $p < 0.00002$ for 1 versus 2 plays and $z(177) = 5.94$, $p < 0.00001$ for 2 versus 3 plays. These missed opportunities occur when a person enjoys a song


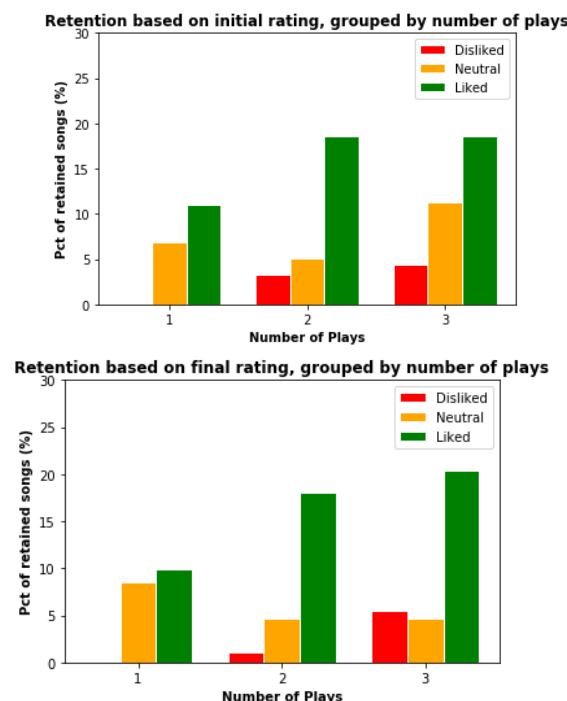
but does not save it and forgets its name or the artist name and is unable to search for it later.


Figure 4. The percentage of forgotten songs by initial rating (top) and play count (middle), as well as the number of forgotten "liked" songs by play count (bottom)

One month after the conclusion of the listening experiment, the subjects received a survey asking them to state whether they listened to each of the songs from the experiment on their own accord (i.e. in a playlist they created or by searching for the song). Of the 19 subjects, 18 of them provided responses, and only one of those did not revisit any songs. Figure 5 shows the percentage of songs which were revisited with respect to both their play counts as well as the initial ratings. Figure 6 groups the songs by play count and shows the percentage of retained songs with respect to both initial and final rating.

A series of paired samples one-tailed z-tests were performed to answer RQ1. First, the songs were grouped by the number of times they were presented, requiring a test comparing R^1 and R^2 and another comparing R^2 and R^3, $z(343) = 2.41$, $p < 0.01$ and $z(342) = 1.22$, $p < 0.2$, respectively. Clearly, there is no significant difference between the retention rate of songs with 2 and 3 plays.

Figure 5. The retention rate with respect to play count (top), initial rating (bottom).

Figure 6. The number of retained songs, grouped by number of plays, with respect to initial (top) and final (bottom) ratings.

However, if we assume that all additional plays have the same effect on retention, we can combine the songs with 2 and 3 plays. Comparing the retention rate of these songs with R^1, we get $z(514) = 3.42$, $p < 0.0005$. Therefore, we can answer RQ1 affirmatively on the premise that additional presentations of novel songs beyond the first are essentially the same. It is worth noting that this experiment did not test more than 3 presentations of a novel song, and it is likely there are diminishing returns beyond the third presentation. We conducted additional z-tests by grouping

the songs by their initial rating, then comparing the songs with 1 play and the songs with more than 1 play, as follows: for songs rated "dislike," $z(91) = 1.98$, $p < 0.025$; rating = "neutral," $z(159) = 0.62$, $p < 0.3$; rating = "like," $z(264) = 3.37$, $p < 0.0004$. The performance of the "neutral" songs is interesting and could be related to the change in rating for these songs with more than one play. In general, only the "liked" songs had a reasonably high retention rate, so it is possible that a neutral or worse feeling towards a song is insufficient to persuade a person to revisit it. As previously seen, the "neutral" songs increased in rating at a 37% rate, and when looking at the graph in Figure 6 which shows final ratings, the "liked" songs still show an increase with play count, but the remaining neutral songs do not.

We performed similar z-tests to evaluate the relationship between the initial rating of the songs and their retention, one for "dislike" vs "neutral/not sure" and another for "neutral/not sure" vs "like," $z(250) = 3.11$, $p < 0.001$ and $z(423) = 5.08$, $p < 0.00001$, respectively. Clearly, initial rating is a strong predictor of the retention of a song, though this should be obvious and does not deter from the results with respect to play count. In practice, a personalized discovery system can infer liking via user interaction (i.e. button clicks, skips, page visits, etc.), then use that to select which songs to repeat.

6. CONCLUSION AND FUTURE WORK

Previous research has concluded that repeated listens of novel music will increase both memory and liking, but the evaluation has typically involved the subjects self-reporting on their feelings. This study implemented a real-world listening simulation and evaluated the effects of repeated listens of novel songs with respect to the rate at which the songs were revisited by the subjects. We found that when songs were played more than once, in general, their retention rate significantly increased, and the rate at which the songs could be recalled from name and artist alone also increased. Additionally, if the ratings of the songs changed after the first listen, it was significantly more likely to be an increase.

We explored the concept of missed opportunities when assuming a music discovery process which recommends songs to users once and expects them to remember to revisit the songs. By only presenting songs once, liked songs are less likely to be remembered or revisited, and songs users feel neutral or unsure about will not have a chance to improve their favorability. Repetition of novel recommendations clearly decreases the potential for missed opportunities in both cases, giving users a greater chance to broaden their musical tastes.

One aspect we did not evaluate was the proper split between new and repeated songs, which may be a user-specific parameter and likely varies from week to week. In our future work, we intend to explore whether there is a predictable pattern to the amount of new music a person consumes on a weekly basis. In addition, we are planning several studies involving electroencephalography, where we will test memory and attention when listening to new music over a sustained period.

ABSTRACT

This paper focuses on the computational study of *figured bass*, which remains an under-researched topic in MIR, likely due to a lack of machine-readable datasets. First, we introduce the Bach Chorales Figured Bass dataset (BCFB), a collection of 139 chorales composed by Johann Sebastian Bach that includes both the original music and figured bass annotations encoded in MusicXML, **kern, and MEI formats. We also present a comparative study on automatic figured bass annotation using both rule-based and machine learning approaches, which respectively achieved classification accuracies of 85.3% and 85.9% on BCFB. Finally, we discuss promising areas for MIR research involving figured bass, including automatic harmonic analysis.

1. INTRODUCTION

Figured bass is a type of music notation that uses numerals and other symbols to indicate intervals to be played above a bass note, and which can provide insight on underlying harmonies [1]. It was commonly used in Baroque music, and served as a guide for performance, especially for the instruments improvising the *basso continuo* accompaniment (e.g., harpsichord, organ, lute, etc.). Fig. 1 shows an example of figured bass, as well as how a harpsichordist might realize the figured bass as an improvised accompaniment. Such realizations are not typically explicitly included in scores, as the musical tradition of the time left them to be improvised based on the skills and taste of the continuo player. There are three aspects of figured bass annotations (FBAs) that should be highlighted:

(1) The Neue Bach Ausgabe edition [2] uses FBAs consisting of numbers with backslashes through them to indicate raised intervals (e.g., m. 3.3 and m. 3.4). Forward slashes indicate lowered intervals (e.g., 5̸).

(2) FBAs followed by continuation lines indicate that the harmony of the preceding figure is prolonged (e.g., m. 1.4, m. 4.2, and m. 4.4).

(3) Multiple FBAs over a stationary bass (e.g., 4–3 in m. 5) usually indicate a suspension being resolved.

Figured bass also serves pedagogical and theoretical purposes: not only does it provide contrapuntal information on how to conduct the resolution of dissonances, it also offers insights into the chords and harmonic rhythm intended by composers. Figured bass can therefore provide a preliminary description of harmonic structure, and serves as a promising basis for approaching harmonic analysis.

As a useful analytical tool for studying Baroque compositional and performance practices, figured bass has been an important topic in music pedagogy [3], music theory, and musicology [4]. The computational study of figured bass, however, has drawn little attention over the years. We have only found two papers on automatic figured bass annotation, both using a rule-based approach: Barthélemy and Bonardi treated figured bass as a harmonic reduction and devised rules to identify and remove ornamental notes, permitting them to cluster the remaining chord tones as figures [5]; Wead and Knopke, in contrast, manually designed a decision tree to determine the figured bass for a given bass line [6]. Unfortunately, with no open-source code and a lack of quantitative results, it is impossible to objectively evaluate or compare the performances of these models. Furthermore, we are not aware of any previous applications of machine learning to figured bass, nor of any existing digital dataset with figured bass annotations (FBAs). These limitations have likely limited the computational study of figured bass to date.

There are four main contributions of this paper:

(1) We introduce the new Bach Chorales Figured Bass (BCFB) dataset, which consists of 139 chorales composed by Johann Sebastian Bach (Section 2). These chorales came from larger choral works composed by Bach: the cantatas, passions, motets, and the Christmas Oratorio. We chose this repertoire due to its key role in modern music pedagogy and its general historical importance.

(2) In order to facilitate the future creation of more figured bass datasets, we include our methodology for digitizing FBAs in an efficient and effective way.

(3) We present a comparative study of automatic figured bass annotations of BCFB, using both rule-based and machine learning approaches (Section 3). The results are discussed with reference to specific musical examples (Section 4).

(4) We highlight possible applications of figured bass annotation, especially in connection with converting figured bass to chord labels, which could benefit research on automatic harmonic analysis (Section 5).

Figure 1. A sample musical passage we composed, where figured bass annotations (FBAs) are shown below the continuo line, and where we added the harpsichord line as an example of what a continuo player might improvise based on the figured bass. Figures indicate intervals above the continuo line that could be played in the improvisation. For example, the "6" in the first measure corresponds to the pitch class "G", which is a 6th above the bass "B♭". An actual improvisation would likely also typically contain the pitch class "D" (a 3rd above the bass "B♭") in this slice, but this is not explicitly indicated in the figures. This is an example of how FBAs do not always specify all the notes to be played by the continuo player, and usually omit some obvious figures (see Section 3.2.2 for details).

2. BACH CHORALES FIGURED BASS DATASET

To the best of our knowledge, there is no prior publicly available digital figured bass dataset. We therefore present the Bach Chorales Figured Bass dataset (BCFB), a corpus we constructed containing FBAs in MusicXML, **kern, and MEI (Music Encoding Initiative) formats. It consists of all 139 J. S. Bach four-voice chorales that include his own figured bass, based on the Neue Bach Ausgabe (NBA) critical edition [2]. NBA is chosen as the source of BCFB because it is the most up-to-date scholarly critical edition, prepared with exacting methods of source criticism.

2.1. Finding Chorales with FBAs

To find all the chorales attributed to Bach, we constructed a reference table (https://bit.ly/303jzfS) with all 420 chorales indexed by BWV catalogue numbers, and cross-referenced them with the NBA. We checked whether original FBAs are accessible for each of these chorales, and found 139 settings meeting this criterion. We then made an expanded reference table, consisting of the: BWV number,[1] Breitkopf number (when relevant),[2] title of the work of origin (e.g. cantata, passion, etc.), date of the first performance, text setting, location of the score in the NBA edition, and other musicological metadata for each cho-

rale. This table is designed to facilitate musicological research, which, along with the BCFB dataset, is available at: https://bit.ly/2OoWC16.

2.2. Digitization

We began the creation of BCFB by assembling existing symbolic encodings of the relevant Bach chorales from the KernScores repository, which contained 109 of the 139 NBA chorales with FBAs.[3] We automatically translated these 109 **kern files into MusicXML using *music21* (v. 5.1.0),[4] and made changes to match the musical content[5] of the NBA edition before adding Bach's figured bass. We manually encoded the remaining 30 figured chorales found in the NBA edition. We chose MusicXML as our master file format since it is widely supported by music notation software. We used the *MuseScore* 3 score editor[6] for both editing musical content and adding FBAs.[7]

2.3. Converting to Other Symbolic File Formats

BCFB includes encodings in two other symbolic file formats[8] beyond MusicXML: **kern, and MEI.[9] Existing software was used to automatically convert the original MusicXML to the other two formats. Through a series of experiments with a variety of alternatives, we found that converting figured bass from MusicXML to **kern using *musicxml2hum*[10] worked well, except for the continuation lines, and the conversion from **kern to MEI using *Verovio*[11] was perfect. However, direct conversion of figured

---

[1] Bach-Werke-Verzeichnis (BWV) catalogue number, which indexes all the compositions attributed to J. S. Bach.

[2] The Breitkopf edition contains 371 four-voice J. S. Bach chorales, and indexes them differently from BWV.

[3] KernScores (kern.ccarh.org) is maintained by Stanford's Center for Computer Assisted Research in the Humanities, and includes 371 four-part chorales encoded in the Humdrum **kern representation (www.humdrum.org).

[4] https://web.mit.edu/music21

[5] Including: adding a continuo line and/or instrumental voices; transposing; changing the meter, pitch, and duration of certain notes; etc. We did not encode the textual content specified in the NBA.

[6] https://musescore.org

[7] https://musescore.org/en/handbook/figured-bass

[8] This diversity of symbolic formats offers researchers the opportunity to use the format most convenient to their preferred software, because if only one format were offered, which might not be supported by a given piece of preferred research software, then it would need to be converted to the format supported by the software. This could lead to a potential loss of figured bass information or to other conversion errors [7].

[9] We also used *music21* (v. 5.1.0) to generate MIDI files from the master MusicXML, but they do not include FBAs.

[10] https://github.com/craigsapp/humlib

[11] https://github.com/rism-ch/verovio

Figure 2. Measures 3 and 4 from BWV 117.04 *Sei Lob und Ehr dem höchsten Gut*. The original FBAs are annotated underneath the bass voice part. Note that not all slices are necessarily figured and not all the intervals in a sonority are necessarily specified in FBAs. We artificially added the final bottom staff, which collapses all sonorities into one octave so as to more directly reveal the pitch-class content. The number of semitones above the bass implied by the original FBAs have also been added underneath this bottom staff. We can also translate the number of semitones back to FBAs by examining the actual notes in the score and then calculating and labelling the intervals from the bass note.

bass from MusicXML to MEI (using *Verovio*) was problematic, as accidentals, slashes, and continuation lines were not converted. We therefore first converted from MusicXML to **kern, and then manually added the continuation lines to the **kern files using a text editor. The resulting **kern files were then converted to MEI files.

3. AUTOMATIC FIGURED BASS ANNOTATION

We automatically generated[12] FBAs that closely resembles those of Bach for two main reasons: to learn about Bach's figured bass habits, which are of musicological interest, and to provide figured bass for those Bach chorales for which no FBAs exist. We used both rule-based and machine learning algorithms to perform this automatic figured bass annotation:[13] the rule-based approach has the potential to model Bach's style of writing figures in ways that are easily human-interpretable, and machine learning has the potential to model patterns in Bach's style that might be difficult to codify into precise, direct rules. We therefore explored the efficacy of both approaches.

3.1. Data

We used 120 chorales out of the full 139 chorales in BCFB to train and test our models. We excluded 12 interlude chorales[14] because they are significantly different from the

other largely homorhythmic chorales, and we excluded five other chorales[15] that are barely figured. Finally, we excluded BWV 8.06[16] and BWV 161.06 because they feature irregular textures, such as having an obbligato continuo and/or instrumental part.

3.2. Rule-base algorithms

3.2.1. Initial Simple Rule-based Algorithm

We began by implementing a simple rule-based algorithm that labels all the intervals above the bass in the generated FBAs. First, the music is segmented into a series of n*ote onset slices* [8,9]. A new slice is formed whenever a new note onset occurs in any musical voice, and each slice consists of the vertical set of notes sounding at that moment. Take the first slice of Fig. 2 as an example: since the pitch classes above the bass "G" are "G", "D", and "B," the FBA generated is 8/5/3.

We then compared the generated FBAs against Bach's original FBAs, and found that the percentage of exact matches was only 3%. This is partly because Bach did not explicitly label all the intervals above the bass in his FBAs; it is often assumed that both he and other Baroque composers employed FBAs that include what are in effect abbreviations that omit obvious intervals [1,10]. For example, consider m. 3.2.5[17] of Fig. 2: although the pitch classes "A" and "D" are present in this slice above the bass "F♯", only "D" is explicitly specified[18] by the figure "6"; "3" is not explicitly indicated, but is nonetheless implied.

3.2.2. Evaluation Metric

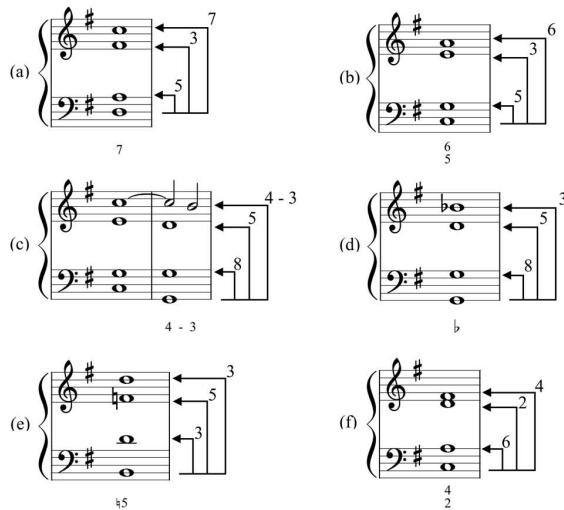
To allow for the equivalence in musical content of different figured bass notation conventions, as discussed above, we created an evaluation metric that treats figures that are musically equivalent as notationally equivalent. The purpose of this metric is to realistically evaluate the generated figured bass when it does not match Bach's figured bass exactly. The equivalence rules are inspired by Arnold [11]:

- A "3" can be omitted (Fig. 3a, 3b, 3d, and 3e) unless there is a 4th in the sonority,[19] or unless the 3rd is the resolution of a 4–3 suspension (Fig. 3c).
- A "5" (Fig. 3a, 3c, and 3d) can be omitted, unless one of the following conditions is true: there is a 6th (Fig. 3b) in the sonority, the 5th is the resolution of a 6–5 suspension, or the 5th has an accidental (Fig. 3e).
- An "8" (Figs. 3c and 3d) can be omitted, unless one of the following conditions is true: there is a 9th (Fig. 3b) in the sonority, the 8th is the resolution of a 9–8 suspension, or the 8th has an accidental.
- A "6" can be omitted if the sonority forms a "6/4/3" or a "6/4/2" chord, as shown in Fig. 3f.

---

[12] The generated FBAs use flats and sharps to respectively indicate lowered and raised intervals, and do not contain continuation lines.

[13] The code is available at: `https://bit.ly/2P8Qbju`.

[14] These chorales have elaborate instrumental interludes between phrases (BWV 24.06, 76.07, 100.06, 105.06, 113.01, 129.05, 167.05, 171.06, 248.09, 248.23, 248.42, and 248.64).


[15] BWV 16.06, 48.07, 149.07, 195.06, and 447.

[16] ".06" in "BWV 8.06" means this chorale is the sixth movement of the "BWV 8" cantata.

[17] "m. 3.2.5" means the third measure, the second and half beat.

[18] Since "D" forms a 6th interval above the bass "F♯".

[19] "Sonority" means the set of pitch classes present in a note onset slice. For example, the added bottom staff of Fig. 2 shows the sonorities of the four voices for each slice. "4th" means that a wrapped interval of a 4th can be found between the bass and an upper voice, regardless of whether it is labelled in the figured bass.

Figure 3. Common examples of standard figured bass abbreviations taken into account by the evaluation metric explained in Section 3.2.2. In each of the six examples (a)-(f), all the intervals above the bass are shown to the right of the notes connected with arrows, and typical abbreviated FBAs for the chords are shown below the notes. For example, (a) consists of a dominant 7th chord in root position, and includes notes that are a 3rd, 5th, and 7th above the bass: the figured bass consists of only a "7", with the "3" and "5" omitted, as is often the practice in FBA.

In order to see how the evaluation metric based on these rules operates in practice, consider Fig. 3a as an example: we can see that "5" and "3" can be omitted, which means "7", "7/3", "7/5", and "7/5/3" are all considered equivalent. Therefore, if the ground truth and the generated figured bass respectively consist of any pairing of "7", "7/3", "7/5", or "7/5/3", then the generated figured bass will be considered correct by the metric.

3.2.3. Improved Rule-based Algorithm

Using this evaluation metric, the simple ruled-based algorithm described in Section 3.2.1 has an effective agreement of 64.5% with Bach's FBAs. We found that when they disagreed, the generated FBAs tend to have more figures than those of Bach. To improve this, we manually developed additional rules for omitting certain figures, permitting us to better predict Bach's style of annotation.[20]

First, we examine each note onset slice and omit the figure for a given note in an upper voice if both of the following two conditions are met: (1) the note is labelled in the previous slice, and (2) the pitch class of the bass in the current slice remains the same as in the previous slice.

Then, we consider slices on fractional beats (e.g., beat 2.5 and 3.5), looking for ornamental notes, such as passing tones, neighbour tones, escape tones, and anticipations, which are all approached or departed by step. If such a note

is in an upper voice, its corresponding number is removed from the figure; if such a note is in the bass, the slice is left entirely unfigured.

After the addition of these rules, the model was able to achieve 85.3% agreement with Bach's figures, a large improvement over the 64.5% agreement achieved with the simple method and equivalency rules.

Although it would have been possible to invest more time manually analyzing Bach's figured bass to develop still more rules to improve agreement, none were readily obvious from the perspective of music theory or performance practice, and we wanted to avoid overfitting our rules. So, we turned our attention to machine learning, to see if it could be employed to model Bach's FBA style with equal or better results.

3.3. Machine learning algorithms

In order to efficiently perform automatic figured bass annotation with machine learning methods—something that has never been explored in the literature—we transformed the FBAs into interval-class vectors.

3.3.1. Transformation from Figured Bass to Interval Classes

Recall that figured bass indicates intervals above the bass note. Thus, for each slice, we convert the figures to an interval-class vector.[21] An interval class, similar to a pitch class, is a set of intervals wrapped by octaves. For example, an interval class of a major second includes a major ninth and all other octave expansions of a major second. As with a pitch-class vector, an interval-class vector contains 12 elements, representing intervals in semitone increments. In our case, each FBA is converted to an interval-class vector that includes all the notes above the bass that are sounding in the current slice. In cases where the figured bass does not specify the exact interval in semitones, such as the "6", which could be either a major 6th or a minor 6th, we rely on the score to determine the exact interval using heuristics-based post-processing. We similarly rely on the score to later convert interval-class vectors back to figures: for example, an interval of three semitones can be interpreted as either a minor third (figure "♭3") or an augmented second (figure "♯2"). We can decide which is appropriate by considering the pitch spelling in the original score.[22] This representation of the figured bass is used for both input and output of the machine learning algorithms.

3.3.2. Input Features

The three feature vectors used as input to the machine learning algorithms are: (1) interval classes (see Section 3.3.1); (2) onsets, which specify which notes above the bass have onsets within the slice, as opposed to being held from a previous slice; and (3) metrical context, which specifies whether a slice occurs on the downbeat of a measure, on another beat (e.g., beat 2, 3, or 4 in 4/4), or on

---

[20] The rules were proposed by observing the generated FBAs and were evaluated against the ground truth FBAs from BCFB. We selected the rules that yielded higher accuracy.

[21] We are using the term "interval class" here to refer to *ordered* interval class. Since we wish to calculate the intervallic relationship *from* the bass *to* and upper voice (in that order), we wish to distinguish between intervals and their inversional equivalents (e.g. minor 7ths are distinguished

from major 2nds). Thus, ordered interval classes range from 0 to 11, while unordered interval classes range from 0 to 6 only.

[22] For example, to distinguish "2" and "9" when unwrapping interval-class vectors, we need to find the actual note above the bass and compare its pitch to the pitch of the bass. If they are one octave apart, the generated figure will be "9", and "2" otherwise.

a fractional beat (e.g., beat 3.5). These binary vectors are specified for each slice. The following example demonstrates each of these feature vectors for m. 4.2.5 of Fig. 2 (the bit-length of each feature is indicated in parentheses):

- *Interval classes (12):* The bass note is "A" (held), with pitch classes of "C♯", "G", and "E" (held) above it, which are respectively four, ten, and seven semitones away from it. The feature vector is thus: [0,0,0,0,1,0,0,1,0,0,1,0].[23]
- *Onsets (12):* "C♯" and "G", which are respectively four and ten semitones above the bass, are the pitch classes with onsets on this slice, so the feature vector will be [0,0,0,0,1,0,0,0,0,0,1,0].
- *Metrical context (3):* Because the slice is on beat 2.5 of a 4/4 measure, the feature vector will be [0,0,1] (i.e., it is a fractional beat).

Each slice, therefore, is represented as a 27-dimensional (12+12+3=27) binary vector. To provide a context for each slice, the machine learning algorithms are also provided with the two 27-dimensional vectors for the previous and following slices (zero-padded for first and the last slices). Thus, the total length of the input vector for each slice is 81 (27×3=81).

3.3.3. Machine Learning Algorithms

We experimented with two machine learning algorithms: Decision Trees (DT) [24] and Deep Neural Networks (DNN).[25] Both algorithms used the input features specified above. Their output each consisted of a 12-dimensional binary vector specifying the number of semitones above the bass,[26] as discussed in Section 3.3.1.

3.3.4. Experimental Setup

Ten-fold cross-validation was used for evaluation. For the DNN experiments, we divided the data into training (80%), validation (10%),[27] and testing (10%) folds. For the DT experiments, the data was divided into training (90%, the union of the DNN training and validation sets) and testing (10%, matching the DNN test sets) partitions.

3.3.5. Results

The Decision Trees and Deep Neural Networks respectively achieved classification accuracies of 84.3±0.5% and 85.9±0.6% on BCFB.[28] These accuracies are calculated based on the evaluation metrics proposed in Section 3.2.2.

4. DISCUSSION

It is useful to examine the types of errors that our model made, in order to better understand its performance and how it can be improved. We will focus this discussion on the two musical examples shown in Fig. 4, as they are representative of the kinds of errors our model made. One

common error made by our model was to miss figures that indicate the resolution of a suspension, such as the 9–8 shown in Fig. 4(a), m. 8.4. This may be because the features we used did not contain sufficient voice-leading information to detect such suspensions.

Two further types of disagreement between our model and Bach's figures are shown in Fig. 4(b). At m. 2.3 our model generated "♯", but the ground truth had no label. In fact, the generated "♯" is technically correct, as the D is explicitly sharpened in the soprano. Turning to m. 3.2, our model's prediction included a "♯7," unlike the ground truth. Perhaps this suggests that Bach might have considered the corresponding "D♯" to be a passing tone? Or perhaps the D♯ was understood as a "diatonic" note in this Dorian chorale tune? At any rate, the "♯7" in the generated figures should not necessarily be considered wrong. Both these figures are in fact theoretically acceptable answers.

Such differences between the ground truth and the predicted figures are intriguing, as they hint at contrapuntally or harmonically meaningful information present in Bach's figures that is not explicit in the four vocal lines. Or, perhaps they are of negligible meaning? It is impossible to know with the information we have now, but future comparisons with models trained not just on Bach but on the figures of many Baroque composers could potentially reveal fascinating insights on compositional style.

We also observed interesting variability in the types of figures Bach used under seemingly similar musical contexts. Three examples are shown in Fig. 4:

- *Accidentals:* in Fig. 4(b), Bach did not label the first "♯" at m.2.3, but did label the second one at m. 3.3.
- *Suspensions:* Bach sometimes labelled suspensions (e.g., m. 8.4 of Fig. 4(a)), and sometimes omitted them (e.g., m. 1.4 of BWV 194.06 [not shown]).
- *The same chord:* Bach sometimes labelled a 6/4/2 chord as a 4/2 chord (e.g., m. 2.1 of Fig. 4(b)), and sometimes as a 6/4/2 chord (e.g., m. 10.4 of BWV 13.06 [not shown]).

So, one cannot expect 100% agreement to be achievable, given such variability. Bach, like everyone, was sometimes inconsistent with himself, which imposes an artificial performance ceiling on our models [12]. Also, these types of variabilities can be of great interest to music theorists and musicologists, and offer significant potential for future research.

---

[23] The first dimension indicates a unison (or collapsed octaves).

[24] We used the "DecisionTreeClassifier" function from the "scikit-learn" library, under default settings. This function is an optimized version of CART (Classification And Regression Tree).

[25] We used a feedforward network with three hidden layers, each with 300 hidden units. Adaptive Moment Estimation was used as an optimizer, with a binary cross-entropy-based loss function. These hyperparameters were tuned using the validation set.

[26] For example, the output vector for m. 4.2.5 of Fig. 2 will be [0,0,0,0,1,0,0,0,0,0,0,0], considering only pitch class "C♯" is indicated by the FBA "♯" and is four semitones above the bass.

[27] The validation set was also used for the selection of the best DNN model using early stopping.

[28] Uncertainty values show standard error across cross-validation folds.

Figure 4. An illustration of figured bass generated by our best-performing model for measure 8 of BWV 108.06 *Es ist euch gut, daß ich hingehe*, and measures 2 and 3 of BWV 145.05 *Ich lebe, mein Herze, zu deinem Ergötzen*, which are labelled (a) and (b) here, respectively. We artificially added the fifth (bottom) staff, which collapses all sonorities into one octave so as to more directly reveal the pitch-class content. As discussed in Section 3.3.1, our model predicts interval classes, and the figured bass is generated based on the intervals between the bass note and each predicted interval class. The agreement of each prediction with Bach's FBAs are shown as well: "✓" means that the generated figured bass exactly matches Bach's FBAs (the ground truth), "✓" in red means they are considered correct by our evaluation metric that treats musically equivalent figures as equivalent (see Section 3.2.2). An example of the latter can be found at m. 2.1 of (b) where the generated figures can be reduced to "2/4" from "2/4/6" (since the "6" can be omitted, as discussed in Section 3.2.2). "✗" means the generated figures are considered to be errors in our evaluations.

5. CONCLUSION AND FUTURE RESEARCH

This paper presents the Bach Chorales Figured Bass dataset (BCFB), which consists of 139 four-voice Bach Chorales with figured bass annotations encoded in MusicXML, **kern, and MEI. This dataset, and others that can be constructed using methodologies similar to those we propose, offer important potential for use in future computational studies in domains such as music theory, musicology, pedagogy, and performance practice.

This paper further shows how BCFB can be used as the basis for developing and evaluating both rule-based and machine learning models for predicting figured bass; our models achieved classification accuracies of 85.3% and 85.9% on BCFB, respectively. A potential reason the machine learning models did not outperform the rule-based model may be the relatively small size of BCFB.

Such automatically generated figured bass could help performers improvise *basso continuo* accompaniment for the remaining unfigured Bach chorales, or inform the design of pedagogical software for teaching Baroque theory or composition. Of particular interest, figured bass can potentially benefit automatic harmonic analysis research. Existing methods tend to either identify chords directly from the music [13–15], or identify and remove non-chord tones from the score and then generate chord labels from the remaining chord tones [16,17]. A new approach would be to first generate figured bass automatically from the music and then convert the figures to chord labels; this would allow a chord classifier to take advantage of knowledge implicitly learned from Bach's ground truth FBAs by a figured bass annotator during its training.

There are several refinements that could potentially improve the quality of the figured bass our approaches generate. The first is to add voice-leading information (how one voice moves horizontally), which may reduce some of the errors discussed in Section 4. The second would be to improve our rule-based model (e.g., by analyzing automatically trained decision trees), which in turn could provide further insights into Bach's approach to figuring bass, and perhaps provide musicological insight on how his methods changed over time or by the context of performance.

Another potential extension to this research would be to incorporate FBAs from other pieces by Bach, such as his chamber music, or from pieces by other Baroque composers, which are usually figured throughout the Baroque period. Once we have a variety of figured bass datasets for different genres and composers, we may then be able to train models that generalize better. Also, by comparing Bach's FBAs to FBAs by other composers, we may gain meaningful insights into Bach's unique compositional style and discover a sense of the degree of stylistic variability with which composers approached figured bass.

A CORPUS-BASED ANALYSIS OF
SYNCOPATED PATTERNS IN RAGTIME

Phillip B. Kirlin

Department of Mathematics and Computer Science, Rhodes College

`kirlinp@rhodes.edu`

ABSTRACT

In this paper, we build on and extend a number of previous studies of rhythmic patterns that occur in ragtime music. All of these studies have used the RAG-C dataset of approximately 11,000 symbolically-encoded ragtime pieces to identify salient rhythmic patterns in the corpus and qualify how they are used. Ragtime music is distinguished from other musical genres by frequent use of syncopation, and previous computational studies have confirmed a number of musicological hypotheses regarding the use of syncopated patterns in ragtime compositions. In this work, we extend these studies to investigate further questions involving the use of syncopation. Specifically, we introduce a new methodological framework for processing the RAG-C dataset and confirm that experiments from previous studies obtain similar results using the new methodology. We investigate the use of the common "short-long-short" syncopated pattern in different time periods and present new results detailing its use by three well-known ragtime composers. We describe how the use of other syncopated patterns has evolved over time and the different distributions of patterns that result from those changes. Lastly, we present novel results identifying statistically significant patterns in the way composers varied the amount of syncopation in consecutive measures in compositions.

1. INTRODUCTION

In this work, we present an analysis of the salient rhythmic patterns that occur in ragtime piano music and quantify how the use of these patterns has changed over time and varies between composers. In particular, we illustrate that the specific sequences of syncopated patterns found in ragtime music and the ways in which they are ordered are not due to chance, but due to deliberate choices made by the composers. We argue that understanding and quantifying the musical choices made by composers is crucial to creating and improving the performance of various music information algorithms, including those for genre classification and algorithmic composition.

Recently, a number of corpus-based studies of ragtime

music have been published [1–4] that use a dataset known as the RAG-collection (RAG-C), a corpus of over 11,000 MIDI files first introduced by Volk and De Haas [1]. This dataset presents particular challenges to use due to its heterogeneous nature: it contains compositions from a wide variety of eras and composers, includes numerous ragtime styles (some of which could be argued are not ragtime at all), and has no standard method for encoding the music in MIDI format: some files are derived from live performances, while others are sequenced from sheet music.

Previous studies using the RAG-C corpus have identified the common usage of certain rhythmic patterns in ragtime, but have varied in their techniques in processing the corpus and interpreting the rhythmic patterns located. We present a new methodology for analyzing the corpus while taking care to confirm that our results align with previously-published studies.

Our contributions are as follows. First, we illustrate the feasibility of using automated algorithmic techniques to extract rhythmic patterns from a collection of MIDI files. We also argue for why our particular techniques work given the heterogeneous nature of the RAG-C dataset, especially involving the different time signatures present in the collection. Second, we extend previous corpus-based studies of ragtime music to illustrate the importance of specific kinds of syncopated patterns across the entire corpus, and also in subsets segmented by era and by composer. Because our methodological techniques are slightly different than those used in previous work, we confirm a number of earlier results and then extend them with new experiments and findings. Third, we show that additional patterns emerge when we study the way composers choose to order the amount of syncopation in successive measures: we statistically illustrate that this is done in a particular, deliberate manner. All the code for the work described here is publicly available. [1]

2. RAGTIME AND SYNCOPATION

In music, *syncopation* occurs when notes that a listener would expect to occur on strong beats in a measure are shifted to weak beats. Syncopation is particularly identified with *ragtime* music; while various definitions of ragtime exist, the unifying characteristic is the presence of certain varieties of syncopated rhythms [5]. Though in the modern era ragtime is often thought of as a form of music

---

[1] https://github.com/pkirlin/ragtime-ismir-2020

Figure 1. Different versions of the 121 pattern. Variations (a) and (b) are untied; (c) and (d) are tied.

restricted to the piano, during ragtime's heyday of roughly 1890–1920, this style of music was composed for all kinds of instrumental ensembles as well as in song form [6]. After 1920, ragtime fell out of compositional favor, though one can still find many rags composed during the modern era.

As syncopation is the defining characteristic of ragtime, it is natural to study how the use of syncopated patterns has changed over time. Ragtime scholars argue that a number of specific syncopated rhythmic patterns that composers gravitated towards changed in their frequency of use during the original ragtime era, with particularly drastic shifts occurring around the turn of the century. In particular, musicologists often focus on the importance of the "short-long-short" or "121" pattern. This pattern occurs with various note durations, but is usually found in the form ♪ ♩ ♪ in $\frac{4}{4}$ or $\frac{2}{2}$ time signatures and ♫♫ in $\frac{2}{4}$. It may occur at various locations within the measure; musicologists focus on how its position within the bar changed as ragtime evolved over time. In an *untied* syncopation, the pattern starts on either the metrical downbeat or halfway through a measure, therefore occurring entirely in the first or second half of a measure, as in Figure 1(a) and (b). In a *tied* syncopation, the pattern begins either one-quarter or three-quarters of the way through a measure, and therefore either crosses the midpoint of a measure or extends into the following measure, leading to a tie displayed in the notation, as in Figure 1(c) and (d). Music historians and previous studies of ragtime have noted that the untied syncopation was more typical of the early ragtime period of approximately 1890–1901, while the tied syncopation picked up in popularity after the turn of the century [5–7].

3. METHODOLOGY

Our methodology is similar to that used in previous studies [1–4], but different enough to warrant some explanation and confirmation that our results align with those of previous work. We begin by preprocessing the RAG-C dataset, with our goal being to identify a set of ragtime pieces sharing a set of basic, consistent properties. We do this by using an established MIR toolkit to identify the time signature and number of parts in each composition. We then use a notation program to automatically quantize the MIDI files and separate the melody from the accompaniment. Because MIDI files do not consistently represent pickup measures (anacruses, or fractional measures at the beginning of a composition), we conduct an experiment to illustrate that they are correctly identified in the dataset. We conclude the preprocessing stage with matching the MIDI files with entries in the RAG-C compendium, which pro-

vides useful metadata for each composition, and extracting the rhythms of all the melodic voices.

The RAG-C Dataset. The RAG-C dataset is a corpus of approximately 11,000 ragtime compositions in MIDI format, compiled over time by many enthusiasts of the ragtime genre. In addition to the compositions, the dataset includes a compendium spreadsheet providing metadata for each piece, including title, composer, year (or approximate year) of composition or publication, subgenre within ragtime such as march or two-step, and information about the source of the MIDI file such as the person who played the recording or sequenced the sheet music.

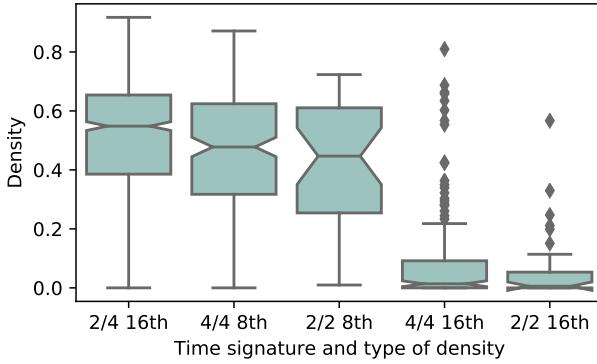
The MIDI file format, having been designed to support communication between electronic music devices, only contains low-level information about the timing of notes in a composition, and therefore MIDI files are more akin to transcriptions of a piece of music rather than a perfect representation of a printed score. A MIDI file is organized into tracks, with each track containing a sequence of *events* specifying when certain notes should be played. Each track also specifies the musical instrument that should play the notes in that track. While it is possible to specify higher-level information such as time or key signatures in a MIDI file, they are not required and are often omitted. Therefore, it is a non-trivial task to extract music-theoretic features from such files [8], especially metrical information. Notes in a MIDI file are only specified as starting and ending at a timestamp given in "ticks" measured from the beginning of the file. It is easiest to infer note durations when a time signature is present in the file and the file is created from a software sequencer, which will ensure that the notes within a MIDI file correspond to a logical metrical grid. When MIDI files are derived from human performances, however, notes that occur simultaneously on the printed page may not match up exactly in terms of ticks due to natural timing variances in performance. *Quantization*, the process of aligning the notes within a MIDI file to a metrical grid, must therefore occur to derive metrical information in such cases.

Melody and Accompaniment Extraction. To address these issues with the RAG-C dataset, we first decided to study only ragtime pieces for solo piano, a decision made in a number of previous studies using the dataset. Within the ragtime piano repertoire, it is common for most of the syncopated action to occur in the right-hand melody part, while the left-hand plays a steady accompaniment. Therefore, isolating the right-hand melody is a clear prerequisite for investigating the syncopated rhythms of ragtime. To accomplish this, we used the `pretty_midi` library [9] to identify MIDI files from the dataset containing exactly two piano tracks in the file. Normally such files contain the melody in one track and the accompaniment in the other; we verified this by calculating the average pitch of the notes in each track and comparing them. The track with the higher average pitch was labeled as the melody, and the other as the accompaniment. To account for files having two piano tracks due to other circumstances (such as two different compositions in one file or a single piano track duplicated twice), we hand-examined all MIDI files where

the difference in the average pitches of the two tracks was smaller than one octave to ensure that the melody identification algorithm functioned correctly. Furthermore, at this point we verified that all files remaining had time signatures of either $\frac{2}{4}$, $\frac{4}{4}$, or $\frac{2}{2}$. While ragtime is occasionally found in other time signatures, the vast majority of ragtime music occurs in these meters.

Quantization. Quantizing a MIDI file means aligning the notes in the file to a metrical grid in order to assign natural note durations to each note. To quantize our data, we ran each two-piano-track MIDI file through the MuseScore music notation program [10] and converted each file to its MusicXML representation. MusicXML is a richer format than MIDI that supports more features of common music notation; we use it here specifically so MuseScore can deduce standard note durations and measure boundaries for the MIDI files. We analyzed the resulting MusicXML output files using the `music21` library [11] and discarded any files for which more than 5% of the note onsets in the piece did not align with a 16th note grid. Most ragtime compositions rarely go beyond the 16th note level; we determined that any file with an overabundance of 32nd notes or notes at other onsets in the metrical grid probably was quantized incorrectly.

Title Matching. After all previous steps were completed, we were left with 1991 MIDI files. However, some of these files corresponded to the same ragtime composition, but encoded by different contributors to the RAG-C dataset. To ensure we only had one instance of each composition in our analyses, we used the Levenshtein edit distance to compare each MIDI filename — usually a combination of the composition title and MIDI encoder — against the set of composition titles in the RAG-C metadata spreadsheet. Any situation where a filename matched more than one title with an edit distance of 5 or less triggered an inspection by hand to assign the proper title. If two or more files matched with a single composition, we kept only the file with the highest quantization percentage; that is, the version with the highest percentage of notes that matched perfectly to the quantization metrical grid. This left us with a final total of 1058 MIDI files in our corpus, each one corresponding to a unique composition.

Accounting for Pickup Measures. Because of the lack of sophisticated metrical information in MIDI files, inconsistencies may arise when processing MIDI files derived from compositions containing a *pickup measure*, that is, an incomplete measure at the beginning of the music. Such music requires special handling as MIDI files do not explicitly store the locations of measure boundaries, and software that assumes such boundaries occur at regular intervals throughout the file will likely incorrectly process a MIDI file containing an incomplete measure. Because we will be investigating syncopation at different points within a measure, it is important that we correctly identify the measure boundaries in such cases.


A common convention is to "pad" a pickup measure with silence at the beginning of a MIDI file, thereby lengthening the first incomplete measure into a complete one. Sometimes this convention is extended to MIDI files that do not have a pickup measure: such files begin with a complete measure of silence. Since any file with silence at the beginning clearly has been padded, we are left with what to do with any unpadded files — we made the decision to treat these files as having full measures throughout, without a pickup measure.

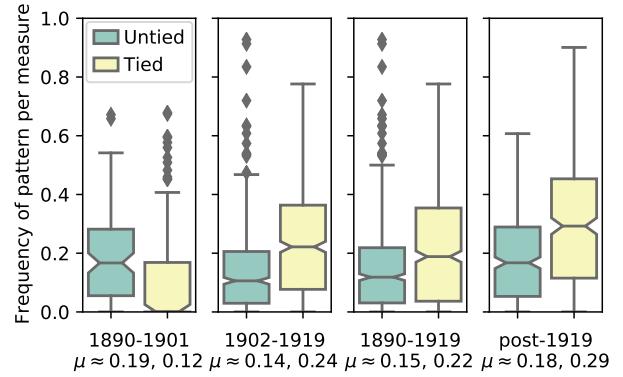
We justify this decision with the following experiment. We identified one particular contributor to the RAG-C dataset who chose to always encode MIDI files with silence at the beginning: a padded partial measure of silence for compositions beginning with a pickup, or a complete measure of silence for compositions without a pickup. This individual encoded 104 compositions in the dataset, and 26 of them began with a partial measure of silence, versus 78 with a complete measure of silence. Because 25% of this particular contributor's files begin with a pickup measure, we would expect that this proportion would hold in the remainder of the corpus as well. Of the 1991 MIDI files remaining after the quantization step, 1887 of them do not come from the contributor in question. Of the 1887, 539 begin with a fractional measure of silence and 1348 begin with a complete measure of silence or no silence. Because 539 out of 1887 is approximately 28.6%, it is reasonable to assume that the files with no silence at the beginning correspond to compositions with no pickup measure.

Binary Onset Patterns. The last remaining step in preprocessing the RAG-C dataset is to identify the rhythms of the melody part. Previous studies of ragtime syncopation used the convention of *binary onset patterns* to represent rhythms. These patterns are sequences of ones and zeros where a one represents the onset of a note and a zero represents a continuation of a note or a rest. These patterns can be computed at different levels of metrical granularity from a score. For instance, the binary onset pattern for a $\frac{2}{4}$ measure of four eighth notes would be "`10101010`" computed at the 16th-note level, but "`1111`" computed at the eighth note level.

Our dataset contains ragtime compositions in three different time signatures, namely $\frac{2}{4}$ (810 pieces), $\frac{4}{4}$ (214 pieces), and $\frac{2}{2}$ (34 pieces). We chose to compute binary onset patterns at the sixteenth note granularity for $\frac{2}{4}$ compositions, and at the eighth note granularity for $\frac{4}{4}$ and $\frac{2}{2}$ pieces. The basis for this decision was the observation that the use of sixteenth notes differed between pieces notated in the three time signatures, verified by the following experiment. We define the *sixteenth note density* for a measure of music as the proportion of the *weak* sixteenth note beats in a measure (that is, onsets 2, 4, 6, and 8 in $\frac{2}{4}$) that contain at least one note onset. We define the *eighth note density* for a measure similarly. We then computed the distribution of densities of sixteenth notes in all three time signatures, and eighth note densities in $\frac{4}{4}$ and $\frac{2}{2}$. We observed that our initial choices of appropriate granularities for binary onset patterns — corresponding to the first three plots in Figure 2 — fall in similar ranges, while the last two plots do not, justifying our mixed use of sixteenth and eighth note binary onset patterns. However, Figure 2 does show a number of outliers in the $\frac{4}{4}$ and $\frac{2}{2}$ sixteenth note density plots, falling more in the range of the first three plots, indicating

Figure 2. Box plots illustrating the distribution of 8th and 16th note densities in the various time signatures.

that in future experiments, we should consider analyzing those particular pieces at the sixteenth note level.

4. EXPERIMENTS


In this section we describe a number of analytical experiments that we conducted to extract information from our corpus about the way syncopation is used in ragtime music.

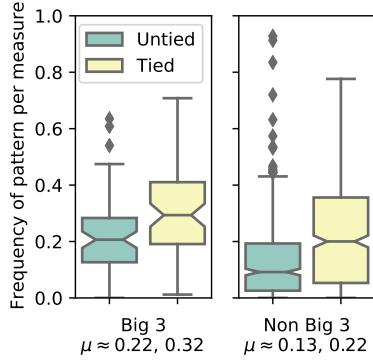
4.1 Exploring the 121 Pattern

Ragtime scholars hypothesized *untied* syncopations were the predominant form of syncopated pattern found in early ragtime compositions from approximately 1890 to the turn of the century, while *tied* syncopations did not become common until around 1902 in the late ragtime period [6,7]. This hypothesis was confirmed by Volk and De Haas [1]; we replicate their experiment due to differing methodologies for processing the RAG-C dataset. These differences in selecting and quantizing MIDI files naturally produce a slightly different corpus with which we are working, and therefore replicating earlier work shows that these results are invariant with a well-rounded corpus and lends credence to our extended results that build on earlier studies.

In this experiment, we compared the frequency of use of the 121 tied and untied patterns in ragtime compositions from three eras: first, we compared the early ragtime period of 1890–1901 (110 pieces) with the late ragtime period of 1902–1919 (582 pieces), and then compared the entire ragtime period of 1890–1919 (692 pieces) with the modern period of 1920 to the present (362 pieces). The 121 patterns were found by looking at the binary onset patterns that were collected earlier and counting the number of times each variety of syncopation appeared in a composition. It is possible for multiple 121 syncopations to appear in a single measure, as each syncopation covers only part of a measure. To account for differing lengths of pieces, we divided the total tallies by the number of measures in each composition, resulting in *frequency per measure*.

Overall, these results are similar to those of Volk and De Haas, taking into account some variation for differing pieces selected from the RAG-C dataset. In particular, we confirm that the number of tied patterns doubled between the early and late ragtime eras, and the number of untied patterns decreased between the eras as well. The left two

Figure 3. Box plots illustrating the distribution of frequencies of 121 patterns per measure, comparing different eras of ragtime. Means (μ) are shown below each plot.

plots in Figure 3 illustrate this. Wilcoxon rank-sum tests confirm (untied: $p < 0.001$, tied: $p \ll 0.001$) that the differences between the eras are statistically significant given the null hypothesis that the distributions are identical.


The right two plots in Figure 3 can be analyzed in a similar fashion, and illustrate that the use of both types of syncopation climbed after the end of the ragtime era. Wilcoxon rank-sum tests again confirm (untied: $p \ll 0.001$, tied: $p \ll 0.001$) that these increases are statistically significant.

The Big Three. Ragtime scholars agree that three ragtime composers stand out from the rest in terms of best exemplifying the ragtime genre: Scott Joplin (1867 or 1868–1917), James Scott (1885–1938), and Joseph Lamb (1887–1960) [12–14]. These composers are well-represented in the RAG-C dataset, and it is instructive to examine if they used syncopation patterns differently than each other or as compared to other ragtime composers.

When comparing the big three among themselves, small differences in usage of the 121 pattern emerge but nothing that cannot be attributed to chance. However, statistically significant differences are evident when comparing the output of the big three against other ragtime composers. In particular, even when controlling for era, the big three composers used more 121 patterns than other composers. In this experiment, we isolated the output of the big three composers during the late ragtime era of 1902–1919 (70 pieces), and compared their compositions against those of the remaining composers from the same era (512 pieces). Wilcoxon rank-sum tests confirm that the differences in the frequency of use of both untied ($p < 0.0001$) and tied ($p < 0.0001$) syncopations are different between the big three and the remaining composers. Figure 4 illustrates how the big three used, on average, almost 70% more untied 121 syncopations and almost 50% more tied 121 syncopations.

4.2 Analyzing other syncopated patterns

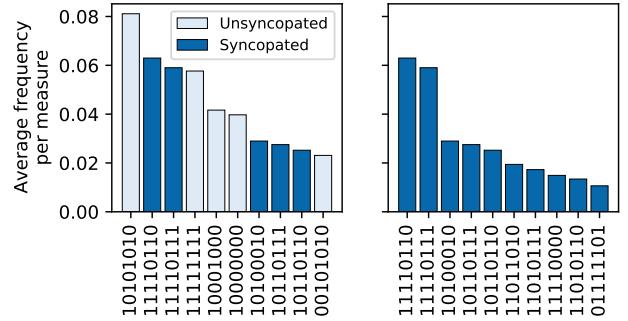
Analyzing frequencies of the 121 pattern is instructive to verify certain hypotheses put forth by musicologists. However, it is not a given that this pattern or its variants are necessarily the most prevalent patterns found in ragtime. In


Figure 4. Box plots illustrating the distribution of frequencies of 121 patterns per measure, comparing compositions by the "big three" ragtime composers in the late ragtime era versus all other compositions from that same era.

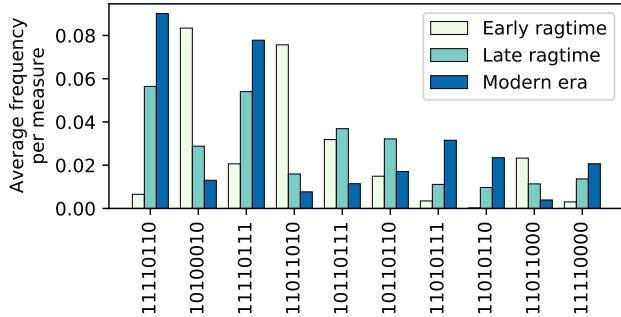
Figure 5. Left: The ten most frequent binary onset patterns overall, differentiating between unsyncopated patterns (LHL > 0) and syncopated patterns (LHL > 0). Right: Then ten most frequent syncopated patterns.

this section, we expand our analysis to explore all possible binary onset patterns and measure the amount of syncopation present in each pattern.

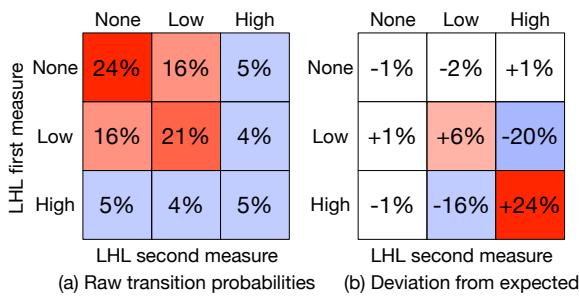
We follow the model of Koops, et. al. [2] and use the Longuet-Higgins and Lee [15] metric, grounded in aural perception of rhythm [16], to quantify the amount of syncopation present in a measure based on its binary onset pattern. The LHL metric is zero for a measure with no syncopation and increases with each instance of a note onset (1) occurring on a weak beat followed by no onset (0) on the immediately-following (strong) beat. The increases are larger for syncopations crossing more significant divisions of the measure. For example, the binary onset pattern 01010101 contains three syncopations (instances of 10). The syncopation in the middle that crosses the midpoint of the measure has an LHL value of 2, and the two syncopations on either side have values of 1 because they cross weaker divisions of the measure. Therefore, this measure by itself has an LHL score of 4. If this measure were followed by no onset on the downbeat of the next measure, the LHL value would increase by 3 for the additional syncopation crossing the barline, for a total LHL value of 7.

In performing the following experiments, we calculated the LHL values for each measure of the melody in the corpus using the binary onset patterns computed earlier. Our corpus of 1058 pieces contained 140,856 measures of music, with the average LHL value for a measure being 1.17, with a standard deviation of 1.35. However, only 77,012 of the measures ($\approx$ 55%) contained any syncopation at all (LHL > 0). If we only consider measures with LHL > 0, the average LHL value becomes 2.14, with a standard deviation of 1.12.

We note that our methodology for computing and interpreting binary onset patterns differs enough here from Koops, et. al. [2] to warrant explanation. In their work, binary onset patterns may be up to 16 bits in length, corresponding to measures in $\frac{4}{4}$ or $\frac{2}{2}$ analyzed at the 16th note level, allowing for the possibility of having LHL values for a single measure of music as high as 15. Here, all our binary onset patterns are of length 8, due to always analyzing measures in $\frac{4}{4}$ or $\frac{2}{2}$ at the eighth note level and measures in $\frac{2}{4}$ at the 16th note level. Therefore, it is difficult to draw

direct numerical equivalences between our studies.


Overall patterns. We first examine the frequencies of all possible binary onset patterns in the corpus. To ensure that the varying lengths of the compositions in the corpus did not affect our results, we divided the number of times each binary onset pattern appeared in a composition by the number of measures in that composition, thereby obtaining the *frequency per measure* for each pattern. We then averaged the frequencies across all pieces in the corpus. The top ten patterns overall, and the top ten with an LHL score greater than 0 are shown in Figure 5. It is noteworthy that for a genre identified with such high levels of syncopation, there are many common non-syncopated patterns. In particular, patterns 1, 4, 5, 6, and 10 do not contain any syncopation.

In analyzing the right side of Figure 5, we note the presence of a tied 121 pattern (1101) in the middle of patterns 1, 2, 4, and 5, along with untied 121 patterns at the beginning of patterns 6, 7, and 9, and at the end of pattern 10. Additionally, pattern 3 is the 121 pattern in augmented form. Only pattern 8 is not connected with the 121 figure.


Patterns by era. We conducted an experiment to determine whether composers of different eras used certain types of binary onset patterns differently. Using our earlier grouping of compositions into the early ragtime era, the late ragtime era, and the modern era, we computed the most popular rhythms in each group, which can be seen in Figure 6; we note that popular patterns in some eras become unpopular in others. We used three Wilcoxon signed-rank tests to compare pairs of eras, using all 256 possible binary onset patterns in each test. The results give us weak statistical significance at the $\alpha = 0.05$ level using the Šidák correction to account for the multiple comparisons, suggesting that composers chose rhythmic patterns differently in the three eras ($p \approx 0.01$ for the early versus late eras, $p < 0.001$ for the early versus modern eras, and $p \approx 0.01$ for the late versus modern eras).

4.3 Transitions Between Patterns

The overall sound of a piece of music depends not only on the contents of the individual measures of music but also on the choice of which measures follow other measures. Ragtime is no exception, and we hypothesize that there are

Figure 6. The most frequent syncopated (LHL > 0) rhythmic patterns, segmented by era.

Figure 7. (a) The joint transition probabilities for observing of the nine possible LHL transition pairs. (b) The deviation from the expected probability if there were no correlation between the LHL value in one measure and the next. The four highlighted deviations in (b) are statistically significant.

relationships between the syncopated patterns in consecutive measures. Specifically, we propose the question of whether the degree of syncopation in a measure of music is related to the degree of syncopation in the surrounding measures.

We chose to answer this question by examining all consecutive pairs of measures of music in the corpus and computing their LHL values separately for the first measure and the second measure of the pair. Recalling that the average LHL value for a syncopated measure of music was approximately 2.14, we binned the LHL values according to having a *high* amount of syncopation (LHL ≥ 3), a *low* amount of syncopation (LHL = 1 or 2), or *no* syncopation (LHL = 0). For each piece of music, we computed the frequencies of each of the nine possible LHL transition pairs, normalizing for the number of measures in each composition, and averaged the frequencies across all compositions. The results are displayed as joint probabilities in a heatmap in Figure 7(a). We observe that transitions between consecutive measures with no syncopation are extremely common, while any transition involving a high amount of syncopation is uncommon.

These joint probabilities, however, do not tell the whole story. Because the distribution of LHL values is highly skewed towards the smaller values, it is worthwhile to test if any of these LHL transition pairs occur with certain tendencies due to chance, or due to deliberate choices on the composer's part. For example, given that almost half of

the measures of music in the corpus do not contain any syncopation, should we be surprised that 24% of the total transitions are between two measures without syncopation? We can answer this question with a final experiment. We compared the LHL transition frequencies obtained from the corpus against corresponding frequencies that would be obtained if one were to randomly reorder the measures in each piece of music. Specifically, for each composition, we generated 1000 random reorderings of the measures, computed the LHL transitions for every pair of consecutive measures, averaged them across the 1000 reorderings, and then proceeded as we did earlier with normalizing and averaging across all compositions. These results, illustrated in Figure 7(b), confirm that a number of the LHL transitions occur significantly more or less frequently than would be expected under a random reordering of measures of the compositions.

We used nine individual binomial tests to compare the the true LHL transition frequencies to the expected frequencies under the null hypothesis that measure transitions resemble those done randomly. At a significance level of $\alpha = 0.05$, taking into account the Šidák correction for multiple comparisons, the four highlighted transitions in Figure 7(b) are statistically significant (all with $p \ll 0.0001$). This tells us, for instance, that even though it is overall rare to find consecutive measures with high amounts of syncopation in a composition, this phenomenon still occurs more often than would be expected if a composer were introducing syncopation at random.

5. CONCLUSION AND FUTURE WORK

In this study, we used new methods to extend a number of previous analyses of ragtime syncopation to confirm existing musicological hypotheses and present new ones. Specifically, we confirmed the earlier finding that the 121 syncopation idiom varies in use between ragtime eras, even when using a different preprocessing scheme for the RAG-C dataset. We demonstrated a new finding that the "big three" ragtime composers also employed this syncopation pattern more often than their contemporaries did. We illustrated how other rhythmic patterns evolved over time and revealed different frequency distributions. Lastly, we displayed novel results showing statistically significant differences in the way the amount of syncopation changes between consecutive measures in a ragtime composition.

In future work, we plan to continue to study the use of syncopation in ragtime, specifically towards uncovering more information about varying musical parameters (rhythmic, melodic, or harmonic) between measures. We believe it will be useful to expand the ideas in this paper to other musical genres as well. Previous research has successfully used information about rhythmic patterns to assist in genre classification [17–19], and we imagine the data presented here could be useful in such circumstances. We also hypothesize that algorithmic composition techniques that rely on probabilistic techniques for rhythm generation [4, 20] might be improved by considering how musical parameters like rhythm change from measure to measure as well as within a single measure.

"PLAY MUSIC": USER MOTIVATIONS AND EXPECTATIONS FOR NON-SPECIFIC VOICE QUERIES

ABSTRACT

The growing market of voice-enabled devices introduces new types of music search requests. As voice assistants can potentially support conversational requests, music requests can be more ambiguous than requests in typed search interfaces. However, these systems may not be able to fulfill ambiguous requests in a manner that matches the user need. In this work, we study an example of ambiguous requests which we term as non-specific queries (NSQs), such as "play music," where users ask to stream content using a single utterance that does not specify what content they want to hear. To better understand user motivations for making NSQs, we conducted semi-structured qualitative interviews with voice users. We observed four themes that structure user perceptions of the benefits and shortcomings of making NSQs: the tradeoff between control and convenience, varying expectations for personalization, the effects of context on expectations, and learned user behaviors. We conclude with implications for how these themes can inform the interaction design of voice search systems in handling non-specific music requests in voice search systems.

1. INTRODUCTION

Voice assistants and smart speakers are rapidly becoming ubiquitous. Globally, an estimated 600 million people use voice assistants at least once a week [7]. In the U.S., roughly a quarter of adults own a smart speaker, such as an Amazon Echo or Google Home [16, 28]. One of the most popular use cases for smart speakers is music listening [1, 5]. If a user approaches a music search with a specific piece of content in mind and requests it by artist and track name [14], current voice assistants are typically able to fulfill such requests.

However, voice assistants also provide users with the opportunity to search for music in a conversational and open-ended manner without mentioning specific entities. We focus on non-specific queries (NSQs) in this research, which are requests to play music but which lack any specifications in the user's language about which music to return. An example of a non-specific voice query would be "Play music" (since no specifics are provided) but not "Play me some hip hop," since "hip hop" specifies a genre.

Due to the current limitations of voice search systems, interactions that do not exactly specify what music to request are less likely to be successful. When faced with a potentially unbounded space of conversational interactions with a voice assistant, users may simply not know what to say [9, 25]. As a result, users can end up falling back on habits they developed when they first obtained their voice assistants [5] and resort to more simple interactions. In addition, users' mental models of the voice assistant's capabilities do not always match its actual capabilities [22]. This makes it difficult for users to know what types of voice searches will end up providing the desired results.

Our research questions are as follows: (1) what are user motivations for making non-specific queries (NSQ) and (2) what do users expect from the system when they make NSQs? To study these questions, we conducted a qualitative interview study with users who make such requests. Finally, we conclude with implications for how voice assistants can better meet these user needs and propose avenues for future work.

2. RELATED WORK

2.1 Voice Assistants and Music Search

Voice has become a common interaction modality for users to search for information. In particular, music has emerged as a popular domain for voice search. This has been observed across device types, ranging from mobile phones to smart speakers. Guy's [11] analysis revealed that music videos were the top triggered results on voice search on mobile phones. In the case of smart speakers, music listening is not only the most commonly requested functionality but requests for information about music (e.g., "Who sings this song") also emerged as a prevalent search [1]. However, while voice interactions can potentially enable quick

---

[1] The third author is now at Google and has not contributed to the paper after joining Google.

music playback on a smart speaker, issues such as difficult to pronounce artist names can pose a challenge for users, making these interactions more effortful [32].

2.2 Music Search and Discovery

To observe how users would use natural language to search for music and to better understand users' information needs, researchers have turned to general domain repositories such as Google Answers. Bainbridge et al. [3] observed that users typically employ a variety of metadata to form music searches, such as bibliographic information including performer, title of work, or date of recording. Lee [19] also observed that music searches in Google Answers are typically known-item queries.

Music discovery on music streaming services also occurs through personalized recommendations, which can be potentially supported through natural language voice queries. Such discovery often requires a user to be receptive to novelty, suggesting that listeners are selective about the situations where this would be a positive experience [18]. Lee and Price [20] observe that music listeners with more 'adventurous' music habits are more positive about novelty in recommendations while more 'discerning' listeners expect recommendations to not be novel enough to meet their tastes. Because users of voice assistants can use natural language for ambiguous queries for a variety of reasons, these systems will have to account for a listener's appetite for discovery.

We extend the research on music search and discovery by studying a common query employing non-specific language that may not necessarily indicate a tolerance for exploration. In addition, we note that the prior research covered in this section has predominantly focused on typed search and modalities that offer visual feedback.

3. METHOD

3.1 INTERVIEWS

To elicit a rich descriptive user-centric dataset about non-specific queries that may carry meaning to users despite their simple format, we chose to employ semi-structured interviews. The data collection took place over a one month period in 2018 and consisted of 17 in-person 60 minute interviews. We sent a recruitment email to a random sample of Spotify users in a city in the Northeastern United States. The user selection criteria were: (1) owning a voice-enabled device and (2) making at least one NSQ on that device within the previous 30 days. The recruitment email also asked users to indicate what voice-enabled devices they owned and which music streaming services they used.

We sampled participants who used smart speakers, such as Google Home, Amazon smart devices as well as mobile voice assistants to cover a broader range. To better reflect the diversity of the listener population, we selected participants from a range of ages, occupation, and gender. Participant age ranged from 21 to 52 (mean = 31) with a wide range of occupational backgrounds. Table 3.1 summarizes

P#	Age	Gender	Job or Industry	Used Device(s)
1	29	f	Health care	AA, MVA, Other
2	23	m	Student	GH, MVA

Table 1. Demographic information of our study participants and their voice assistant usage. Google Home (GH), Amazon Alexa (AA), Mobile Voice Assistant (MVA)

the demographic characteristics of the participants. Participants were paid $100 for their time, consistent with the compensation level for industry user research.

Our interviews consisted of two parts. The first part focused on presenting scenarios to elicit user motivations for making NSQs. The second part employed specific examples of common NSQs as probes to investigate user expectations for the results of NSQs.

3.1.1 Part 1: Scenarios

The interviewer began by asking questions related to user's daily listening habits to develop an understanding of each user's unique music listening style. The participant would then answer questions about their voice device habits regarding general domain voice interactions as well as those specific to music streaming and recommendation. We probed users' motivations for requesting music through voice, and any factors that might discourage them. Following this discussion, we prompted participants with eight different scenarios in randomized order to describe whether and how they would choose to issue NSQs to their voice devices. We included the following scenarios: listening to music right now, during a workout, with friends at party, in the morning, after work or school, during chores, during the commute, while starting the day.

3.1.2 Part 2: Utterances as probes

Next, the interviewer presented five different wordings of NSQs selected from a pool of the 50 most common NSQs appearing in logged data in the 30 days preceding the month of the study. The interviewer then asked the participants to provide the utterances verbatim to the voice assistant in the room, which matched the assistant that participants reported owning and interacting with most frequently in our recruitment email. The five utterances used dur-

ing this part of the interview were: "Play Spotify playlist", "Turn on the music","Play music from Spotify","Play music","Play my Spotify."

3.2 Analysis

To identify broader themes encompassing the original annotation codes, researchers analyzed the interview transcripts using Braun & Clarke's 6-step framework [6]. Thematic analysis [24] was used to develop annotation codes to identify common themes and pervasive concepts. Three coders verified the codes by annotating the transcripts independently. The annotation tags were subsequently grouped into larger conceptual categories to provide insight into participants' behaviors, motivations, expectations and desired experiences.

4. FINDINGS

Our findings can be categorized along four themes that characterize user perceptions of the benefits and shortcomings of NSQs.

4.1 Trade-offs Between Effort and Control

We observed that our participants perceived NSQs as a convenient way to start listening to music with little effort by ceding control to the voice assistant. On the other hand, participants refrained from making NSQs when they believed that the returned content would be unpredictable. In this section, we describe how participants actively weigh the tradeoffs between user control and effort when deciding whether to make an NSQ.

4.1.1 Starting music effortlessly is more important than a specific outcome

Participants reported that they made non-specific queries as a lower effort way to request music. For instance, they described wanting to easily start a 'lean back' (or 'hands off') music listening session where the music comprised a soundtrack or background effect to the user's activity. In these situations, participants prioritized the convenience of making a lower effort NSQs rather than requesting something specific.

> I just need something to play in the background and accompany my morning. - P6, 25

Users also reported a desire to not add an additional level of effort to a current activity, especially when that activity required the use of the user's hands or eyes. In these cases, any keyboard or typed search would require an extra level of effort, as it would involve interrupting their current activity. Below, a participant enumerates the situations where they would choose voice search and NSQs over text-based search.

> Yeah, I would definitely say cooking, cleaning, housework type stuff, where I probably have my hands full. - P8, 36

Some users identified NSQs as an effortless way to discover novel music. Here, a user describes using NSQs as a fallback to specific queries when they needed an accessible and low-effort way to seek music that is new to them. For this user, a willingness to make an NSQ for low-effort music discovery is closely tied to their understanding of Spotify's reputation. When this user does not see one service as allowing for new music discovery, they switch to an alternative service when experiencing this NSQ intent.

> I've been using [music service X] longer than [music service Y]. And I consider [X] my go-to, let's say...But [Y] I like when I don't want to be so hands on...so, I would say if I can find new music, it's normally through [Y], but I create lists – playlists on [X]. And so, a little music that I've basically cultivated for at least a decade...I typically go to [Y] when I'm trying to be mindless about what I'm listening to - P16, 32

Participants reported providing NSQs when they did not have something specific in mind that they wanted to hear but still wanted to begin a listening session without having to expend decision-making effort.

> I don't want to make a decision necessarily, or I can't really think of what I want to listen to at that point. - P1, 29

This effect was particularly strong when the act of choosing a more specific piece of content felt like an obstacle or burden.

> [An NSQ] also sort of takes the edge off of having to make your own playlist, which is something I like doing, but if I didn't feel like putting the effort then. - P11, 26

This is consistent with findings observed by Hosey et al. [14] in which users reported being open to various results when they did not have anything specific in mind when searching for music. In the current study, we observed this as well, in particular when participants also wanted to initiate listening to music with as little effort and mental load as possible.

4.1.2 Desire for predictable outcome and associated feedback

Users consistently expressed the belief that they could not exercise as much control through voice search, compared to keyboard or touch searches. This was partly because users felt more context was available through typed queries.

> I'm a visual person. I guess I kind of like to read all the songs that might come up in a playlist or something like that. Whereas if I'm [providing a voice request] I can't really do that, it's just whatever [music streaming service] picks out. - P2, 23

This perceived lack of control is at least partially tied to real-world limitations of voice assistants, which can break down at multiple points. For instance, ASR systems can struggle to correctly transcribe the non-standard spellings (e.g., for artist "6lack"), difficult or ambiguous pronunciations (e.g., for the hip hop duo "Rae Sremmurd"), foreign languages and non-Latinate alphabets (e.g., Hebrew, Arabic, Greek) [32]. Named entity-recognition systems can struggle with ambiguous requests, e.g., "Play Changes." Here, the voice system might still return an unintended result, such as playing "Changes" by David Bowie rather than "Changes" by 2Pac.

In an attempt to avoid these errors, users often make voice requests that they perceive as *safe bets*, such as artists they expect the system to understand. Below, a participant discusses not requesting a particular album because ASR systems often incorrectly transcribe it.

> I definitely default to playing an artist rather than a specific album...I try to have it play like 'Citsuoka' [an album by My Morning Jacket]– there've been times when I've struggled and it hasn't been able to recognize that. And so some of it is definitely a habit that I've developed where it's more reliable to just go with the artist. - P3, 39

These experiences with voice systems can influence how a user will engage with NSQs. Users who trust the recommender system may start to consider NSQs as *safe bets*. Users who experience a sense of distrust due in part to NLU errors may refrain from making NSQs, believing that they would be too difficult for the system to fulfill.

4.2 Expectations for Personalization

Participants' perceptions of NSQs are tied to their expectations of whether or not the requests would yield a personalized result. In particular, we observed that participants had varying levels of trust in the quality of recommendations that they would receive in the first turn of their voice interactions.

4.2.1 Trust that generic queries would lead to personalized results

Participants who were open to musical exploration or felt comfortable relinquishing control over their listening session often used NSQs. By making such open-ended requests, users were aware of the possibility of hearing something new or unexpected by requesting music in such an open-ended manner. This was particularly marked with participants who expressed high degrees of confidence in the service's recommendation algorithms.

> I think the algorithms on here are super sharp and I think that it does a really great job of condensing what I'm into, what I have saved, and pulling something up. - P4, 26

We observed that participants created their own theories about how they would receive personalized results from NSQs, consistent with Eslami et al. [8]. For instance, participants hypothesized that they received personalized recommendations based on prior music listening behavior.

> I'm assuming it bases it off of whatever kind of music I like. I mean, it started playing a song that I was okay with...Or, I assume, based on whatever the app thinks that I would like based on the kind of music that I currently like and have favorited and stuff. - P10, 39

Participants also expressed a varying level of comfort with proactive recommendations that could be fulfilled with an NSQ. For instance, a participant describes a desire for an NSQ result that could be personalized to meet a user need for music discovery and exploration to return something novel.

> I would know at this point 'play my [music streaming service]' is my default where I'm at at that time, where I usually and if I want something different in the usual time and space, I have to look for something specific. Because it doesn't know that I don't want the usual. - P17, 38

In addition, some participants expected that personalization could be sufficiently proactive to be predictive of user need without explicit input from the user.

> I think the ideal situation is I want [music streaming service] to know what I want to hear before I know what I want to hear. - P4, 26

When participants had positive expectations about the personalization capabilities of the voice assistant, they were more optimistic about making NSQs and receiving a successful result.

4.2.2 Fear that generic requests might lead to unfamiliar content

In contrast, participants who were less open to musical exploration refrained from making NSQs out of a reported fear that the returned content will be outside the range of music they normally listen to. As a result, familiar content would be more likely to result in an enjoyable listening experience to these participants.

> I'm usually really specific because I like certain things. Well, as you get older, you realize this is what you like, and there's enough music for me to go back to and things I like. I don't discover too much anymore. Occasionally, but not as much as I used to. - P9, 52

> I'm not too adventurous with my music, so I opt and like to listen to songs that are similar to songs that I have heard before. - P6, 25

These findings are consistent with Li et al.'s [21] observations that users who conduct non-focused music

searches consume more novel songs. When users want to hear familiar content, they will not use non-specific language to request it.

Finally, our qualitative interview responses indicate that users do not perceive all NSQs identically and had different expectations for outcomes depending on unique meaningful linguistic markers in the NSQ. For instance, there was a consensus among users that the presence of a personal pronoun in a non-specific request was tied to an elevated desire to hear personalized content that is suited specifically to their musical taste.

> I just assumed that 'play my [music streaming service]' would yield a different thing than just turning on the music because the 'my', to me, indicates the music that I've already liked or downloaded. - P11, 26

4.3 Context Affects User Motivation to Make NSQs

Our participants reported on different contextual factors that affected their motivation to make a non-specific request.

4.3.1 More openness to discovery at certain times of day

Our participants reported that certain times of day were more conducive to openness to new music and searching for music in an exploratory mindset in the manner described by Hosey et al. [14].

> I can see myself doing this in the mornings when I just need something to play in the background and accompany my morning. When I'm working out or when I'm sleeping or when I'm reading, I kind of want a certain mood, but in the mornings, I'm more open to exploration. - P6, 25

Participants further noted that there were certain activities that would occur at certain times of the day, which may make time of day a potentially good proxy for sensing context. This is consistent with other research suggesting that listening preferences change throughout the day [27].

4.3.2 Less individual control needed in a group setting

Social context can influence how participants perceive the utility of making NSQs. Below, a participant expressed her willingness to make NSQs with others in a group.

> If I'm with a bunch of other people, my friends, they're like, 'Oh, you're still listening to this playlist? Put something else on.' Just having – it's like a nice neutral third party, where it's like, 'Oh, I'm not dominating the radio, and neither are you.' - P8, 36

Here we see social context play a role in how participants would make NSQs. In social settings, participants reported using non-specific queries to purposely relinquish control over their music listening experience. In this specific context, being able to abdicate control allowed the music streaming service to step in as a DJ and provide music for their social listening session. This was motivated not only by the aforementioned desire for an effortless experience, but also for users to avoid being judged for their personal taste in music.

4.3.3 Desire for specific results to fit moods and activities

Because participants perceived the results of NSQs to be unpredictable, they were less willing to make NSQs when they wanted to hear music that would fit their current mood or emotional state. This user motivation aligns with previous work on how music serves to regulate affect [15,27,29,33]. We distinguish this motivation from the observation that participants make NSQs as a low-effort way to start a background music session. Here, the stakes felt higher to participants when the resulting music did not match one's mood, potentially even altering into an unwanted state.

Some users do not expect that music recommendation systems can accomplish this level of emotional congruence in the context of NSQs. Below, a participant describes how unexpectedly hearing an album called "Planetarium" as the content returned for an NSQ–music which she describes as having a deeply emotional quality and unpleasant associations–would have a negative impact on her if she wasn't prepared to hear it.

> I would probably be more specific than that because the last thing I want is to be like, 'Play music' and it puts on 'Planetarium' and now I'm on my back on my bed with a jug of ice cream like, 'How did this happen?' - P4, 26

To avoid such situations, she exercises control by asking for specific artists or albums that fit her current mood rather than handing control to the music streaming service.

4.4 Learned User Behaviors

As users become more familiar with the capabilities of voice assistants, they fall fairly quickly into settled routines and habits [5]. We observed similar behaviors with our participants in how they adopted NSQs over time.

4.4.1 Tool to learn about boundaries of the voice assistant

Participants reported making NSQs out of initial curiosity. Consistent with Mennicken et al. [23], we observed that participants perceived NSQs as an opportunity to test the limits of the system and playfully learn the rules for what they can accomplish through their voice-enabled device.

> I just said 'Hey Google play some good music' or something like that just to see what it would do, or I've also just [said] 'play music' before just because I was curious what it would play. - P2, 23

Participants felt that if they received a result that they deemed enjoyable, this would increase the likelihood that they would use these types of queries in the future again. This aligns with prior research in general web search that suggests that users will change their request strategies if their results are unsatisfactory [2, 13].

4.4.2 Simple requests facilitate habit formation

Participants who reported making NSQs frequently developed their mental models of how the system would respond and then learned to integrate NSQs into their daily routine.

> I think I've kind of just made it a habit. Go up the stairs, set your keys down, set the backpack down, talk to [music streaming service], take the shoes off, so I think it's kind of ingrained into that coming home routine. - P8, 36

Similar to developing hypotheses about how the voice assistant would return personalized content, participants also created folk theories of how the system would interact with them depending on prior behavior.

> I expect it to be some default behavior that happens all the time, whether it's resuming whether it's starting from like alphabetical like the stuff I've tagged in my library [...] different stuff like over time that I've gotten used to. - P3, 39

For those participants who were more familiar with possible results of NSQs, a final motivation for issuing NSQs was to resume a previous listening session.

> When I come home from work [and provide an NSQ] it picks up [...] whatever thing I was listening to on my phone, so that's kind of nice. It picks up where you left off. - P8, 36

> For days like that, again, where I would prefer to use [an NSQ], it's when I'm in and out of the Jeep constantly. That way I could just jump in the Jeep, I throw the phone up on the dashboard, I tell the Jeep to start playing the music and I'm already rolling out of the parking lot. If I'm gonna be in the Jeep for an extended period of time like when I'm on my way to work, then I just pick it manually. But, [...] Running errands and stuff where you're constantly in and out, it'd be nice to actually just say, [an NSQ] and it just picks up right where I left off. - P10, 39

5. DISCUSSION

Based on our findings, we discuss (1) how the user experience of NSQs could be improved through a better integration of feedback; and (2) what additional linguistic cues could be considered in the NSQs to better address user needs.

5.1 Design for Feedback

When participants perceived a lack of control over their results, they were less inclined to make NSQs. One possible way to address that concern through design is to provide contextualized results when appropriate. For example, voice output, such as text-to-speech, can be used to give additional information about how the content is personalized. Metadata, such as an artist's collaborators or genre, can be used to feed into text-to-speech contextualization of the results of an NSQ [4].

Our results revealed that participants were willing to make NSQs when they wanted to start a low-effort listening session. However, this was balanced with a reluctance to receive overly surprising results. For users who make NSQs on a device with text-to-speech output, conversational search can help guide users by offering personalized options in a dialogue. This guidance can help balance a listener's need to retain control while minimizing cognitive load [12]. To generate candidate responses in a conversational agent for music discovery and exploration, systems can employ various NLP techniques to take advantage of the semantic relationships between entities found in music corpora and catalogs [26]. This can be helpful for the 'discerning' users, observed by [20], who are not satisfied with their recommendations or users who are willing to put in effort for exploration, as observed by [14, 17].

5.2 Leverage Linguistic Cues

Our findings can also be applied to queries slightly more specific to the ones currently studied. Our observations about NSQs can provide insight into descriptive music queries, such as "Play hip hop" or "Play something calming." While there are indeed categorically 'wrong' answers for descriptive queries such as returning a classic rock song for "Play hip hop," we suggest that expectations of personalization and the trade-off between effort and control remain important motivators for users who make descriptive queries.

Another future research direction related to non-specific language would be requests such as "recommend me something". While this type of request does not specify the type of content, the intent expressed by "recommend" suggests that a user is open to new content or to personalized results. Prior research [10] has uncovered different user goals for discovery-related content, suggesting that fulfillment of these voice requests should be aware of the different user needs behind these recommendation-related requests. Additionally, if the assistant has knowledge of user context such as location or time of day, the fulfillment of parsimonious "recommend me something" utterances can potentially be highly personalized [30, 31].

In summary, our research suggests that user intent when making ambiguous and non-specific requests can vary depending on user tolerance for effort and novelty, and that this tolerance can impact the level of user trust with the system. Future directions include iterating on system design to better support NSQs and further investigating utterance language to better understand user intent.

ABSTRACT

While deep generative models have become the leading methods for algorithmic composition, it remains a challenging problem to *control* the generation process because the latent variables of most deep-learning models lack good interpretability. Inspired by the content-style disentanglement idea, we design a novel architecture, under the VAE framework, that effectively learns two interpretable latent factors of polyphonic music: chord and texture. The current model focuses on learning 8-beat long piano composition segments. We show that such chord-texture disentanglement provides a controllable generation pathway leading to a wide spectrum of applications, including compositional style transfer, texture variation, and accompaniment arrangement. Both objective and subjective evaluations show that our method achieves a successful disentanglement and high quality controlled music generation.[1]

1. INTRODUCTION

With the development of artificial neural networks, deep learning has become one of the most popular techniques for automated music generation. In particular, we see recurrent and attention-based models being able to generate creative and human-like music without heavily hand-crafted rules [1–3]. However, the main drawback of these deep generative models is that they behave like "black boxes", and it is difficult to interpret the musical meaning of their internal latent variables [4]. Consequently, it remains a challenging task to control the generation process (i.e., to guide the music flow by manipulating the high-level compositional factors such as melody contour, accompaniment texture, style, etc.). This limitation restricts the application scenario of the powerful deep generative models.

In this paper, we improve the model interpretability for music generation via constrained representation learning. Inspired by the content-style disentanglement idea [5],

we enforce the model to learn two fundamental factors of polyphonic music: *chord* (content) and *texture* (style). The former refers to the representation of the underlying chord progression, and the latter includes chord arrangement, rhythmic pattern, and melody contour. The current design focuses on learning 8-beat long piano composition segments under a variational autoencoder (VAE) framework.

The core of the model design lies in the encoder. We incorporate the encoder with two **inductive biases** for a successful **chord-texture disentanglement**. The former applies a rule-based chord recognizer and embeds the information into the first half of the latent representation. The latter regards music as 2-D images and uses a chord-invariant convolutional network to extract the texture information, storing it into the second half of the latent representation. As for the decoder, we adopt the design from PianoTree VAE [6], an architecture that can reconstruct polyphonic music from the latent representation in a hierarchical manner.

We further show that the interpretable representations are **general-purpose**, empowering a wide spectrum of controllable music generation. In this study, we explore the following three scenarios:

Task 1: Compositional style transfer by swapping the chord and texture factors of different pieces of music, which can help us re-harmonize or re-arrange a music piece following the style of another piece.

Task 2: Texture variation by sampling the texture factor while keeping the chord factor, which is analogous to the creation of "Theme and Variations" form of composition.

Task 3: Accompaniment arrangement by predicting the texture factor given the melody using a downstream encoder-decoder generative model.

In sum, the contributions of our paper are as follows:

- We design a representation disentanglement method for polyphonic music, which learns two interpretable factors: chord and texture.

- We show that the interpretable factors are general-purpose features for controllable music generation, which reduces the necessity to design heavily-engineered control-specific model architectures. As far as we know, this is the first attempt to explicitly con-

---

[1] Code and demos can be accessed via `https://github.com/ZZWaang/polyphonic-chord-texture-disentanglement`

trol the compositional texture feature for symbolic polyphonic music generation.

- We demonstrate that control methods are effective and the quality of generated music is high. Some style transferred pieces are rated even higher than the original ones composed by humans.

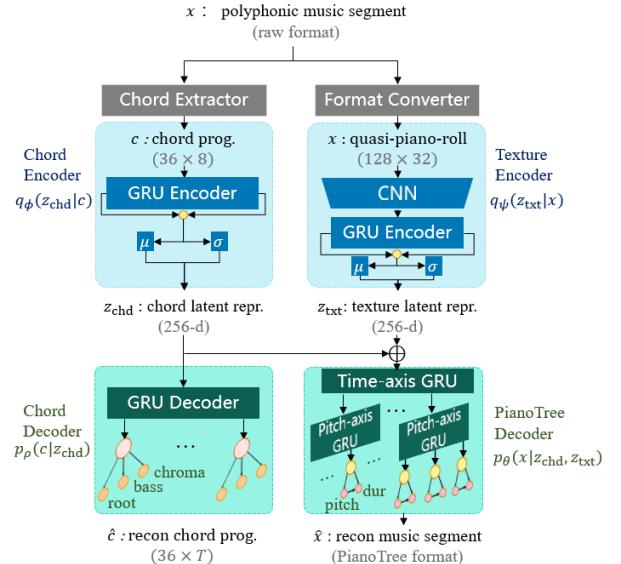
2. RELATED WORK

We review two techniques of automated music generation related to our paper: controlled generation (in Section 2.1) and representation disentanglement (in Section 2.2). For a more general review of deep music generation, we refer readers to [7, 8].

2.1 Controlled Music Generation

Most existing learning-based methods regard controlled music generation a *conditional estimation* problem. That is, to model $p(\text{music}|\text{control})$, in which both music and control are usually time-series features. Another approach that is closely related to conditional estimation is to first learn the joint distribution $p(\text{music}, \text{control})$ and later on *force* the value of control during the generation process.

The above two methods have been used in various tasks, including generating chords based on the melody [9], creating the melody based on the chords [10, 11], completing the counterparts or accompaniment based on the melody or chord [3, 12–16], and producing the audio waveform based on timbre features [17, 18].

However, many abstract music factors, such as texture and melody contour, could hardly be explicitly coded by labels. Even if such labels are provided, the control still does not allow continuous manipulation, such as sampling and interpolation. Consequently, it remains a challenging task to control music by more abstract factors without complex heuristics [19].


2.2 Music Representation Disentanglement

Learning disentangled representations is an ideal solution to the problem above, since: 1) representation learning embeds discrete music and control sequences into a continuous latent space, and 2) disentanglement techniques can further decompose the latent space into interpretable subparts that correspond to abstract music factors. Recent studies show that VAEs [20, 21] are in general an effective framework to learn the representations of discrete music sequences, and the key to a successful disentanglement is to incorporate proper inductive biases into the representation learning models [22].

Under a VAE framework, an inductive bias can be realized in various forms, including constraining the encoder [23–25], constraining the decoder [26], imposing multitask loss functions [27, 28], and enforcing transformation invariant results during the learning process [29, 30]. This study is based on our previous work Deep Music Analogy [27] in which we disentangle pitch and rhythm factors for monophonic segments. We extend this idea to polyphonic composition while the model design is more similar to [24].

3. MODEL

In this section, we introduce the model design and data representation in detail. The goal is to learn the representations of 8-beat long piano compositions (with $\frac{1}{4}$ beat as the shortest unit) and disentangle the representations into two interpretable factors: chord and texture.

Figure 1: The model diagram.

Figure 1 shows the overall architecture of the model. It adopts a VAE framework and contains four parts: 1) a chord encoder, 2) a chord decoder, 3) a texture encoder, and 4) a PianoTree decoder. The chord encoder and chord decoder can be seen as a standalone VAE which extracts the latent chord representation z_{chd}. On the other hand, the texture encoder aims to extract the texture representation z_{txt} using a chord-invariant convolutional mapping. Finally, the PianoTree decoder takes in both z_{chd} and z_{txt} and outputs the original music in a tree-structured data format.

3.1 Chord Encoder

The chord encoder first applies rule-based methods [31,32] to extract the chord progression under one-beat resolution. Each extracted chord progression is a 36 by 8 matrix, where each column denotes a chord of one beat. Each chord is a 36-D vector consisting of three parts: a 12-D one-hot vector for the pitch class of the *root*, a 12-D one-hot vector for the *bass*, and a 12-D multi-hot *chroma* vector.

The chord progression is then fed into a bi-directional GRU encoder [21], and the last hidden states on both ends of the GRU are concatenated and used to approximate the posterior distribution of z_{chd}. Following the assumption of a standard VAE, z_{chd} has a standard Gaussian prior and follows an isotropic Gaussian posterior.

Note that although the chord progression here is extracted using algorithms, it can also be provided by external labels, in which case the whole model becomes a conditional VAE [33].

3.2 Chord Decoder

The chord decoder reconstructs the chord progression from z_{chd} using another bi-directional GRU. The reconstruction loss of a chord progression is computed as a summation of 8 beat-wise chord loss using cross entropy functions [34]. For each beat, the chord loss is defined as the product of three parts: 1) the root loss, 2) the bass loss, and 3) the chroma loss. The root and bass are both considered 12-way categorical distributions and the chroma is regarded as 12 independent Bernoulli distributions.

3.3 Texture Encoder

The input of the texture encoder is an 8-beat segment of polyphonic piece represented by an image-like data format slightly modified from the piano-roll [14]. Each 8-beat segment is represented by a 128 by 32 matrix, where each row corresponds to a MIDI pitch and each column corresponds to $\frac{1}{4}$ beat. The data entry at (p, t) records the duration of the note if there is a note onset, and zero otherwise.

The texture encoder aims to learn a chord-invariant representation of texture by leveraging both the translation invariance property of convolution and the blurry effect of max-pooling layers [35]. We use a convolutional layer with kernel size 12×4 and stride 1×4, which is followed by a ReLU activation [36] and max-pooling with kernel size 4×1 and stride 4×1. The convolutional layer has one input channel and 10 output channels. The convolutional layer design aims at extracting a blurry "concept sketch" of the polyphonic texture which contains minimum information of the underlying chord. Ideally, when such blurry sketch is combined with specific chord representation, the decoder can identify its concrete pitches in a musical way.

The output of the convolutional layer is then fed into a bi-directional GRU encoder to extract the texture representation z_{txt}, similar to how we encode z_{chd} introduced in Section 3.1.

3.4 PianoTree Decoder

The PianoTree decoder takes the concatenation of z_{chd} and z_{txt} as input and decodes the music segment using the same decoder structure invented in PianoTree VAE [6], a hierarchical model structure for polyphonic representation learning. The decoder works as follows. First, it generates 32 frame-wise hidden states (one for each $\frac{1}{4}$ beat) using a GRU layer. Then, each frame-wise hidden state is further decoded into the embeddings of individual notes using another GRU layer. Finally, the pitch and duration for each note are reconstructed from the note embedding using a fully-connected layer and a GRU layer, respectively. For more detailed derivation and model design, we refer the readers to [6].

3.5 Training Objective

Let x denote the input music piece and $c = f(x)$ denote the chord progression extracted by algorithm $f(\cdot)$. We assume standard Gaussian priors of $p(z_{\text{chd}})$ and $p(z_{\text{txt}})$, and denote the output posteriors of chord encoder and texture encoder by $q_\phi(z_{\text{chd}}|c)$, $q_\psi(z_{\text{txt}}|x)$, the output distributions of chord decoder and PianoTree decoder by $p_\rho(c|z_{\text{chd}})$ and $p_\theta(x|z_{\text{chd}}, z_{\text{txt}})$. The objective of the model is:

$$
\begin{aligned}
\mathcal{L}(\phi, \psi, \rho, \theta; x) = \\
- \mathbb{E}_{\substack{z_{\text{chd}} \sim q_\phi \\ z_{\text{txt}} \sim q_\psi}} \big[\log p_\rho(c|z_{\text{chd}}) + \log p_\theta(x|z_{\text{chd}}, z_{\text{txt}}) \big] \\
+ \text{KL}(q_\phi || p(z_{\text{chd}})) + \text{KL}(q_\psi || p(z_{\text{txt}})).
\end{aligned} \tag{1}
$$

4. CONTROLLED MUSIC GENERATION

In this section, we show some controlled generation examples of the three tasks mentioned in the introduction.

4.1 Compositional Style Transfer

By regarding chord progression *content* and texture *style*, we can achieve compositional style transfer by swapping the texture representations of different pieces. Figure 2 shows the transferred results ((c) & (d)) based on two 16-bar samples ((a) & (b)) in the test set by swapping z_{txt} every 2 bars (without overlap).[2]

We see that such long-term style transfer is successful: The generated segment (c) follows the chord progression of (b) while mimicking the texture of (a), while (d) follows the chord progression of (a) while mimicking the texture of (b). As shown in the marked scores, the style transfer is effective. E.g., the cut-offs, melody contours, and the shape of the left-hand accompaniment are all preserved.

4.2 Texture Variation by Sampling

We can make variations of texture by sampling from z_{txt} while keeping z_{chd}. Here, we investigate two sampling strategies: sampling from the posterior $q_\psi(z_{\text{txt}}|x)$, and sampling from the prior $p(z_{\text{txt}})$.

Sampling from the posterior distribution $q_\psi(z_{\text{txt}}|x)$ yields reasonable variations as shown in Figure 3a. The variations of the right-hand melody can be seen as an improvisation following the chord progression and the melody. On the contrary, there is only small variation in the left-hand part, showing that the model regards the left-hand accompaniment as the dominant feature of texture.

Sampling from the prior distribution $p(z_{\text{txt}})$ changes the texture completely. Figure 3b shows a series of examples of prior sampling under the same chord progression C-Am-F-G. The resulting generations follow exactly the chord progression but with new textures.

4.3 Accompaniment Arrangement

We use a downstream predictive model to achieve accompaniment arrangement. For this task, we provide extra vocal melody tracks paired with the piano samples, and the model learns to generate 16-bar piano accompaniment *conditioned* on melody in a supervised fashion.

We encode the music every 2 bars (without overlap) into latent representations. For the accompaniment, we use the proposed model to compute the latent chord and texture representation, denoted by $\mathbf{z}_{\text{chd}} = [z_{\text{chd}}^{(1)}, ..., z_{\text{chd}}^{(4)}]$ and $\mathbf{z}_{\text{txt}} = [z_{\text{txt}}^{(1)}, ..., z_{\text{txt}}^{(4)}]$. For the melody, we use the

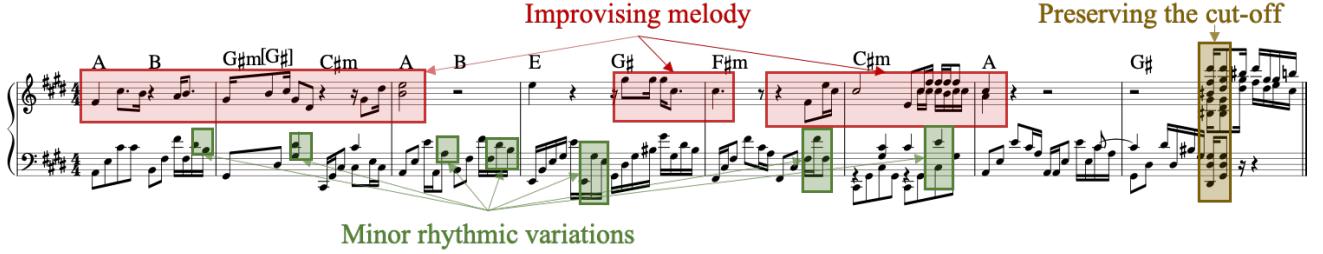
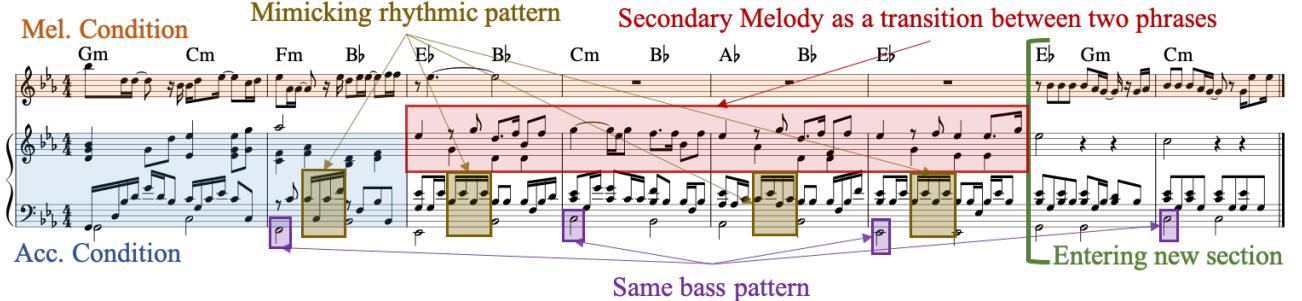
(c) The generated piece by combining z_{txt} from (a) and z_{chd} from (b).




(d) The generated piece by combining z_{txt} from (b) and z_{chd} from (a).

Figure 2: An example of compositional style transfer of 16-bar-long samples when $k = 2$.

EC^2-VAE [27] to compute the latent pitch and rhythm representations, denoted by $\mathbf{z}_{\text{p}} = [z_{\text{p}}^{(1)}, ..., z_{\text{p}}^{(4)}]$ and $\mathbf{z}_{\text{r}} = [z_{\text{r}}^{(1)}, ..., z_{\text{r}}^{(4)}]$. Then, we adopt a vanilla Transformer [37] to model $p(\mathbf{z}_{\text{txt}}, \mathbf{z}_{\text{chd}} | \mathbf{z}_{\text{p}}, \mathbf{z}_{\text{r}})$, in which the encoder takes in the condition and the decoder's input is a shifted right version $[\mathbf{z}_{\text{chd}}, \mathbf{z}_{\text{txt}}]$. Both encoder and decoder inputs are incorporated with a *positional encoding* indicating the time po-

sitions and a learned *factor embedding* indicating the representation type (i.e., pitch, rhythm, chord or texture).

Figure 4 shows an example of accompaniment arrangement, where the first staff shows the melody and the second staff shows the piano accompaniment. In this case, the whole melody, together with the complete chord progression and the first 2 bars of accompaniment are given. The chord conditioning is done by forcing the decoded chord

(a) An example of posterior sampling of z_{txt} of the first 8 bars of the segment (a) in Figure 2

(b) An example of prior sampling of z_{txt} under given chord progression C-Am-F-G. Each two-bar segment is independently sampled, having different texture.

Figure 3: Examples of texture variations via posterior sampling and prior sampling.

Figure 4: An example of accompaniment arrangement conditioned on melody, chord progression, and first 2 bars of accompaniment.

representation to match the given input during inference time. (A similar trick is used in [15].) From Figure 4, we see that the model predicts a similar texture to the given accompaniment. Moreover, it fills in a secondary melody line as a transition when the lead melody is rest.

Note that the arrangement can be generated in a flexible way by conditioning on different sets of latent factors. Much longer examples and more conditioning settings are available on our github page.

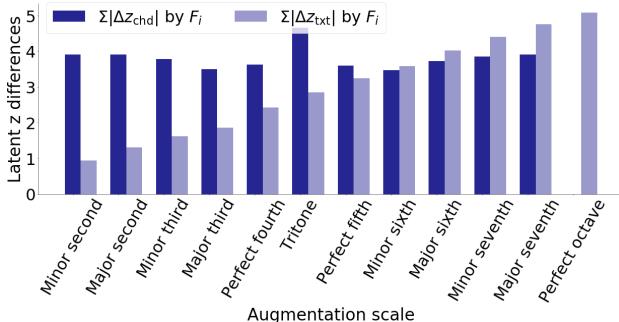
5. EXPERIMENTS

5.1 Dataset and Training

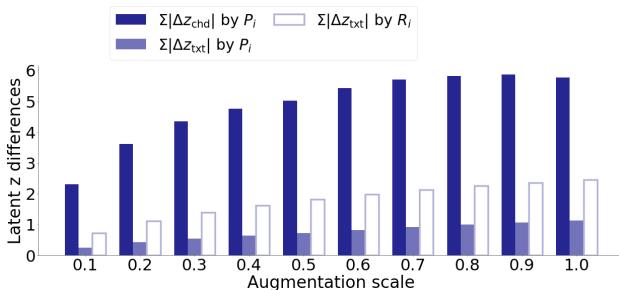
We train our model on the POP909 dataset [38], which contains about 1K MIDI files of pop songs (including paired vocal melody and piano accompaniment). We further extract the chord annotations using [31, 32]. We only keep the pieces with $\frac{2}{4}$ and $\frac{4}{4}$ meters and cut them into 8-beat music segments (so that each data sample in our experiment contains 32 time steps under 16th note resolution). In all, we have 66K samples. We randomly split the dataset (at song-level) into training set (90%) and test set (10%). All training samples are further augmented by transposing to all 12 keys.

In our experiment, the VAE model uses 256, 512, and 512 hidden dimensions for the GRUs in chord encoder, chord decoder and texture encoder respectively. The latent dimension of z_{chd} and z_{txt} are both 256. The model size of the PianoTree decoder is the same as the implementation

in the original paper [6]. The transformer model has the following size: hidden dimension $= 256$, number of layers $= 4$ and number of heads $= 8$.

For both models, we use Adam optimizer [39] with a scheduled learning rate from 1e-3 to 1e-5. Moreover, for the VAE model, we use KL-annealing [40], i.e. setting a weight parameter for the KL-divergence loss starting from 0 to 0.1. We set batch size to be 128 and the training converges within 6 epochs. For the downstream transformer model, we use 12K warm-up steps for learning rate update [41]. We use the same batch size and the model converges within 40 epochs.


5.2 Objective Measurement

When z_{chd} and z_{txt} are well disentangled, small variations over the note pitches of the original music should lead to a larger change on z_{chd}, while variations of rhythm will influence more on z_{txt}. Following this assumption, we adopt a *disentanglement evaluation via data augmentation* method used in [42] and further developed in [27].


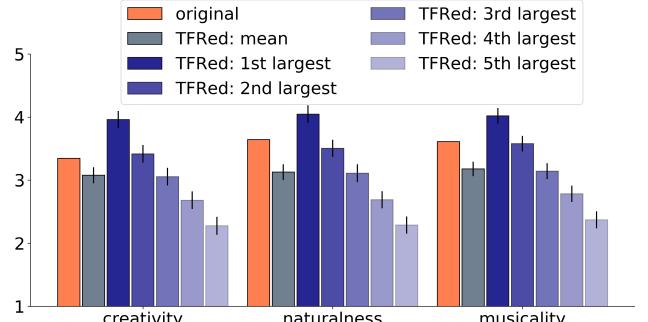
We define F_i as the operation of transposing all the notes by i semitones, and use the L_1-norm to measure the change of latent z after augmentation. Figure 5a shows a comparison between $\Sigma|\Delta z_{chd}|$ and $\Sigma|\Delta z_{txt}|$ when we apply F_i to all the music pieces in the test set (where $i \in [1, 12]$).

It is conspicuous that when augmenting pitch in a small range, the change of z_{chd} is much larger than the change of z_{txt}. At the same time, the change of z_{txt} gets higher as the

augmentation scale increases. Similar to the result in [27], the change of z_{chd} reflects human pitch perception as z_{chd} is very sensitive to a tritone transposition, and least sensitive for a perfect octave.

(a) A comparison between Δz_{chd}, Δz_{txt} after pitch transposition on all notes.

(b) A comparison among Δz_{chd}, Δz_{txt} after beat-wise pitch transposition and texture augmentation with different probabilities.

Figure 5: Results of objective measurement.


We further define P_i as the function to randomly transpose all the notes in one beat either up or down one semitone under a certain probability i, and R_i as the function to randomly reduce the note duration by half. Figure 5b shows a comparison between $\Sigma|\Delta z_{\text{chd}}|$ and $\Sigma|\Delta z_{\text{txt}}|$ when we apply P_i and R_i to all the music pieces in our test set (where $i \in [0.1, 1.0]$).

For each value of i in the figure 5b, the first and second bars demonstrate $\Sigma|\Delta z_{\text{chd}}|$ and $\Sigma|\Delta z_{\text{txt}}|$ caused by P_i function, while the third bar indicates $\Sigma|\Delta z_{\text{txt}}|$ caused by R_i function. (We did not show $\Sigma|\Delta z_{\text{chd}}|$ caused by R_i since they are all zero.) It again proves that the chord representation is more sensitive than texture representation under pitch variations, and conversely, texture representation is more sensitive than chord representation under rhythm variations.

5.3 Subjective Evaluation

Besides objective measurement, we conduct a survey to evaluate the musical quality of compositional style transfer (see Section 4.1). Each subject listens to ten 2-bar pieces with different chord progressions, each paired with 5 style-transfer versions generated by swapping the texture representation with a random sample from the test set. In other words, each subject evaluates 10 groups of samples, each of which contains 6 versions of textures (1 from the original piece and 5 from other pieces) under the same chord progression. Both the order of groups and the sample order

within each group are randomized. After listening to each sample, the subjects rate them based on a 5-point scale from 1 (very low) to 5 (very high) according to three criteria: *creativity*, *naturalness* and *musicality*.

Figure 6: Subjective evaluation results. Here "TFRed: xth largest" denotes the xth (largest) order statistic of the transferred segments.

A total of 36 subjects (26 females and 10 males) participated in the survey. Figure 6 shows the comparison result among the original pieces (indicated by the orange bars) and the transferred pieces in terms of their mean and *order* statistics. The heights of bars represent averaged ratings across the subjects and the error bars represent the confidence intervals computed via paired t-test [43]. The result shows *if we randomly transfer a piece's texture 5 times, the best result is significantly better than the original version (with p-value < 0.005)*, and there are only marginal differences between the second-largest statistics and the original (with p-value > 0.05) in terms of creativity and musicality. We also see that on average the transferred results are still rated lower than the original ones. How to automatically decide the quality of a transferred result is considered a future work.

6. CONCLUSION AND FUTURE WORK

In conclusion, we contributed an effective algorithm to disentangle polyphonic music representation into two interpretable factors, chord and texture, under a VAE framework. Such interpretable representations serve as an intuitive human-computer co-creation interface, by which we can precisely manipulate individual factors to control the flow of the generated music. In this paper, we demonstrated three ways to interact with the model, including compositional style transfer via swapping the latent codes, texture variation by sampling from the latent distribution, accompaniment arrangement using downstream conditional prediction, and there are potentially many more. We hope this work can shed light on the field of controllable algorithmic composition in general, especially on the paradox between model complexity and model interpretability.

We acknowledge that the learned music factors are still very basic. In the future, we plan to extract more abstract and longer-range features using hierarchical models. We also plan to explore more ways to control the music generation for practical usage.

ABSTRACT

Recent machine learning techniques have enabled a large variety of novel music generation processes. However, most approaches do not provide any form of interpretable control over musical attributes, such as pitch and rhythm. Obtaining control over the generation process is critically important for its use in real-life creative setups. Nevertheless, this problem remains arduous, as there are no known functions nor differentiable approximations to transform symbolic music with control of musical attributes.

In this work, we propose a novel method that enables attributes-aware music transformation from any set of musical annotations, without requiring complicated derivative implementation. By relying on an adversarial confusion criterion on given musical annotations, we force the latent space of a generative model to abstract from these features. Then, reintroducing these features as conditioning to the generative function, we obtain a continuous control over them. To demonstrate our approach, we rely on sets of musical attributes computed by the jSymbolic library as annotations and conduct experiments that show that our method outperforms previous methods in control. Finally, comparing correlations between attributes and the transformed results show that our method can provide explicit control over any continuous or discrete annotation.

1. INTRODUCTION

For a long time, music composition has been considered a skill reserved for highly-trained experts. However, since the emergence of new technologies, it appears possible for non-expert and untrained users to indulge in this task. One such way is to rely on machine learning models, which train on existing sets of music to produce pieces with similar characteristics. The importance of music generation is growing in the industrial world as well, for instance, in the generation of soundtracks for video games and movies [1, 2].

In this context, models that provide control over the attributes of the generated music are of critical importance [1, 3–5]. Indeed, the simple generation of "self-contained" music through a single button rapidly becomes dull. Instead, users are rather looking to transform aspects of the music to make it fit their intent in terms of musical attributes such as pitch, rhythm, and melody. Ideally, these controls should be continuous, providing flexibility akin to the *knobs* of musical synthesizers. For instance, if a user wants to generate music with longer notes, the system should provide a way to decide *how much* the notes are extended, not just whether extend them or not.

Nevertheless, obtaining explicit controls over music generation is still an open and complex problem [5]. Although recent generative models can produce a large variety of music genres, they usually do not provide any mechanism on *how to modify* the generation with musical attributes in a controllable way. However, acquiring such controls seems to require the implementation of complicated derivatives or approximation for each attribute [6].

In this paper, we introduce a novel method to generate symbolic music similar to a given dataset, while being able to control its musical attributes continuously. Our method can be trained using raw annotations, without requiring access to their computational functions nor derivative implementations. This allows us to rely on any form of musical annotations, even high-level semantic or subjective characteristics. To demonstrate this aspect, we rely on attribute vectors computed by jSymbolic [7] as annotations to make the model learn a continuous control for each. This produces numerical descriptions of music, such as pitch ranges and mean note durations, which enables us to learn understandable control over the generation.

To empower our generative model with continuous control over non-differentiable musical attributes, we rely on adversarial learning. Our model is based on a latent encoder-decoder model, where the decoding function takes continuous musical attributes as conditioning information. As the model is trained to reconstruct input data, the latent encoding potentially contains all the information necessary for reconstruction. Hence, this would lead to a decoding function that can generate the output without reflecting changes in the conditioning. Aiming to prevent this situation, we introduce an adversarial discriminator on the latent space of the model. The role of this discriminator is to drive the encoder to remove any attribute information from the latent vector. This adversarial framework with an encoder-decoder model is similar to Fader Networks [8]. However, one major difference is that we handle continuous values instead of binary ones. Hence, a major contribution of this paper is to define an approach to train an adversarial discriminator on continuous values. Indeed, discriminators across the literature [8–15] predict

binary values such as real/fake or with/without attributes, whereas we aim to deal with continuous values. We solve this problem in two steps. First, we quantize attribute values and compute balanced class labels. Second, we extend the discriminator so that it relies on multivariate class vectors. As usual in adversarial training, the encoder is trained to prevent the discriminator from predicting the labels correctly. This produces continuous controls over the musical characteristics by shifting the condition to the decoder. This behavior stems from the need for the model to correctly utilize the decoder condition so as to reconstruct the input data. That way, we force the generated data to reflect the musical control values, for any attribute annotation.

For the purpose of evaluation, we demonstrate the ability to gain interpretable control over musical attributes by conducting extensive experiments. We show that our method outperforms previous proposals [6, 16, 17] and also allows us to rely on unconstrained sets of attributes. We evaluate these results by computing the correlation between control attributes and generation results. This enables us to evaluate quantitatively how the generation reflects the control. Our contributions are: (1) We propose a novel training framework to learn from ordered annotation values. (2) We solve the above problem by quantizing annotations and adversarial training to obtain controllability of musical attributes without their derivatives.

2. RELATED WORK

2.1 Generative Models

Generative models allow production of new data samples $\tilde{x}$, by training on a collection of examples x, with the most popular approaches being Generative Adversarial Networks [9] and Variational Auto-Encoder (VAE) [18, 19].

2.1.1 Variational Auto-Encoder

The VAE is based on an encoder-decoder architecture. The encoder takes input data $\mathbf{x} \in \mathbb{R}^{d_{\mathbf{x}}}$ and outputs a compressed latent vector $\mathbf{z} \in \mathbb{R}^{d_{\mathbf{z}}}$. The decoder takes this latent vector $\mathbf{z}$ as input and tries to reconstruct the input data $\mathbf{x}$. Hence, this approach models two distributions: $\mathbf{z} \sim p_{enc}(\mathbf{z} \mid \mathbf{x}, \theta_{enc})$ and $\tilde{\mathbf{x}} \sim p_{dec}(\mathbf{x} \mid \mathbf{z}, \theta_{dec})$, where θ_{enc} and θ_{dec} are parameters of the encoder and the decoder. The original objective function for training a VAE approximates the distribution $p(\mathbf{x})$, that we wish to model by a lower bound (Evidence Lower Bound (ELBO)) [18, 19].

$$\text{ELBO}_{\{\theta_{enc}, \theta_{dec}\}} = -(\mathcal{L}_R + \mathcal{L}_{KL}) \leq \log p(\mathbf{x}) \quad (1)$$

Here, $\mathcal{L}_R$ and $\mathcal{L}_{KL}$ are mean reconstruction error and Kullback-Leibler divergence, respectively.

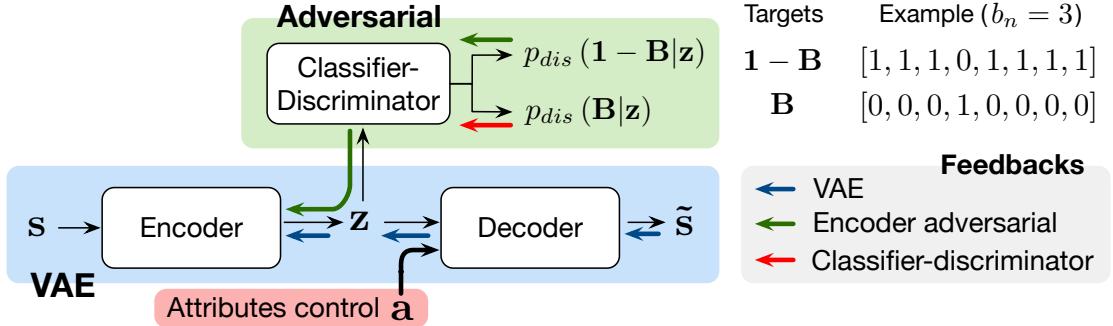
$$\mathcal{L}_R = -\mathbb{E}_{p_{enc}(\mathbf{z}|\mathbf{x})}\big[\log(p_{dec}(\mathbf{x} \mid \mathbf{z}))\big] \quad (2)$$
$$\mathcal{L}_{KL} = D_{KL}\big(p_{enc}(\mathbf{z} \mid \mathbf{x}) \,||\, p(\mathbf{z})\big) \quad (3)$$

Therefore, the model optimizes its parameters by minimizing the reconstruction error $\mathcal{L}_R$, while regularizing the latent space through $\mathcal{L}_{KL}$, so that the encoded latent variables match with a Gaussian prior.

2.1.2 Attribute Control in Generative Models

Several works have focused on attribute control for generative models in the image domain [8, 20–23], which enable changing properties of the generation, such as facial attributes. In some cases [21], learning is not performed on the attributes themselves, but rather through a rich pre-trained model. This allows computing the mean directions of interpolation, which maximize attribute change in feature space, in order to re-apply the obtained direction.

In Fader Networks [8], an encoder-decoder-based model is trained to generate facial images given binary visual attributes through adversarial learning. As the decoder is expected to rely on control attributes for generation, this requires that the other latent vector input does not contain any information about the attributes. Thus, they introduce a discriminator on those latent vectors, which tries to classify the input latent vectors based on target binary attributes, such as wearing glasses or not. The encoder is simultaneously trained to prevent the discriminator from predicting target attributes correctly. Therefore, this adversarial criterion enables the model to learn an attributes-invariant representation by forcing the encoder to remove any attribute information from the latent vector. In a similar way, [20, 22] also proposed to gain attributes control by removing attribute information from a latent vector.

Given the success of these methods for facial image-specific components, our proposed model explores a similar approach. However, our model needs to train on continuous ordered values instead of binary attributes.


2.2 Controllable Music Generation

Several works have been focusing on music generation conditioned on composer styles [1, 24] or chord progression [10]. In contrast, our work focuses on the direct and continuous transformation of music.

2.2.1 Music Interpolation

In most music interpolation approaches, the models do not rely on annotations while training [16, 17]. Instead, they interpolate musical data by moving the latent vector in different directions. These directions are usually defined by reference points from the training set. In some cases, musical annotations are also used to learn the characteristics or certain styles of music, or even sequences of features [4, 25], which mean the models have annotation values in every time step. For instance, [4] relies on contour and fragmentation & consolidation sequences in addition to rhythmic ones, and they split the latent vector between a target attribute and the other unsupervised dimensions. Although these models are able to account for target attributes, their precise control remains unclear. Moreover, only a single attribute can be learned in each model, requiring a full model per attribute. In [26], the authors train separate models to explore the latent space based on gradient descent using binary annotations or user-defined functions.

Similarly, [6] explicitly maps the number of notes to a dimension of the latent vector with geometrical regularization. However, it requires access to a differentiable compu-

Figure 1. Overview of our proposed model. It is based on the Variational Auto-Encoder, and the decoder is conditioned on an attribute vector $\mathbf{a}$. To force the output to reflect the conditioning, our model has a classifier-discriminator in addition, which induces the encoder to remove the attribute information from the latent vector $\mathbf{z}$. The classifier-discriminator predicts the class labels $\mathbf{B}$, which are calculated by quantizing musical attributes $\mathbf{a}$, and trains the encoder in an adversarial way.

tational function of attributes. Thus, there is no guarantee that this model can deal with more complex attributes nor multiple attributes at the same time. Recent works [27, 28] also map the musical attributes to certain dimensions.

2.2.2 Music Style Transfer

A field related to our research is music style transfer. In this task, models aim to apply a *target style* while preserving the *content* of a given music piece. This task appears more complex than music interpolation as the precise definition of *style* is somewhat elusive. Depending on papers, style is either defined as genre, composer, or other undefined factors. The wide array of researches on music style transfer [15, 29–31] can be broadly separated between supervised and unsupervised approaches.

In the supervised realm, [31] relies on synthesized data of the same content in a variety of target styles, which can be considered as a ground-truth for transfer. Although this work appears to perform transfer successfully, its problem setting appears unrealistic, as we usually do not have access to paired ground truth data for every style.

Unsupervised music style transfer [15, 29, 30], provide a more realistic approach, by simply collecting random data with style labels and aiming to learn a model of the different musical styles. Therefore, these approaches avoid the pitfall of providing a clear definition of *content* or *style*. However, this leads to models which are extremely difficult to evaluate and does not provide controls on the precise characteristics of the generated material.

In our work, we aim to provide explicit control over a set of interpretable musical attributes, which can be defined as *musical style* collectively. Hence, we believe that our research can provide the first step towards a more grounded, interpretable music style transfer.

3. METHODOLOGY

In this paper, our goal is to devise a method for symbolic music generation, providing understandable controls over musical attributes of the generation. Furthermore, these controls should provide continuous modifications to the output, akin to the parameters of a modern synthesizer.

This implies that we need to control the extent of different transformations, ensuring the quality of the generation.

3.1 Model Overview

To achieve our goal, we rely on a VAE architecture with an adversarial classifier-discriminator on the latent vector, as depicted in Figure 1. The encoder-decoder model is trained to reconstruct the input data, as in usual VAE frameworks. Moreover, as we aim to address the explicit control of musical attributes, the decoder takes these musical attributes as additional conditioning information to the latent vector. However, this latent vector potentially already contains all the information required to reconstruct the input data. This would lead to a decoder that simply does not use the information of conditioned attributes. In this degenerate situation, the model would not account for control modifications in the generation. The classifier-discriminator solves this problem, by driving the encoder to remove any information on the attribute from the latent space. Hence, the decoder is forced to use the attribute information to reconstruct the input data adequately, as this information is missing from the latent vector.

Although this architecture is similar to Fader Networks [8], our model is based on the VAE, and the attributes in our work are continuous ordered values, instead of binary indicators. This means that we cannot make direct use of existing discriminators [8–15]. To overcome this problem, we extend the discriminator mechanism so that it acts as a classifier as well. To do so, we quantize the attributes into K balanced classes and use these as targets to a multivariate discriminator. As a result of adversarial training, the encoder prevents the discriminator from predicting the class labels correctly. Hence, the resulting latent vectors should not contain any musical attributes information.

3.2 Model Architecture

We consider a monophonic pitch sequence $\mathbf{s}_{1:T}$ as input, where T represents time steps, encoded in a piano-roll representation, as a sequence of its one-hot vectors (Eq. 4).

Encoder: The encoder is simply defined as a one-layer bidirectional Gated Recurrent Unit (GRU), followed by

linear layers (denoted as MLP) to generate the mean and variance of the latent vector $\mathbf{z}$.

$$\mathbf{E}_t = \text{onehot}(s_t) \tag{4}$$
$$(\mathbf{O}, \mathbf{H}) = \text{GRU}(\mathbf{E}_{1:T}) \tag{5}$$
$$p_{enc}(\mathbf{z} \mid \mathbf{s}) = \mathcal{N}\Big(\mathbf{z}\Big|\text{MLP}(\mathbf{O}_T), \text{diag}\big(\exp(\text{MLP}(\mathbf{O}_T))\big)\Big) \tag{6}$$

where $\mathbf{O}$ is the output feature, and $\mathbf{H}$ the hidden state.

Decoder: The decoder reconstructs the input $\mathbf{E}_t$ at time t, based on the latent vector $\mathbf{z}$, the one-hot vector of the previous step $\mathbf{E}_{t-1}$, and the vector of musical attributes $\mathbf{a}$. The difference between our decoder and a conditional VAE is that this musical attributes vector is used along with the latent information, based on the premise that the latent vector does not have information about these attributes. This decoder is composed of a two-layer GRU.

$$p_{dec}(\mathbf{z}) = \mathcal{N}(\mathbf{z} \mid 0, \mathcal{I}) \tag{7}$$
$$(\mathbf{O}_1, \mathbf{H}_1) = \text{GRU}\big([\mathbf{E}_0; \mathbf{z}; \mathbf{a}], \text{MLP}(\mathbf{z})\big) \tag{8}$$
$$(\mathbf{O}_t, \mathbf{H}_t) = \text{GRU}\big([\mathbf{E}_{t-1}; \mathbf{z}; \mathbf{a}], \mathbf{H}_{t-1}\big) \tag{9}$$
$$p_{dec}(s_t \mid \mathbf{s}_{1:t-1}, \mathbf{z}, \mathbf{a}) = \text{Cat}\big(s_t \mid \sigma(\text{MLP}(\mathbf{H}_t))\big) \tag{10}$$

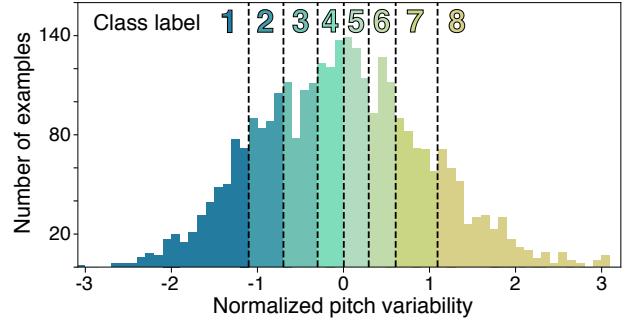
where $[;]$ is a concatenation of vectors, Cat the categorical distribution, and σ the softmax function.

3.3 Attribute Control

In this section, we detail our method to provide understandable control over musical attributes in the music generation process.

3.3.1 Musical Attributes

We rely on the jSymbolic [7] software to calculate statistical musical attributes from symbolic music data. It provides 246 kinds of features, such as pitch statistics, melodies, intervals, rhythm, instrumentation, texture, and dynamics. Out of these, we picked twelve features based on their interpretability such as the total number of notes, pitch variability, and rhythmic value variability [1]. Each feature is normalized to have zero mean and unit variance. We obtain a set $\mathbf{a} = (a_1, \ldots, a_N)$ of N attributes, where each attribute is averaged across a given input example.

3.3.2 Quantize Attributes


To train our discriminator, we first quantize the attributes into class labels $b_n \in \{1, 2, 3, \ldots, K\}$, where $K = 8$ in this work. The quantization operation $b_n = \text{quantize}(a_n)$, which is a μ-law compression, leading to an equal number of training data in each class, as depicted in Figure 2.

3.3.3 Classifier-Discriminator

The classifier-discriminator takes a latent vector $\mathbf{z}$ and predicts the class which the data belongs to. Hence, the target of the classifier-discriminator can be described as follows

$$gt(n, k) = \begin{cases} 1 & (k = b_n) \\ 0 & (\text{else}) \end{cases} \tag{11}$$

---

[1] The detailed set of features along with their meaning is available in associated webpage of this paper (https://lisakawai.github.io/music_transformation/).

Figure 2. Data distribution of pitch variability, showing how the data is split.

where $k \in [1, K]$ is the index of the quantized class and $n \in [1, N]$ is the attribute index. In order to define the adversarial criterion, the target of the encoder is $1 - gt(n, k)$.

The classifier-discriminator is defined as linear layers followed by *tanh* activation functions for all layers, except the last layer, which uses a *sigmoid* function. Thus, this network outputs a matrix $\mathbf{B} \in \mathbb{R}^{N \times K}$. Hence, this is a major difference of our classifier-discriminator, which relies on a multivariate output, instead of a scalar one [8].

3.4 Loss Function

In this work, three separate loss functions are used to optimize the model, namely, the reconstruction loss $\mathcal{L}_R$, the Kullback-Leibler divergence $\mathcal{L}_{KL}$, and the adversarial loss $\mathcal{L}_D$. The first two functions are used to optimize the VAE, as detailed in Section 2.1.1. $\mathcal{L}_D$ is used to train the classifier-discriminator and influences the encoded latent vectors, as detailed in the following section.

3.4.1 Adversarial Loss

To compute $\mathcal{L}_D$, we rely on the vectors of attribute class labels $\mathbf{b} = (b_1, \ldots, b_N)$, as detailed in Section 3.3.2. The classifier-discriminator aims to predict the class labels, by optimizing its probability distribution p_{dis}. On the other hand, the encoder aims to prevent the classifier-discriminator from predicting the class labels correctly. Hence, the targets of the encoder for the classifier-discriminator prediction is the complement vector of the class labels instead of a scalar in [8], defined as $\mathbf{1} - \mathbf{B} \in \mathbb{R}^{N \times K}$, where all the elements of $\mathbf{1}$ are equal to 1.

$$\mathbf{B} = \text{onehot}(\mathbf{b}) \tag{12}$$
$$\mathcal{L}_D(\theta_{dis}|\theta_{enc}) = -\mathbb{E}_{p_{enc}(\mathbf{z}|\mathbf{s})}[\log(p_{dis}(\mathbf{B}|\mathbf{z}))] \tag{13}$$
$$\mathcal{L}_D(\theta_{enc}|\theta_{dis}) = -\mathbb{E}_{p_{enc}(\mathbf{z}|\mathbf{s})}[\log(p_{dis}(\mathbf{1} - \mathbf{B}|\mathbf{z}))] \tag{14}$$

where θ_{dis} is parameters of the discriminator. Note that each element of the one-hot vectors $B_{n,k}$ is equal to $gt(n, k)$ in Eq (11).

3.4.2 Total Loss Function

The complete loss function of our method is defined as:

$$\mathcal{L}(\theta_{enc}, \theta_{dec} \mid \theta_{dis}) = \mathcal{L}_R + \alpha\mathcal{L}_{KL} + \beta\mathcal{L}_D(\theta_{enc} \mid \theta_{dis}) \tag{15}$$
$$\mathcal{L}(\theta_{dis} \mid \theta_{enc}) = \mathcal{L}_D(\theta_{dis} \mid \theta_{enc}) \tag{16}$$

where α and β are hyperparameters for controlling the impact of each loss in the optimization of the model.

4. EXPERIMENTS

4.1 Dataset

In our experiments, we rely on Nottingham dataset [32], a collection of monophonic British and American folk tunes, including both melodies and chords information. The examples are divided between 694 train, 170 test, and 173 validation instances. We filtered the dataset to retain only examples with 4/4 signature and used only the melody information. We split the data to obtain every sequence of four bars and performed pitch augmentation by shifting pitches from -5 to 6 for the training set. In the final dataset, the pitch ranges from 50 (D3) to 95 (B6).

4.2 Input Representation

In this work, we use a piano-roll-like input representation of monophonic music, which is a sequence of one-hot vectors, representing fixed-bar melodies as a matrix of dimension $time \times (pitch+2)$. The difference from a piano-roll is that we add two dimensions to represent *continue* (holding the previous note) and *rest* (no pitch is on) information. We choose this representation as it allows distinguishing short repeated notes more precisely. We compute the final matrix from the input $\mathbf{s} = (s_1, s_2, \ldots, s_T)$, where $T = 64$.

4.3 Baselines

We compare our proposal with two baselines: *naive VAE* and *GLSR-VAE* [6]. The implementation of the naive VAE is the same as ours without the attribute conditioning and the classifier-discriminator, and we calculate mean latent vectors with/without an attribute to decide an interpolation direction for a given latent vector following [16,17]. To apply binary attributes information, in this case, we split the data into two classes so that the instance is considered *with* an attribute if $a_n \geq 0$ and *without* the attribute if $a_n < 0$. We define the mean latent vector of the attribute presence as $\mathbf{z_w}$ and absence as $\mathbf{z_{wo}}$ and perform the interpolation by moving a latent vector as $\mathbf{z} + \delta \times (\mathbf{z_w} - \mathbf{z_{wo}})$, where δ ranges from -0.5 to 0.5 by steps of 0.1, which is within the interquartile range of $\mathcal{N}(0, \mathcal{I})$.

In the implementation of the GLSR-VAE, we simply add its regularization term to the naive VAE model. In this model, one dimension of the latent vector z_0 corresponds to the *number of notes* attribute. The interpolation is performed by computing $z_0 + \delta$, where δ is as defined previously. Note that this model is only able to interpolate the number of notes with existing implementation, while ours is applicable to any attributes.

4.4 Implementation Details

We train all of the models by using a batch size of 64, the learning rate is set to 1e-4, and we use the ADAM optimizer [33] for 50K iterations. The GRU layer has a hidden size of 1024 for both the encoder and the decoder, and the latent vector has 128 dimensions. In the VAE loss function (see Eq (15)), we use $\alpha = 0.1$ and $\beta = 0.1$.

attribute	Naive	GLSR	Ours
total number of notes	0.973	0.975	**0.981**
pitch variability	0.807	-	**0.938**
rhythmic value variability	0.830	-	**0.938**
pitch kurtosis	0.528	-	**0.723**
pitch skewness	0.366	-	**0.492**
most common rhythm val.	0.795	-	**0.851**
average note duration	0.968	-	**0.983**
note density variability	0.677	-	**0.855**

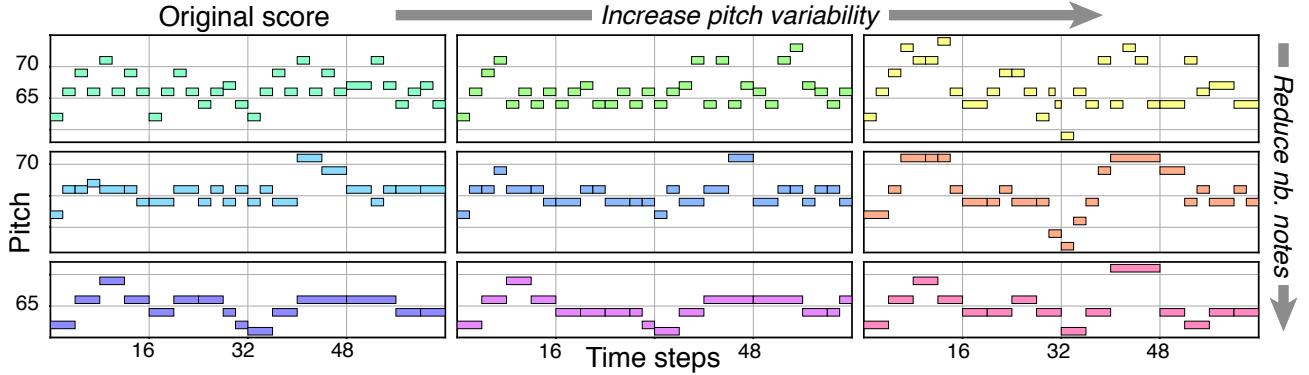
rhythmic value variability	0.809	-	**0.849**

Table 1. Correlation coefficient comparison of musical attributes. **Top**: Results of transformed outputs by changing δ. **Bottom**: Results of *cycle* transformation reverting original attributes as condition to already transformed outputs.

4.5 Evaluation Metrics


To evaluate our model performance, we need to assess both the reconstruction accuracy and the efficiency of the attributes control. Hence, the outputs generated by the model should adequately reflect the changes in the attributes. To evaluate this aspect, we rely on Spearman's rank-order correlation coefficient between conditioning attribute a_{in} and the resulting attribute a_{out} calculated from the output. The conditioning attribute a_{in} is calculated from the original attribute a_{org} depending on the change made in the control, so that $a_{in} = a_{org} + \delta$, where δ is the same as Section 4.3.

5. RESULTS

5.1 Results with Single Attribute

We compute the correlation coefficient between the target attributes and the corresponding jSymbolic features calculated on the interpolated outputs. All the interpolation results can be found in Table 1 (Top). Although some attributes such as the *total number of notes* and the *pitch variability* are easily handled by a naive VAE, some others such as *chromatic motion* and *amount of arpeggiation* are largely more difficult to detect. Our model allows us to obtain control over all the features, while outperforming others on the interpolated results.

Cycle consistency check. We also perform an experiment to check the *consistency* of attribute control. Ideally, based on a transformed output, if we revert the attribute to its original value, and use it as a condition to regenerate the interpolated results, the model should be expected to reproduce the original score. According to Table 1 (Bottom), our model is able to maintain high correlation coefficients even after successive interpolations. Oppositely, GLSR-VAE is unable to maintain this correlation, as the model cannot control the degree of attribute change.

Figure 3. Generated samples by changing the *total number of notes* and *pitch variability* attributes. Top left shows the original score and the others are outputs from our model, which is able to transform multiple musical attributes simultaneously.

	Naive	GLSR	Ours
NLL	2.269	**1.002**	1.679
accuracy	0.759	**0.808**	0.790

Table 2. Negative log-likelihood (NLL) and accuracy comparison when models are trained on an attribute, the *total number of notes*.

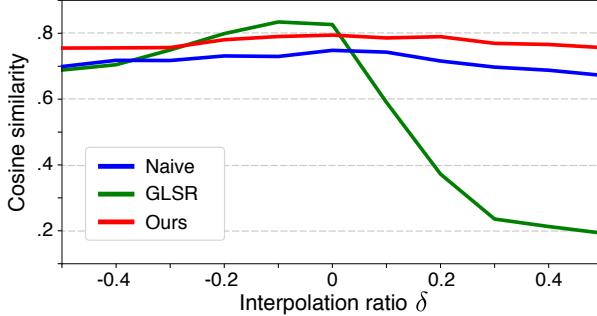
Figure 4. Cosine similarity of chroma features changing the *total number of notes* to compare chord consistency.

Reconstruction quality. We compute the negative log-likelihood (NLL) and reconstruction quality (accuracy) for unchanged attribute values and display results in Table 2. It seems that the GLSR-VAE approach provides slightly better results in the pure reconstruction scenario. However, our proposed model does not deteriorate the reconstruction quality as seen with the naive VAE.

Chord consistency check. Previous works in the field of music style transfer [30, 31] rely on chord consistency analysis to evaluate the capacity of the model to transfer the style in a given music piece while keeping its content. In [14], the authors use chroma feature as one of the criteria for the evaluation of music similarity. We follow this evaluation metrics to observe how different models can preserve the chord structures. This feature possesses 12 dimensions, each of them representing the intensity of a given pitch across octaves in one bar. To evaluate consistency, we compute the cosine similarity between chroma features of the original data and the interpolated one. The results for the *total number of notes* attribute are displayed

N	attribute	corr
2	total number of notes	0.983
	pitch variability	0.944
3	total number of notes	0.978
	pitch variability	0.936
	rhythmic value variability	0.922

Table 3. Correlation coefficient with multiple attributes used in experiments for our model.

in Figure 4 for varying values of δ. As a result, our method performs better than baselines for preserving chord consistency. Although GLSR-VAE provides better results for $\delta \approx 0$, its cosine similarity significantly drops for a positive δ, where its chord consistency quality rapidly degrades as $|\delta|$ becomes larger.


5.2 Results with Multiple Attributes

We display in Figure 3 the samples generated by our model trained on multiple attributes simultaneously (here the *total number of notes* and *pitch variability*). It shows that we can obtain interesting transformations on a given original score, while using interpretable controls. This emphasizes the ability of our model to control multiple attributes.

To further analyze this behavior, we compute the correlation coefficient of multiple attributes by shifting only one attribute at the same time, while inputting the original values for the others, as displayed in Table 3. These results indicate that the correlation coefficient remains stable, even when successively adding new controls. This shows that our model is able to produce *independent* control of multiple musical attributes, which is of prime importance for precise and intuitive music creation.

6. CONCLUSION

In our work, we proposed a new model for deep music transformation. We relied on musical attributes and introduced a model able to learn how to generate music based on these attributes. This was done by quantizing the attributes and introducing an adversarial classifier-discriminator on latent features. The experimental results showed that our model leads to independent and robust controls of musical attributes for monophonic music.

ABSTRACT

A Dhrupad vocal concert comprises a composition section that is interspersed with improvised episodes of increased rhythmic activity involving the interaction between the vocals and the percussion. Tracking the changing rhythmic density, in relation to the underlying metric tempo of the piece, thus facilitates the detection and labeling of the improvised sections in the concert structure. This work concerns the automatic detection of the musically relevant rhythmic densities as they change in time across the *bandish* (composition) performance. An annotated dataset of Dhrupad bandish concert sections is presented. We investigate a CNN-based system, trained to detect local tempo relationships, and follow it with temporal smoothing. We also employ audio source separation as a pre-processing step to the detection of the individual surface densities of the vocals and the percussion. This helps us obtain the complete musical description of the concert sections in terms of capturing the changing rhythmic interaction of the two performers.

1. INTRODUCTION

Dhrupad is one of the oldest forms of North Indian classical vocal music. A typical Dhrupad concert setting comprises a solo vocalist or vocalist duo as the lead and a pakhawaj player for the percussion accompaniment, with a tanpura in the background for the harmonic drone [1]. A Dhrupad performance lasts for over an hour and consists of an elaborate, unaccompanied *raga alap* followed by a composed piece, the *bandish*, performed along with the percussion instrument [2]. The bandish is not only presented as composed but also used as a means for further rhythmic improvisation (*laykari*), where the vocalist sings the syllables of the bandish text at various rhythmic densities and in different patterns [3, Chapter 10]. All the while, the pakhawaj accompaniment is either playing a basic pattern (*theka*) of the metric cycle (*tala*), a rhythmic improvisation to match the vocalist's improvisation, or a free solo

improvisation while the vocalist presents the lines of fixed composition. The simultaneous rhythmic improvisation by both players is peculiar to the Dhrupad genre.

Figure 1 depicts the structure of a bandish performance from the vocalist's perspective. The intermediate refrain portions are the un-improvised sections where the artist sings a portion of the bandish before diving back into another spell of improvisation. A complete segmentation of

Figure 1: The structure of a bandish performance - vocalist's perspective [3]

a Dhrupad bandish performance would thus involve providing rhythmic descriptions of un-improvised and improvised sections pertaining to each - the vocals and the pakhawaj.

The goal of this work is to develop automatic methods for the structural segmentation of the Dhrupad bandish concert. With tempo and the relationships of the rhythmic densities of the individual instruments defining the distinct sections of a Dhrupad bandish concert, we explore new approaches to the reliable detection of these musical attributes as they vary across the concert. Given that vocal onsets are difficult to detect (even in isolated vocals due to the diversity inherent to singing), we turn to alternate methods for the direct estimation of the local rhythmic density. Advances in deep learning have led to the development of methods that treat the estimation of the predominant tempo from the raw audio spectral representation as a classification task [4–6]. We explore a similar approach for our task of estimating the changing surface tempo or rhythmic density across a concert audio. In view of the significant improvements reported in audio source separation in recent years, we also consider the use of source separation followed by tempo estimation for the constituent instruments in order to give a more complete description of each section.

The chief new contributions of our work are as follows: (i) a dataset of tempo markings and rhythmic density based structural segmentation annotations for Dhrupad bandish concerts, (ii) adapting a state-of-the-art tempo estimation method to the task of estimating local rhythmic density of the polyphonic mix, and (iii) the use of source separa-

tion to extend this to each instrument(vocals and pakhawaj) to eventually obtain a musically relevant segmentation of bandish concerts with section labels defined in terms of the rhythmic density inter-relationships.

2. BACKGROUND

Compositions in Hindustani music are sung at a tempo in one of roughly three broad ranges - *vilambit* (10.4-60 BPM), *madhya* (40-175 BPM) or *drut* (170-500 BPM) [3, p. 86]. This tempo is determined by the interval between the *matras* of the tala (a cyclic pattern of beats) that the composition is set to, and is referred to as the metric tempo. The metric tempo is fairly stable with only a gradual upward drift across the performance. However there are local variations in the rhythmic density of the singing or playing during what can be called episodes of improvisation that constitute the surface rhythmic density or surface tempo. For the voice, this is calculated using the number of syllables or distinct notes uttered in a unit interval and for the pakhawaj, the number of strokes played in a unit interval [3, p. 86], [7]. The surface tempo is found to generally be an integer multiple (ranging between 2 and 16) of the underlying metric tempo and we use the term 'surface tempo multiple'(*lay* ratio) to refer to this integer. The metric and surface tempi in this form of music thus have fairly objective definitions in terms of the performers' intentions and do not necessarily coincide with 'perceptual tempo'. And indeed as stated in [3, p. 85], the perceived tempo at extreme values of the metric or surface tempo may be quite different due to subdivisions at the lower end and grouping and accenting at the higher.

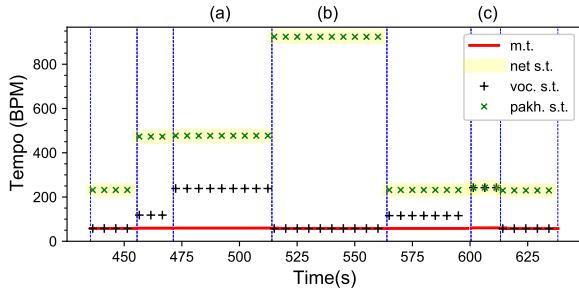
Related work on structural segmentation for Hindustani classical music can be found in [8–11]. The work in [8] relates to the segmentation of the initial unaccompanied alap portion of a Dhrupad vocal concert into the alap, jod and jhala sections. The methods exploit the changing nature of the energy, pulse clarity (salience), speed, and timbre of the vocals. In [10, 11], the task of segmenting the unaccompanied, and in [9] the accompanied portion of instrumental concert audios consisting of a lead melodic instrument(sitar, sarod) and a tabla accompaniment, was addressed. Signal processing methods based on finding onsets followed by periodicity detection were made use of for tempo and rhythmic density estimation. Section boundaries were obtained with the help of a similarity detection matrix, using frame-level ACF vectors of the detected onsets in [9], and using additional acoustic features and feature transformations in [11]. Faced with the problem of two instruments playing together, differences in the instrument timbres were exploited to separate the plucked string and tabla onsets in [9] to determine separately the metric and the surface tempo. Other source separation methods like HPSS [12, 13] and PLCA [14] have also been used to obtain tempo estimates for individual sources, which are then combined together to refine the overall tempo estimate.

In this work we address the structural segmentation of the bandish section in Dhrupad vocal performances, which

has not yet been attempted. We propose to achieve this by first estimating the surface tempo using the CNN-based approach of [4] with a modified architecture to predict it directly as a multiple of the metric tempo. To obtain the surface tempo of each instrument, we make use of a pre-trained model provided by spleeter [15] that separates vocals from the accompaniment. We then detect section boundaries in a concert audio using changes in the estimated local surface tempi.

3. DATASET DESCRIPTION

To the best of our knowledge there is no existing dataset of tempo and segmentation related annotations for Dhrupad bandish performances. The dataset chosen for this work contains 14 concert audios in the *vilambit* and *madhya laya* - 8 from the Dunya corpus [16] and the rest from publicly available, good quality recordings. 9 of the 14 are by the vocalist duo Gundecha brothers, and the others by Uday Bhawalkar. Each recording is of a single bandish performance by the vocals, accompanied by pakhawaj, with a tanpura in the background. The recordings are 8-15 minutes long and the total duration of the dataset is about 3 hours. The performances are not all in the same raga or tala with at least one composition in each of 4 distinct talas commonly found in Dhrupad. 7 more publicly available audios were partially annotated to balance the cross-validation dataset described in Section 3.2.

3.1 Annotations


Annotations are of (i) the *sam* positions of the tala, i.e., the cycle boundaries, across the concert (ii) boundaries marking changes in the surface tempo multiple of each instrument and (iii) a label for each section in terms of the surface tempo multiple of each instrument. The annotations were marked by one of the authors, who is a trained musician, using the relatively objective criteria described here.

Information about the tala was obtained from the metadata accompanying the recording. With this, the sam positions were inferred either from the particular stroke of the pakhawaj or the syllable of the bandish refrain that appears on the sam in performance [17], or the number of matras elapsed since the previous sam. Although slight deviations are commonly observed in the metric tempo, large abrupt jumps do not occur. Hence, once a pass was made over the entire audio, the annotations were corrected at points of ambiguity to ensure coherence with adjacent sam markings. The metric tempo was then calculated versus time, once for every cycle, by dividing the cycle duration by the number of matras in the tala.

A section boundary was marked whenever the rhythmic density of either instrument changed and the new density was maintained for at least a duration of 5s. As mentioned earlier, the surface tempo is typically related to the metric tempo as an integer multiple. Therefore every section was labelled with the surface tempo multiple of each instrument, determined by calculating the rate of events (syllables for the vocals and strokes for the pakhawaj) as a mul-

tiple of the metric tempo in the section. Pauses at the pulse level occurring between syllables or strokes were considered as musical events contributing to the surface tempo, while pauses longer than 5s were labeled as having no surface tempo. A more detailed discussion on this appears in [7]. The maximum of the vocal and pakhawaj surface tempo multiples was then added to the section label as the net surface tempo multiple denoting the overall level of rhythmic density. Henceforth, we use the abbreviations m.t., s.t. and s.t.m. to refer to the metric tempo, surface tempo and surface tempo multiple.

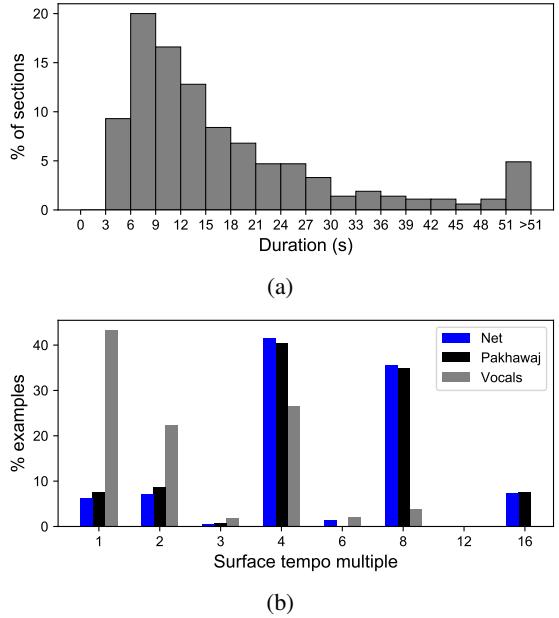
Figure 2 is a visualisation of the annotations for a portion of a bandish audio in the dataset [1]. This roughly 4 minute long snippet captures a few sections - (a) vocal s.t. at 4 times the m.t.($\sim$60 BPM) and pakhawaj at 8, (b) vocals at the m.t. and pakhawaj at 16 times - in each of these the net is due to the pakhawaj, and (c) both at 4 times, where the net is due to both.


Figure 2: The ground truth metric tempo (m.t.) and surface tempo (s.t.) annotations for a portion of an audio in the dataset. Vertical dashed lines indicate section boundaries.

3.2 Dataset Statistics and Train-test Split

Every annotated section is homogenous in the sense that the s.t. of each instrument remains the same throughout its duration. We therefore pool the sections from all the concert audios into a dataset for training and testing our methods, treating each section as an independent entity. The total number of sections comes up to 634 (593 from the completely annotated and the rest from the partially annotated audios), but they are not all of similar durations. Figure 3 (a) shows the distribution of section durations with a single bar at the end for values more than 51s. We see that a section is mostly between 6 and 20s long. With the goal of tracking the s.t. as it is changing across a performance, we need to perform tempo estimation on shorter examples from each section. The duration of these examples is set to be 8s since a higher value would give us no examples from the large number of sections that are only 6-9s long. Further, for the slowest tempo in the dataset of about 30 BPM, an 8s duration would contain at most 4 beats, fewer than which may not be sufficient for accurate tempo estimation.

The distribution of s.t.m. in the dataset for each instrument and the net is shown in Figure 3 (b) in terms of the

(a)

(b)

Figure 3: Distributions of (a) section duration and (b) net, pakhawaj and vocal s.t.m. across our dataset of 1127 examples.

relative number of non-overlapping 8s examples (extracted from sections) available at each integer multiple, out of a total of 1127 examples. The dataset has a narrow m.t. range of 30 - 85 BPM, but the observed range of s.t. extends upto a large 960 BPM, due to the nature of the *lay* ratios. For the pakhawaj, we find that the multiples 4 and 8 are more abundant than 1, 2 and 16, while the multiples 3, 6 and 12 are nearly absent. For the vocals, 1, 2 and 4 are most represented and even though the multiples 3, 6 and 8 have a similar share, the sections for 8 were found to come from several concerts, while 3 and 6 were only found in a couple. We thus retain only the sections with s.t.m. values from the set {1, 2, 4, 8, 16}.

To manage the data imbalance, while generating the 8s training examples, the hop between consecutive examples is kept shorter for sections belonging to the less populous s.t.m values. We also augment the dataset by time-scaling the audio of each section [18] using one or more factors in the range {0.8, 0.84, 0.88, ... 1.2} (the s.t.m. label remains the same), generating more time-scaled versions for the less populous classes. The whole pool of examples is divided into three folds such that all the examples from a single audio section are assigned to the same fold, and each fold has a similar distribution of the s.t.m. values.

4. METHODS

We consider the recent CNN-based tempo estimation method from [4] (denoted as tempo-cnn) for our work. After examining the viability of the pre-trained model, we first attempt to train new models with the same architecture on our dataset, and then propose some suitable modifications.

4.1 Metric Tempo Estimation

The m.t. of a Dhrupad bandish performance gradually drifts across a performance. Hence, we are interested in estimating it locally and tracking it versus time. With the m.t. range of our dataset being a subset of the tempo-cnn output range, the pre-trained model can be used as it is to observe the nature of its predictions. Upon obtaining estimates frame-wise at 0.5s hops and picking the output class with the highest confidence in each frame, it is found that the model almost always makes octave errors, which is to be expected since the m.t. in our case is not always the perceptual tempo that the model was trained to estimate. We fix these errors by constraining the predicted tempo to lie in the range of m.t. values in the dataset.

We do not attempt to train a new model for m.t. estimation and instead compare the above with a non-learning based approach from [9]. A spectral flux based method is used to obtain the onsets and the autocorrelation function is calculated on 12s long windows at 0.5s hops for values of lag upto 2s. The tempo candidates are constrained to be in the required range and an additional Viterbi smoothing step is used to penalise jumps and obtain a consistent estimate across a concert. We refer to this as the odf-acf method. We also note that the metrical cycle tracking work of [19] offers an alternative that can be investigated for m.t. estimation in future work.

4.2 Surface Tempo Estimation

The s.t. values in our dataset fall outside the tempo-cnn output range. And since the task requires correct identification of tempo without octave errors, using the pre-trained tempo-cnn is not possible. If we are to re-train tempo-cnn on our dataset by increasing the output range, the huge size of the range presents a problem due to the resulting target class imbalance. Therefore, given that the s.t.m. is one of a small set of integer values, we modify the task to predicting this multiple instead of the actual s.t. value.

An attempt to train new models using the tempo-cnn architecture on our dataset by reducing the final softmax layer dimensions does not turn out to be fruitful as the model overfits due to its high capacity and the small size of our dataset. The main issues seem to be the high number of dense layers at the end and the large filter lengths in the multi-filter modules. After a series of simplifications with some inspiration from [5], the architecture summarised in Table 1 is found to be promising (details in [7]). The reduction of dense layers and the addition of dropout layers is found to be crucial in overcoming overfitting. To prevent too much information from getting cut-off due to the dropout, the p value is set to 0.1 in the first three conv. layers, and 0.5 in the later ones. As for the multi-filter conv. layer, fewer filters in parallel and smaller filter lengths are found to make the network easier to train. However, to ensure adequate capacity, the number of filters in each layer is kept moderately high.

Every 8s training example is transformed to a log-scaled mel-filtered magnitude spectrogram, using the following parameters - 40ms windows, 20ms hops and 40 mel filters

Layer	Dimensions
Input	40 x 400
(BN, Conv, ELU, DO) x3	16 x 1 x 5
AvgPool	5 x 1
BN, MF Conv, DO	12x {1x16, 1x32, 1x64, 1x96}

AvgPool	1 x 400
BN, DO, FC, Softmax	# output classes

Table 1: Proposed model architecture, adapted from [4] & [5]

over the band 20-8000 Hz, at a sampling rate of 16kHz. The input to the network is a spectrogram of size 40 x 400 with the values normalized to lie in the range 0 - 1, and the target is one of 5 classes corresponding to the 5 s.t.m. values - 1,2,4,8,16. The network is trained using CCE loss on examples from two folds, with the other fold as the validation set, for a maximum of 500 epochs. Training is carried out using the Adam optimizer with a learning rate of 1e-4 and a batch size of 32, and is halted early if the validation loss does not decrease for 50 epochs.

4.3 Extension to Separated Sources

Given our interest in estimating the s.t. of each instrument to obtain a more complete rhythmic description and the section boundaries in a concert, the pre-trained 2-stems model by spleeter [15] is used to separate the mixture audios into vocals and accompaniment, and new models with the same architecture as proposed above are trained to predict the s.t.m. for each. The dataset of sections remains the same but the input examples are of the separated sources and the training and validation folds are generated again for each source to balance the number of examples across the corresponding classes. The target classes for the pakhawaj are the same as earlier but those for vocals do not include the s.t.m. 16.

4.4 Boundary Detection and Section Labelling

We aim to automatically identify sections in a concert by looking for abrupt changes in the s.t.m. values of each instrument across the concert duration. For this task only the completely annotated 14 concert audios are used. Estimates of s.t.m. are obtained once every 0.5s using 8s long excerpts over the entire duration of each audio. While doing so, each excerpt is presented to that saved model out of the three from the 3-fold CV procedure, to which no portion of the section that this excerpt lies in was presented as a training example, thus preventing any train-test leak. The output class with the highest confidence is taken as the s.t.m. estimate. This procedure is applied to the mixture and the source separated audios. A boundary is marked wherever the s.t.m. of either instrument changes, and the section label is the tuple of the three s.t.m. estimates.

We experiment with two methods for obtaining the three s.t.m. estimates. One, the three values are estimated

Method	Accuracy 1	Accuracy 2
tempo-cnn	5.2	73.8
tempo-cnn with range constraint	71.6	74.7
odf-acf	72.0	72.0

Table 2: Metric tempo estimation accuracies (%) at 4% tolerance using tempo-cnn [4] and the odf-acf method [9].

independently, and we refer to this method as seg1. Here the net s.t.m. may not be equal to the higher of the other two (which should be true by definition). We thus report results using the model output for the net s.t.m. as well as by simply taking the maximum of the other two as the net s.t.m. value. Two, to investigate whether using the expected relationship between the three s.t.m. values helps improve performance, instead of obtaining them independently, we pick that tuple of the three estimates in every frame which has the highest average classifier confidence value and in which the net s.t.m. is the maximum of the other two. We refer to this method as seg2. To reduce the number of false alarms, a post-processing step is used with each method to smooth the outputs by constraining the duration of a detected section to be at least 5s. This is implemented by removing the boundaries of any section that is shorter and replacing the label by that of the previous section.

5. EXPERIMENTS AND RESULTS

5.1 Metric Tempo Estimation

To evaluate m.t. estimation we calculate *accuracy1* and *accuracy2* (allowing for octave errors) with a tolerance of 4% across each audio at a 0.5s frame-level and then average it across the dataset. We find that both the methods fare equally well (Table 2) and the simple fix of including a range constraint significantly improves *accuracy1* for tempo-cnn (except in cases where the prediction is an octave off but already in the m.t. range).

A closer look at concert-wise scores revealed that the accuracy was below 70% in the same 4 (out of 14) concerts in both the methods, where most of the errors were due to the predicted value being either 1.5 or 0.75 times the actual m.t. value. The tempo-cnn makes errors only in small portions of such concerts, but in the odf-acf method, due to the imposed penalty on jumps, the predicted tempo was found to be incorrect over longer durations. Even so, what we take away from the overall results is that for most of the concerts, m.t. is estimated well across the entire duration despite the presence of sections where both the instruments are improvising and playing at different multiples of the m.t.

5.2 Surface Tempo Estimation

Here, we first report the average 3-fold cross-validation accuracy values. This accuracy measures the proportion of 8s

Case	Net s.t.m	Vocal s.t.m	Pakhawaj s.t.m
Accuracy	75.2	69.1	76.9

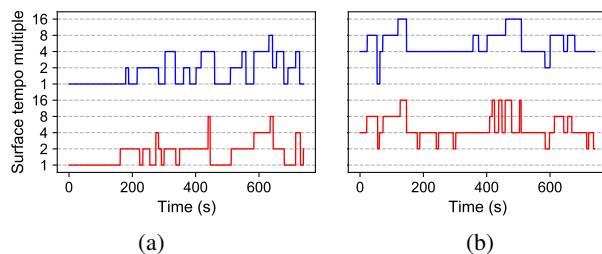
Table 3: Average 3-fold cross-validation accuracies (%) for surface tempo multiple estimation

examples for which the s.t.m. was correctly identified. Table 3 shows the results for all three cases - estimation of net s.t.m. from the original mixture, and that of the individual instruments from separated audios.

The results are poorer for separated vocals and better for pakhawaj, which reflects also in the net score, given that the net s.t.m is dominated by that of the pakhawaj. The class-wise performance is shown using a confusion matrix for each case in Table 4. In the case of vocals, classes 1 and 8 are estimated more accurately. For class 8, this could be due to the distinct nature of vocalisation and the limited diversity of examples due to fewer available sections. For class 1, most examples come from sections where the bandish is sung at a steady rate without improvisation thus making tempo estimation easier. For class 2, sections often come from the earlier stages of improvisation in a concert where the singing is not fully rhythmic and is characterized by pauses, melismatic singing and changes to other s.t.m. levels, making the estimation harder. The confusions between classes 2 and 4 could also be due to some bleed of pakahwaj into the vocals during source separation.

In the case of net and pakhawaj s.t.m., classes 1 and 2 are estimated quite accurately, while the other classes are confused with their immediate neighbours. The class 16 being confused with 8 is most likely because of the presence of accents on every other stroke. We also notice a drop in the performance of this class in the case of separated pakhawaj when compared to the mixture audios, possibly due to a further loss of weak onsets after separation.

5.3 Boundary Detection and Section Labelling

We evaluate boundary retrieval performance using precision, recall and F-score (Table 5a). A predicted boundary is declared a hit if it falls within a certain duration of an unmatched ground truth boundary, and a false alarm otherwise. Results are reported at two values of temporal tolerance: ±1.5s and ±3s. The latter value is as used in [20] and the former is included with the reason that since a large number of sections are 6-9s long, even if both the detected boundaries are off by 1.5s, the detected section still captures at least half of the ground truth section.


To evaluate section labelling, we report labelling accuracy (Table 5b) as the fraction of the duration of each concert that is correctly labelled (excluding regions where the ground truth is not one of {1,2,4,8,16}), averaged across the dataset, as defined in [21]. Each of the three s.t.m. labels are first evaluated individually and also when taken together (i.e., a frame is said to be correctly labelled only if all three labels are correct). We expect these scores to be different from the cross-validation accuracies reported in Table 3 as the test set is now no longer balanced, with

		Predicted				
		1	2	4	8	16
(a)	1	**90.1**	2.2	6.4	0.0	1.3
	2	5.8	**82.0**	10.8	0.8	0.5
	4	4.5	13.4	**66.9**	11.9	3.3
	8	2.4	1.8	14.4	**65.7**	15.7
	16	1.8	1.0	6.5	15.1	**75.5**

	16	1.4	1.1	6.1	**24.8**	66.6

(Ground truth — row labels, left vertical axis)

Table 4: Confusion matrix of (a) net, (b) vocal, and (c) pakhawaj s.t.m. predictions (values in %)

the confused classes being the more common ones.

The individual labelling accuracies are quite similar for the pakhawaj and net tempo labels, slightly lower for the vocals, but much lower for getting all the labels right in every frame. With `seg1`, we see that the vocal and pakhawaj estimates are reliable enough that taking their maximum as the net s.t.m. instead of using the model estimate improves the net s.t.m. labelling accuracy. Hence, for the evaluation in the last column, the net is taken as the maximum of the other two. Although this seemingly renders the model trained to predict the net s.t.m. not very useful, we see in `seg2` that using it to obtain all the estimates together improves all the accuracies, proving its utility.

Figure 4: The ground truth (above) and estimated (below) s.t.m. labels of the (a) vocals and (b) pakhawaj across the concert *GB_AhirBhrv_Choutal*.

Although better tempo estimation should result in better boundary detection since the boundaries are based entirely on tempo changes, the boundary detection results using `seg2` are only slightly better than `seg1`. In both the cases, the smoothing step was found to improve the results (detailed in [7]). Looking at the vocal and pakhawaj s.t.m. estimates obtained using `seg2` in Figure 4, we see that for both the instruments, at a coarse level, the various sur-

	±1.5s tolerance			±3s tolerance

face tempo regions are captured well. And while for the pakhawaj, finer section changes are also estimated accurately, such changes are not tracked well in the case of vocals, thus reducing the overall boundary detection scores.

6. CONCLUSIONS

We have presented a system that provides a complete rhythmic description of a Dhrupad bandish performance, enabling its segmentation into musicologically relevant sections based on the rhythmic interaction between the instruments. The metric tempo is estimated by adapting existing methods whereas the surface tempo, with its much larger dynamic range, is estimated in a novel manner by predicting its relationship with the m.t. to directly obtain the musically significant *lay* ratio. Because of the challenges presented by imperfect source separation, we benefit from using a model trained also on the mixture audios. We find that s.t.m. values at the lower and higher extremes are estimated better than the intermediate values. This, despite the intermediate values being the more represented classes in the dataset, points to the diversity in the acoustic realisations of the different surface densities. Future work could involve extending the dataset to encompass more singers and compositions in the *drut* lay, where we might see the same s.t.m. manifesting completely different acoustic properties. In such a scenario, estimating m.t. could help provide useful 'conditioning', and ways to jointly estimate the metric and surface tempi could be explored. Source separation can be improved by introducing new loss functions that preserve onsets better and hence allow better tempo estimation on separated audios. Finally this work provides an example of adapting available MIR methods to music genre specific problems.

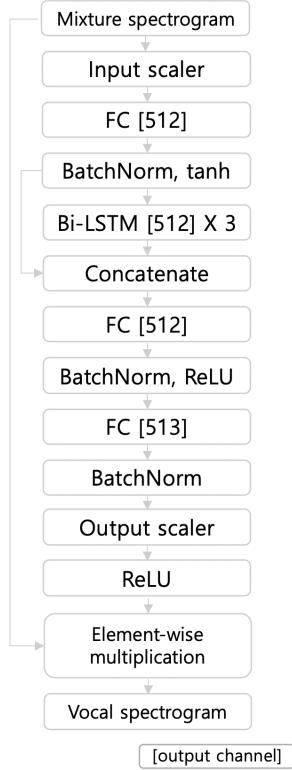
ABSTRACT

In this paper, we propose a method of utilizing aligned lyrics as additional information to improve the performance of singing voice separation. We have combined the highway network-based lyrics encoder into *Open-unmix* separation network and show that the model trained with the aligned lyrics indeed results in a better performance than the model that was not informed. The question now remains whether the increase of performance is actually due to the phonetic contents that lie in the informed aligned lyrics or not. To this end, we investigated the source of performance increase in multifaceted ways by observing the change of performance when incorrect lyrics were given to the model. Experiment results show that the model can use not only just vocal activity information but also the phonetic contents from the aligned lyrics.

1. INTRODUCTION

Singing voice separation is one of the most widely studied areas in the field of audio signal processing. In particular, the importance of research is greatly emphasized because it can contribute to the pre-processing step of research in various fields of Music Information Retrieval (MIR), such as automatic music transcriptions and automatic lyrics alignments. With the recent development of deep neural networks, a number of music source separation studies have been published and showed excellent performance. These studies have a common feature of separating music source by using only information from the sound source itself, such as a 1-dimensional waveform [1,2] or a 2-dimensional spectrogram [3–5].

One of the distinguishing characteristics that differentiate music signals from other audio signals is that usually there exists the corresponding music scores or lyrics. Therefore, several studies attempted to separate the sources by utilizing additional information other than the informa-

tion of the sound source itself. For example, the additional information such as pitch [6] or even the whole score [7] can be used as a prior to help separate the source of interest from the mixture. In general, however, music scores for certain songs are not readily available, while lyrics can be easily collected on the web.


The lyrics are particularly closely related information to singing voice; thus, have promising possibility to be used as additional information for singing voice separation. Recent studies proposed the ways of using linguistic features extracted from the end-to-end automatic speech recognition model [8] or voice conversion model [9] to the singing voice separation framework. However, the way of using explicit lyrics information has not been studied enough so far, which motivates us to study the possibility of lyrics-informed singing voice separation. We expect that singing voice separation systems can benefit from lyrics information because of the rich information contained in the phonetic features such as formant frequencies.

To utilize the lyrics, we combined the highway network-based lyrics encoder [10] into the current state-of-the-art music source separation network, *Open-unmix* [5]. In addition, we tried two conditioning methods — 1. local conditioning, 2. concatenation — and compare the performance. Note that the alignment between the lyrics and songs itself is another separate line of research [11, 12]. For our study, we assume that the alignment is already done and only focus on the use of the *aligned* lyrics.

The information in the aligned lyrics can be seen from two perspectives: 1. The timing information of vocal activity, 2. phonetic information. Therefore, it is important to check if the network is using the phonetic information other than the vocal activity information. Various evaluations were conducted to examine whether the phonetic information of the aligned lyrics actually contribute to improving the performance. We found that the proposed model trained with the aligned lyrics clearly show better performance than the baseline model trained without any additional information. Furthermore, the experiment results show that the performance of the proposed model even exceeds the model trained only with additional vocal activity information. To the best of our knowledge, this is the first research to directly use the lyrics information for a singing voice separation task.

Figure 1: The structure of the baseline *Open-unmix* network.

Figure 2: The structure of the lyrics encoder.

tures of *Open-unmix*, differentiating from other studies that use decibel scales.

We used *Open-unmix* network as our baseline model because we wanted to check whether the aligned lyrics information could improve the performance of the current state-of-the-art model. The channel inputs and outputs are mono in our study although the original study used stereo. This is because our singing dataset is made up of a clean singing voice without any reverberation, chorus, or doubling, as opposed to the singing tracks in MUSDB18's singing voice dataset, which are already processed for the stereo. Details and the full structure of the baseline *Open-unmix* are illustrated in Figure 1.

2. RELATED WORK

2.1 Informed Source Separation

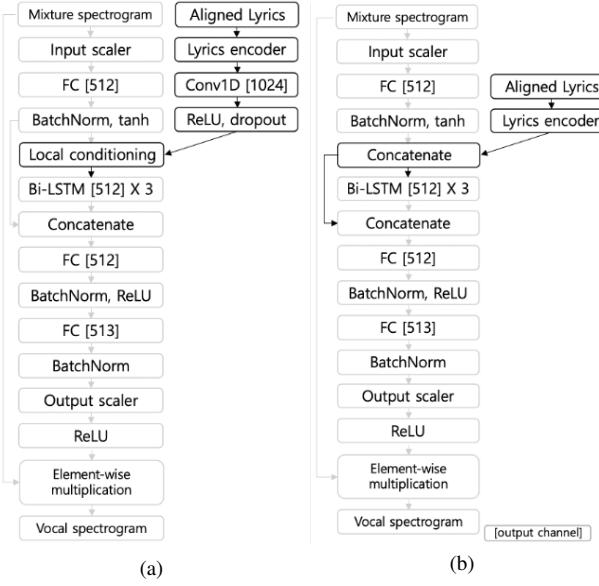
Several studies using machine learning algorithms other than deep neural networks attempted to separate singing voice with side information. For example, robust Principal Component Analysis (rPCA) was used with additional vocal activity information [13]. Also, rPCA and Non-negative Matrix Factorization (NMF) were used with pronounced lyrics [14].

Although only few studies have tried to use additional information for singing voice separation using deep neural networks, it was reported that vocal activity information can be used as an input to the network along with spectrogram to enhance the performance of the singing voice separation network [15]. Very recently, in the speech enhancement field, attempts have been made to utilize text information to increase the separation performance [16].

2.2 Open-unmix

Open-unmix [5] is the state-of-the-art music source separation network using the MUSDB18 dataset [17]. In particular, it consists of 3 bi-directional Long Short-Term Memory (LSTM) layers for source separation with 3 additional fully-connected layers. Batch normalization [18] was used after every fully-connected layer and skip connection [19] was used between the inputs and outputs of 3 consecutive bi-directional LSTM layers. Trainable input and output scalers through frequency-axis are also the special fea-

2.3 Singing Voice Synthesis

Singing voice synthesis and lyrics-informed singing voice separation tasks share a similar framework in that the input and output are the same as lyrics and singing voice spectrograms, respectively. Recently, [10] proposed the singing voice synthesis network that succeeds in creating high-quality singing based on 60 Korean songs sung by a single singer. It is based on the Text-to-Speech model [20], which consists of 1-dimensional convolutional neural networks and highway networks [21]. Therefore, we borrowed the idea of using the highway network-based lyrics encoder and integrated it into the source separation network.


3. PROPOSED METHOD

3.1 Lyrics Encoder

The detailed structure of the lyrics encoder is shown in Figure 2 and the structure of the highway networks used in the lyrics encoder is defined as follows,

$$y = ReLU(x*W_H)\cdot\sigma(x*W_T)+x\cdot(1-\sigma(x*W_T)), \quad (1)$$

, where x and y are input and output of the network and $\cdot$ refers to the element-wise multiplication. $x*W_H$ and $x*W_T$ are the 1-dimensional convolution layers which

Figure 3: The structure of the *Open-unmix* networks combined with the lyrics encoder using (a) local conditioning and (b) concatenation method.

have the same input and output channel sizes. Biases are omitted in Eqn (1). Zero-padding was applied to keep the input and output length the same in every convolution layer. Dropouts [22] with 0.05 dropout rate, were applied after the activation functions. Dilated convolution [23] were used to expand the receptive field to 165 frames. It is about seven times larger than the model without the dilation. In our experimental settings, 165 frames are equal to about 1.915 seconds.

3.2 Local Conditioning of Lyrics Encoding

The local conditioning method [10] was used to insert the encoded lyrics information into the singing voice separation network. The local conditioning is defined as follows,

$$y = ReLU(x * W_f + L_1) \cdot \sigma(x * W_g + L_2), \quad (2)$$

where, $x * W_f$ and $x * W_g$ are the 1-dimensional convolution layers which have same input and output channel sizes. L_1 and L_2 are equally separated features through the channel axis from the output of the consecutive lyrics encoder and the 1-dimensional convolutional layer. The 1-dimensional convolution layer with filter size 1 was added on the output of the lyrics encoder so that the channel size of each L_1 and L_2 could be 512. σ refers to the sigmoid activation function. Details of the full structure are in Figure 3a.

3.3 Concatenation of Lyrics Encoding

A concatenation method, which is a simple but powerful conditioning method, was also used in our study to pass the encoded lyrics information into the singing voice separation network. By concatenating the output of the first fully-connected layer and the lyrics encoder output, the

Singer	Gender	Train	Validation	Test	Total
1	Female	79	5	8	92

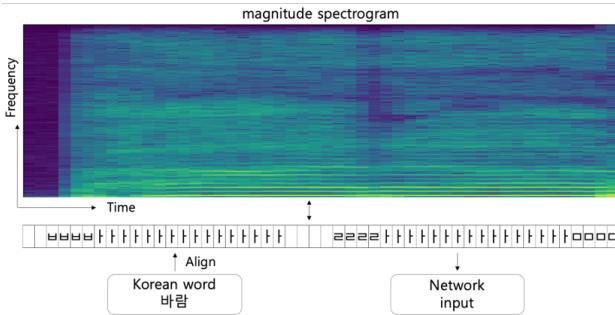
Table 1: The composition of our singing dataset.

channel size of LSTM layers input becomes 1024. Also, the channel size of the second fully-connected layer input becomes 1536 by the skip-connection of LSTM input and output. Details of the full structure is in Figure 3b.


4. EXPERIMENTS

4.1 Dataset

Here we used a total of 201 Korean pop songs sung by 13 amateur singers as target clean singing sources. This dataset has a total length of 11 hours and 44 minutes. Of these, we used 162 songs (9h 3m) for training, 19 songs (1h 7m) for validation, and 20 songs (1h 7m) for test dataset. The detailed composition of the dataset is described in Table 1.

We aligned Korean syllable following [10]; one Korean syllable is made up of onset (consonant), nucleus (vowel) and coda (consonant), we aligned onset and coda for 4 frames, and nucleus for other frames. The example of the alignment applied to the spectrogram is shown in Figure 6.

A total of 19,113 instrumental songs were used as accompaniment for training networks because we did not have real accompaniment tracks corresponding to the singing voice dataset. Since various studies using MUSDB18 [17] or DSD100 [24] dataset also used random mixing techniques, i.e. creating random accompaniment for each iteration that was not related to the original singing, we decided that using arbitrary accompaniments would not be a problem for training. In addition, if we used the same specific accompaniments for the test singing voice dataset, we assumed that it is reasonable for identifying how the information containing the phonetic features of the aligned lyrics has changed the performance of the network, the fact we wanted to identify. Therefore, for the validation and test dataset, we randomly chose each 19 and 20 instrumental songs which have a longer length than the singing data, and shorten the length to the same with the singing.

Figure 4: The example of inserting the aligned lyrics to the networks.

4.2 Training

In our singing dataset, the number of songs recorded by the first singer is outnumbered compared to the others, accounting for about 46 percent of the total. In order to prevent bias to a particular singer when training the networks, a singer was first selected with the same probability when constructing a batch to be used for each iteration, and the vocal source to be used for training was sampled only for the songs recorded by the selected singer.

A mono sound source with a sample rate of 22050 Hz was used in the experiment. FFT point size and window size were set to 1024 samples (0.0464 seconds) to convert them into a spectrogram, and Short-time Fourier transform (STFT) hop size to 256 samples (0.0116 seconds). Adam optimization method [25] was used for training with a learning rate of 0.001, β_1 for 0.9, β_2 for 0.999. Mean squared error (MSE) loss function between the ground-truth and the outputs of the models were used in our study. We trained the models for 500 epochs with calculating validation loss for every epoch. The learning rate was reduced to 30 percent if there was no decrease in validation loss during 25 epochs. Early stopping was applied after 50 epochs without a decrease in validation loss.

4.3 Evaluation Methods

Here we briefly summarize the various experiments that will be shown in the following Section 5. The experiments will be conducted in three following ways.

First, in Section 5.1, we compare and analyze how much performance improvement there are between the baseline model trained without the lyrics and the model trained with the aligned lyrics.

Second, in Section 5.2, we check if the network exploits the vocal activity information included in the aligned lyrics. The lyrics include both the vocal activity information and phonetic information, and thus expected to use the vocal activity information correctly.

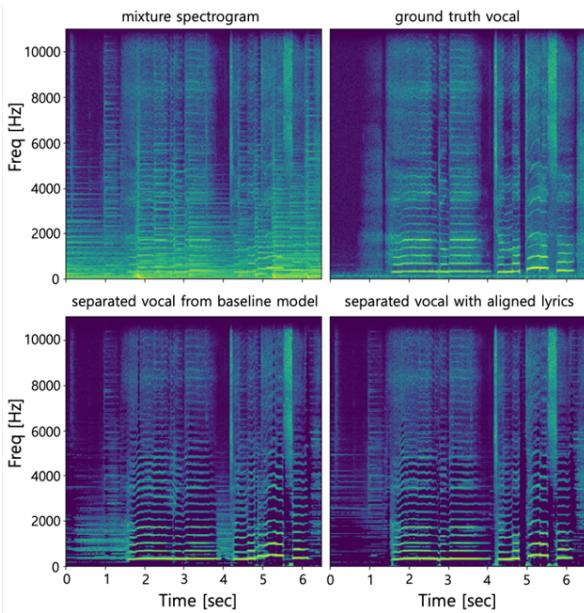
Third, in Section 5.3, we check if the given input is correctly being used by the network trained with aligned lyrics. This experiment was done by giving incorrect inputs in the evaluation stage. It is expected that the incorrect inputs will significantly reduce performance.

For network performance evaluations, Signal-to-

Model name	Inputs to the lyrics encoder
model 1	None
model 2	Meaningless inputs (all 0)
model 3	Vocal activity information
model 4	Aligned lyrics

Table 2: The description of each models in our experiments.

Distortion Ratio (SDR), Signal-to-Interference Ratio (SIR), Signal-to-Artifact Ratio (SAR) scores [26] were computed by museval python library [27].

5. RESULTS


The configuration of the models we trained in our experiments is in Table 2. We trained four models each using local conditioning and concatenation method. *model 1* is the baseline model that trained without the lyrics encoder. *model 2* is the model that trained with meaningless 0 value inputs to the lyrics encoder. This model is only for checking the performance change of the networks caused by the extended network capacity. *model 3* is the model that trained with only vocal activity information to the lyrics encoder. We simply used 0 value as unvoiced sections and 1 as voiced sections so that the 128-dimensional embedding can train useful meaning from it. *model 4* is that trained with aligned lyrics information. For both *model 3* and *model 4*, note that 0 value has clear meaning, unvoiced sections, unlike 0 value in *model 2* is meaningless. Since the baseline model is the same for each local conditioning and concatenation method, we trained a total of 7 models for the experiments. Except *model 1*, we will use the abbreviation of local conditioning and concatenation methods, each *LC* and *CC*, in front of the model names for convenience. For example, the model trained with aligned lyrics and the local conditioning method is *LC-model 4*.

5.1 Performance Evaluation

The quantitative performance evaluation scores of the models are shown in Table 3. Median scores were taken from the median values of 20 songs, which were calculated for every frame (a median of frames, a median of tracks). Mean scores represent the scores taken by a mean of frames, a mean of tracks. Each frame was set to 1 second.

It was confirmed that the separation performance of both *LC-model 4* and *CC-model 4* improved from the *model 1*. This implies that aligned lyrics information can be used as helpful features for singing voice separation networks. Comparing to *LC-model 3* and *CC-model 3*, we could verify that there were clear performance gains not only from the lyrics alignment information but also the phonetic features of the lyrics itself. It was also confirmed that the performance gains do not come from just network capacity growth, given that there are no significant differences in the performance of *model 1* and *model 2*. The spectrograms of the separated sample are in Figure 5.

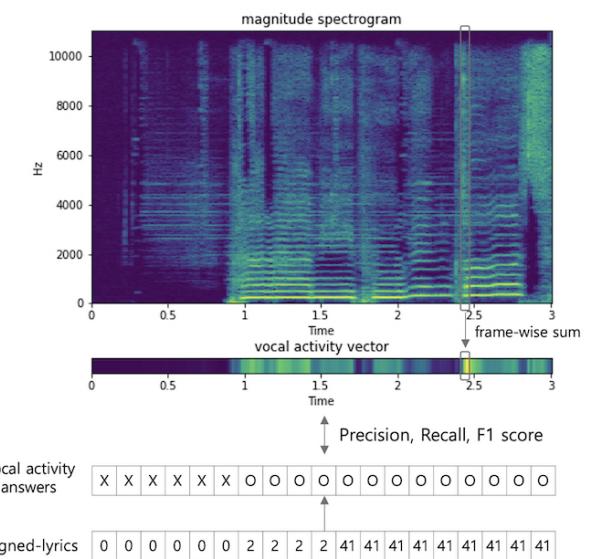
Models	Median			Mean		
	SDR	SIR	SAR	SDR	SIR	SAR
model 1	9.956	18.674	9.847	8.595	16.062	9.145
LC-model 2	10.140	18.465	9.766	8.589	16.001	9.093
LC-model 3	10.090	18.713	9.763	9.250	16.298	9.153
LC-model 4	**10.767**	19.505	10.223	9.723	17.116	9.699
CC-model 2	10.110	18.434	9.909	8.691	16.164	9.207
CC-model 3	10.444	19.328	10.169	9.718	17.031	9.609
CC-model 4	10.757	**19.623**	**10.371**	**9.752**	**17.250**	**9.803**


Table 3: Evaluation scores of our singing voice separation models. All scores are in [dB] scale.

Figure 5: The examples of the mixture, ground truth vocal, separated vocal spectrograms of baseline *model 1* and *CC-model 4*.

Figure 6: The example of making the vocal activity vector from the separated vocal spectrogram.

Despite the expectation that the vocal activity information is powerful information to the networks, performance gains observed in *LC-model 3* were very slight. It was much smaller than the improvements achieved from *CC-model 3*. By these, we analyzed that the concatenation method is slightly better for making the networks to reflect the vocal activity information. Nevertheless, we considered that both conditioning methods were effective when giving the networks aligned lyrics information.

5.2 Analysis of Vocal Activity Information Usage

In this section, we quantitatively assessed how well the networks leverage vocal activity information of aligned lyrics. The purpose of this is to see if the models have not been trained by focusing only on either one of the vocal activity information or the phonetic information of aligned lyrics, which are both critical for the separation performance.

To this end, the separated spectrogram values were divided by the largest values of each source for normalization, so that the minimum and maximum values become 0 and 1. Then, the energy of each time axis was summed to

create a vector that contains vocal activity information. It was decided whether vocal activity exists or not based on whether the values were larger or smaller than 0.1 as was done in [15]. Precision, recall, and F1 scores were calculated with the created vocal activity vectors by taking the place where the lyric exists as the ground-truth voiced sections. Scores are contained in Table 4.

From the results of Table 4, we have confirmed that *model 4* can separate the vocal source by reflecting the vocal's timing information more accurately than *model 1* for both lyrics conditioning methods. Also, it was confirmed that *model 3* achieved higher scores for all measures than *model 4*. This is a reasonable result because *model 3* were trained with vocal activity information only, while *model4* needed to learn how to leverage both vocal activity information and phonetic information appropriately while training. Nevertheless, F1 score differences were negligible, which means *model 4* was also capable of reflecting timing information as well as *model 3*.

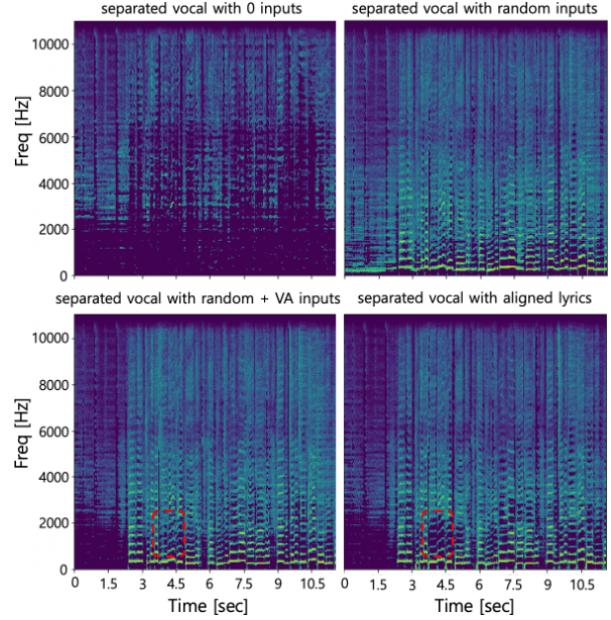
5.3 Analysis with Using Incorrect Lyrics

To check if *model 4* effectively uses the information in lyrics, we observed the performance change when incor-

Models	Precision	Recall	F1 score
model 1	0.807	0.853	0.828
LC-model 2	0.810	0.852	0.830
LC-model 3	0.887	**0.857**	0.872
LC-model 4	0.876	0.854	0.865
CC-model 2	0.814	0.853	0.833
CC-model 3	**0.896**	0.855	**0.875**
CC-model 4	0.879	0.855	0.867

Table 4: The precision, recall, and F1 scores to evaluate how well the networks used the vocal activity information from aligned lyrics.

Models	Inputs	SDR	SIR	SAR
LC-model 4	Zero	0.001	8.040	-4.286
	Random	5.317	15.802	4.845
	VA+Random	7.899	19.270	6.403
	AlignedLyrics	**10.767**	19.505	10.223
CC-model 4	Zero	0.002	7.246	-3.671
	Random	0.946	14.837	0.341
	VA+Random	7.164	19.545	6.290
	AlignedLyrics	10.757	**19.623**	**10.371**

Table 5: Performance comparisons when different inputs are given in the evaluation stage. `Zero` : 0 value inputs. `Random` : Random value inputs. `VA+Random` : Replace voiced sections with random value. `AlignedLyrics` : Aligned lyrics (The proposed method). All scores are in [dB] scale.


rect lyrics were given as input during the evaluation stage. The results are shown in Table 5.

If the networks had learned to effectively use the information in lyrics it is expected to output silence when the lyrics meaning unvoiced sections are given in the evaluation step. To validate this assumption, we inserted 0 values (`Zero`) to the lyrics encoder in to *model 4* in the evaluation step. As expected, almost every sound has been erased from the mixture with only a little noise left as seen in Figure 7 and critical performance degradation, over 10 dB in SDR score, has occurred.

Furthermore, performance degradation was observed when all the lyrics were replaced with random values (`Random`). This also shows that the network is significantly dependent on the encoded lyrics information and the proposed conditioning method is effectively applied.

Next, we experimented to see if the network is able to use the phonetic information included in the lyrics. We show this by removing all the phonetic information from the aligned lyrics. In other words, the changed lyrics still contain the vocal activity information. More specifically, it was done by replacing all the voiced sections with random values and leaving the unvoiced sections intact (`VA+Random`). Interestingly, the performance was still far below than the model trained tested on aligned lyrics, which indicates that the network can reflect the phonetic information into the separation process.

It is noteworthy that the SIR scores of `VA+Random`

Figure 7: The examples of the separated vocal spectrograms with incorrect inputs and correct aligned lyrics inputs were given to *LC-model 4*. The dashed line shows the enhanced parts when the aligned lyrics are used. Note that the region is closely related to the formant frequencies.

are not much different from the aligned lyrics input (`AlignedLyrics`). Since SIR scores are heavily related to the remained accompaniment sources of the separated singing voice, we expected that the networks were still capable of removing the accompaniments only using the vocal activity information. On the other hand, the impact on SDR and SAR scores were significant. This implies that while the network was able to erase the accompaniment well by using vocal activity information only in unvoiced sections, it was able to remove the accompaniment better by using phonetic information in voiced sections.

In the experiments of using (`Random`) and (`VA+Random`) inputs, median values of 5 different experimental tries with different random seeds were taken.

6. CONCLUSION

In this study, we proposed an integrated framework of combining the lyrics encoder into the state-of-the-art *Open-unmix* separation network. Local conditioning and concatenation methods were shown to be able to effectively condition the aligned lyrics into the singing voice separation networks. Through various experiments, it was confirmed that the phonetic information of aligned lyrics can contribute to the performance improvements as well as the vocal activity information. We plan to use the unaligned lyrics for the singing voice separation for the future works.

SCORE FOLLOWING WITH HIDDEN TEMPO USING A SWITCHING STATE-SPACE MODEL

ABSTRACT

A score-following program traces the notes in a musical score during a performance. This capability is essential to many meaningful applications that synchronize audio with a score in an on-line fashion. Existing algorithms often stumble on certain difficult cases, one of which is piano music. This paper presents a new method to tackle such cases. The method treats tempo as a variable rather than a constant (with constraints), allowing the program to adapt to live performance variations. This is first expressed by a Kalman filter model at the note level, and then by an almost equivalent switching state-space model at the audio frame level. The latter contains both discrete and continuous hidden variables, and is computationally intractable. We show how certain reasonable approximations make the computation manageable. This new method is tested on a dataset of 50 piano excerpts. Compared with a previously established state-of-the-art algorithm, the new method shows more stable and accurate results: it reduces fatal score-following errors, and improves accuracy from 65.0% to 69.1%.

1. INTRODUCTION

The score-following problem involves building a computer program that can trace musical events in a given musical score during a live performance. This is called "on-line audio-to-score alignment", which constantly figures out the current position in the score while the performance is going on; the program can only access the audio received before the current moment. In contrast, *off*line audio-to-score alignments start the task *after* the performance is done, allowing the program to access the entire recording.

Score following enables a number of useful applications: a musical score page turner [1], automatic accompaniment systems [2], virtual scores designed to react to a live performance [3], real-time audio enhancement during a music performance, and even a computer tutor [4].

A typical score-following algorithm infers the score positions by evaluating the hypothesis paths through a state graph, each path representing a possible performance. From the Bayesian point of view, the evaluation criteria

for a path include two aspects: how much a hypothesis is consistent with the *prior model*, which represents the anticipation of the musical performance *before* observing any data, and how much the data support a hypothesis, which is called the *data model*. This paper focuses on improving the former aspect, which is essentially about timing—when a note appears and how long it lasts.

Many researchers have considered timing in their prior models. [5, 6] used a hidden semi-Markov model where the duration of each state represents a note length. Others chose to directly model the tempo as a latent variable: [7, 8] treated the tempo as a discrete variable, while [9–12] adopted continuous state-space models, and used particle filter to approximate the results. [13] developed a hybrid graphical model, and tested it by aligning orchestra music offline. [13] provides a jumping-off point for the proposed method here. Note that feature-based methods (e.g., DTW or DNN) are beyond the scope of this discussion.

Unfortunately, existing score-following algorithms can still stumble on some challenging cases, especially when the data model is not reliable; e.g., shared notes among neighboring chords, extended sound from previous chords by pedaling, and blurring effects caused by fast playing, as in piano music. This paper presents a new method aiming to improve the timing model—this aspect is especially meaningful in those challenging cases. In practice, we can assume that the tempo tends to be smooth: the tempo is steady most of the time, sometimes floating around slowly, but rarely jumps up and down abruptly. Therefore, the new method models the tempo as a continuous variable, and it is smooth. This allows the note lengths (or the local tempo) to adapt to the performance data. One of the most popular state-space models, the Kalman filter model, is suitable for tracking such a tempo variable (Section 3.1). It becomes a *switching* state-space model after changing the scope of time (Section 3.2). Section 4 shows how the increased computational complexity is manageable with approximations. This new method was tested on real piano performance data presented in Section 5.

2. REPRESENTING SCORE AND AUDIO

We can view the musical score in a "homophonic" way, representing the score as a sequence of chords, as in Figure 1. It enables polyphonic music to be linearly represented as the same fashion as in monophonic music—a sequence of chords, each chord associated with a score position.

Figure 1. "Homophonic" view of polyphonic music [14]. The left bar is the original score with two voices. The right bar is its "homophonic" view.

Figure 2. Dependency graph for the tempo and the onset.

The audio is sampled, and evenly segmented into frames, with some overlap between adjacent frames. Each frame is transformed into a Fourier spectrum [15]. The *data model* here defines the likelihood of observing the data spectrum given the chord index. Denote y as the spectrum of a frame, a vector $\{y_w\}$, $1 \leq w \leq W$. Denote the template (see [13]) of the kth chord as $q^k = \{q_w^k\}$, which sums to 1. The likelihood of observing the data y given the index k is:

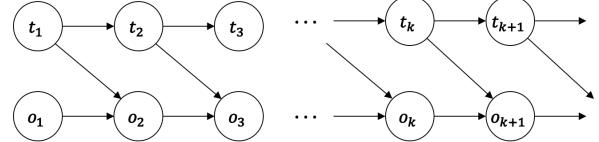
$$p(y|k) = \prod_{w=1}^{W} (q_w^k)^{y_w'} \tag{1}$$

where $y_w' = y_w / \sum_{w=1}^{W} y_w$.

3. THE MODEL

3.1 Kalman Filter Model for Tempo

The polyphonic score is represented as a sequence of chords, with a new chord appearing whenever any note is added, ended, or changed in the current chord. Let's assume there are K such chords in the musical score, each chord with a nominal musical length (e.g., 1/4 for a quarter note and 1 for a whole note) represented by l_k, $k = 1, \ldots, K$. We assume every chord has its own tempo value, and it doesn't change within a chord's lifetime. Let t_k be the tempo of the kth chord (seconds per whole note), and o_k be this chord's onset time (in seconds). The joint evolution of the tempo and the onset is modeled as a linear dynamical system. If we treat the onsets as observable data, the formula is the same as a Kalman filter model:

$$o_{k+1} = o_k + l_k t_k + \varepsilon_{k+1} \tag{2}$$
$$t_{k+1} = t_k + \eta_{k+1} \tag{3}$$


where all random variables have normal distributions:

$$o_1 \sim N(\mu_{o,1}, \sigma_{o,1}^2)$$
$$t_1 \sim N(\mu_{t,1}, \sigma_{t,1}^2)$$
$$\varepsilon_k \sim N(0, \sigma_{\varepsilon,k}^2), \ k = 2, \ldots, K$$
$$\eta_k \sim N(0, \sigma_{\eta,k}^2), \ k = 2, \ldots, K$$

The ε_k's and η_k's are all mutually independent, and they are independent from o_1 and t_1 as well. (In the experiments, however, $\sigma_{\varepsilon,k}$ was modified to be proportional to t_k, and $\sigma_{\eta,k}$ proportional to $l_k t_k$, with manually set scales.) The dependency graph is in Figure 2. In the rest of this paper, we refer to a "chord" as a "note" for simplicity's sake.

3.1.1 Marginal Likelihood of Onsets

This linear dynamical system can be viewed as a Markov process of generating the onsets, $o_1^K = (o_1, o_2, \ldots, o_K)$,

demonstrated as follows. According to the chain rule and the described model, we can write

$$p(o_1^K) = p(o_1) \prod_{k=1}^{K-1} p(o_{k+1}|o_1^k)$$

$$= p(o_1) \prod_{k=1}^{K-1} \int_{t_k} p(o_{k+1}|t_k, o_k) p(t_k|o_1^k) \, \mathrm{d}t_k$$

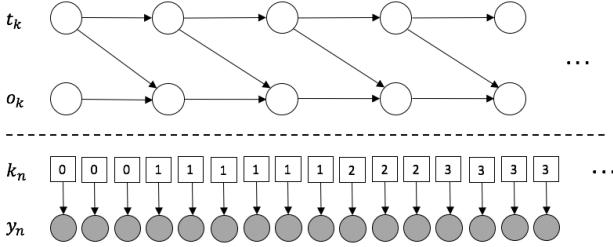
Because $o_{k+1} = o_k + l_k t_k + \varepsilon_{k+1}$, the integral factors can be further simplified as

$$\int_{t_k} N(o_{k+1}; o_k + l_k t_k, \sigma_{\varepsilon,k+1}^2) N(t_k; \mu_t(o_1^k), \sigma_t^2(o_1^k)) \, \mathrm{d}t_k$$

$$= N(o_{k+1}; o_k + l_k \mu_t(o_1^k), \sigma_{\varepsilon,k+1}^2 + l_k^2 \sigma_t^2(o_1^k))$$

where $\mu_t(o_1^k) = E(t_k|o_1^k)$ and $\sigma_t^2(o_1^k) = Var(t_k|o_1^k)$, which can be iteratively calculated using a Kalman filter as the system receives $o_1, o_2, \ldots, o_k$ [16]. Thus, we have

$$p(o_1^K) = \tag{4}$$
$$p(o_1) \prod_{k=1}^{K-1} N(o_{k+1}; o_k + l_k \mu_t(o_1^k), \sigma_{\varepsilon,k+1}^2 + l_k^2 \sigma_t^2(o_1^k))$$

which can be computed iteratively as k increases.


3.2 Frame-wise Representation

The discussions in Section 3.1 is based on the linear dynamical system at the note level, as in Figure 2 where the discretized "time step" is the note index. However, in real-world applications, the audio is received frame by frame (every 16 milliseconds in the experiments). In order to incorporate such audio frames as observed data, we have to change the scope and view the model in Figure 2 at the *frame* level, with each audio frame as a time step. Let's use n to denote the index of a frame, $n = 1, \ldots, N$, where N is the total number of frames in the audio. Any frame, n, has a label variable, $k_n \in \{0, \ldots, K\}$, which is the index of the sounding note at that frame. Frames before the first note being played are labeled as 0, i.e., $\{n : k_n = 0\}$. Denote y_n as the observed audio at the nth frame. We can assume the distribution of the audio frame data only depends on this frame's label—which note is being played. Figure 3 shows the model at both levels in the same graph.

The note onsets and the frame labels are nearly interchangeable. Let Δ be the time difference between adjacent frames (in milliseconds), a sequence of frame labels, k_1^n, can be recovered from a sequence of onsets, o_1^k, or vice versa, like this:

$$k_n = \min \left\{ k \in \{0, \ldots, K\} : n\Delta < o_{k+1} \right\} \tag{5}$$
$$o_k \approx \Delta \cdot \min \left\{ n \in \{1, \ldots, N\} : k_n = k \right\} \tag{6}$$

694

Figure 3. Dependency graph. Upper panel is note level; lower panel is frame level. Circles are continuous variables; squares are discrete. Observed variables are shaded.

The note-wise representation and the frame-wise representation are almost equivalent, except that there are two additional assumptions in the latter. First, the note onsets are now discrete because they have to be multiples of Δ, as in Equation 6. Second, a note must last at least one frame long, so $o_{k+1} - o_k \geq \Delta$. Because the labels and the onsets can be derived deterministically from each other as in the above two equations, the onsets can actually be viewed as "discrete" variables, and the tempo variables are the only real continuous (hidden) variables. Such state-space models that involve both discrete and continuous hidden variables are called *switching* state-space models [17].

3.2.1 Marginal Likelihood of Labels

This section describes a generative model for the frame labels, k_1^N, (almost) equivalent to the generative model in Section 3.1.1, but at the frame level. Using the chain rule, we have

$$p(k_1^N) = p(k_1) \prod_{n=1}^{N-1} p(k_{n+1}|k_1^n) \tag{7}$$

Following the assumptions in the frame-wise representation, there could be only two possible values for k_{n+1} in each factor $p(k_{n+1}|k_1^n)$: the same as k_n if it "decides" to stay at the current note, or $k_n + 1$ if it "decides" to move on to the next note. From Equation 4, we know that the onset of the pending note $k_n + 1$, given all previous onsets $o_1^{k_n}$ (equivalent to k_1^n), has a density function

$$p(o_{k_n+1}|o_1^{k_n}) = \tag{8}$$
$$N(o_{k_n+1}; o_{k_n} + l_{k_n}\mu_t(o_1^{k_n}), \sigma_{\varepsilon,k_n+1}^2 + l_{k_n}^2 \sigma_t^2(o_1^{k_n}))$$

Let's write ϕ as the standard normal density, and define

$$f(x) = \phi(\frac{x-\mu}{\sigma})$$

Then, the density in Equation 8 is $f(o_{k_n+1})$, where

$$\mu = o_{k_n} + l_{k_n}\mu_t(o_1^{k_n})$$
$$\sigma = \sqrt{\sigma_{\varepsilon,k_n+1}^2 + l_{k_n}^2 \sigma_t^2(o_1^{k_n})}$$

We can use this density function to compute $p(k_{n+1}|k_1^n)$ with two cases:

$$p(k_{n+1}|k_1^n) = \begin{cases} p_1, & k_{n+1} = k_n \ (same \ note) \\ 1 - p_1, & k_{n+1} = k_n + 1 \ (new \ note) \end{cases} \tag{9}$$

We can focus on calculating the first case, and the second case has the complimentary probability. In the first case where it stays in the same note at frame $n+1$, the information we know is that the onset of the next note will be *after* frame $n+1$, given we already know that the onset must be after frame n. Therefore, p_1 is a conditional probability:

$$p_1 = P(o_{k_n+1} > (n+1)\Delta \mid o_{k_n+1} > n\Delta, o_1^{k_n}) \tag{10}$$

Writing Φ as the cumulative distribution function of ϕ, we have

$$p_1 = \frac{1 - \Phi(\frac{c+\Delta-\mu}{\sigma})}{1 - \Phi(\frac{c-\mu}{\sigma})} \tag{11}$$

where $c = (n+1)\Delta$. Therefore, we can calculate the probability of any label sequence $p(k_1^N)$ iteratively as in Equation 7, by using Equation 9.

3.2.2 Note Duration and Note Age

In Equation 9, $p(k_{n+1}|k_1^n)$ is calculated based on $f(o_{k_n+1})$, the distribution of the onset for the pending note. In this section, we introduce two variables—note duration and note age—and calculate $p(k_{n+1}|k_1^n)$ from a slightly different perspective.

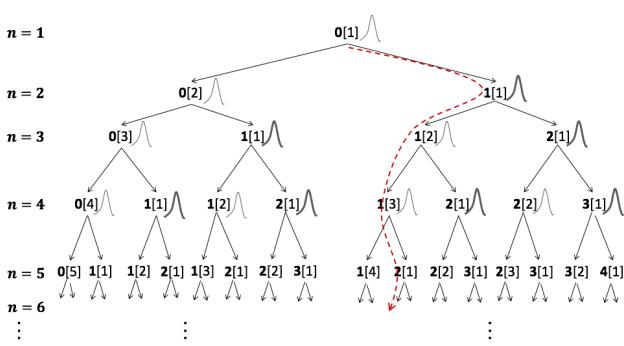
The duration of the kth note is the difference between its two adjacent onsets:

$$L_k = o_{k+1} - o_k = l_k t_k + \varepsilon_{k+1}$$

Given the previous onsets, L_k also has a Gaussian distribution with its mean as $l_k\mu_t(o_1^k)$ and its variance as $\sigma_{\varepsilon,k+1}^2 + l_k^2\sigma_t^2(o_1^k)$. In the frame-wise representation, a note's duration, L_{k_n}, has additional requirements that it should be multiples of Δ, and be at least Δ (milliseconds) long. Let's define a note's age as the number of frames this note has been through so far at the nth frame, denoted as a_n. The age of the note k_n can be calculated by

$$a_n = n - o_{k_n}/\Delta + 1$$

To get p_1 in Equation 9, we can rewite Equation 11 from the angle of the note length: given that this note has lasted a_n frames, what's the probability of it lasting for at least $a_n + 1$ frames. It can be expressed as

$$p_1 = P(L_{k_n} \geq (a_n+1)\Delta \mid L_{k_n} \geq a_n\Delta, o_1^{k_n})$$
$$= \frac{1 - \Phi(\frac{(a_n+1)\Delta-\mu}{\sigma})}{1 - \Phi(\frac{a_n\Delta-\mu}{\sigma})} \tag{12}$$


where $\mu = l_{k_n}\mu_t(o_1^{k_n})$ and $\sigma = \sqrt{\sigma_{\varepsilon,k_n+1}^2 + l_{k_n}^2\sigma_t^2(o_1^{k_n})}$.

4. COMPUTATION

The number of possible label sequences grows exponentially with n, as in the tree structure in Figure 4. This section discusses the computational aspects of the model: what is the filtered probability of the hidden variables, given all observed audio data up to the current frame; how to reasonably approximate the calculation so it is tractable.

4.1 Tree Representation

The tree in Figure 4 represents all possible label sequences, $\{k_1^N\}$. At any frame n, each node has a label for its note index, k_n, and also includes the age information of the note—the number of frames it has been through so far—denoted by a_n. From a label sequence k_1^n, we can thus determine the age sequence a_1^n, and vice versa. The tree includes the age variable because we need it in the generative model (see Equation 12). A node has two children: left means it stays in the same note and thus the age increases by one frame, and right means it moves on to the next note and thus the age resets to 1. Any node in the tree actually represents a label sequence by the path from the root to the node. For example, the dotted line in Figure 4 represents the label sequence of $k_1^6 = 011122$ (or the age sequence of $a_1^6 = 112312$). A path can be viewed as a sequence of decisions of choosing the left or right branch, from the root node at frame 1 to the end node in the path.

Figure 4. Exponential growth of label sequences. Each node has three aspects: note index label, age of this note (in square brackets), and distribution of the tempo. Tempo distributions at *onset* nodes are drawn with thicker lines.

For every node in the tree, denoted by its path of k_1^n, we can calculate two probabilities: the discrete probability of arriving at this node, $p(k_1^n)$, and the continuous probability distribution of the tempo at this node, $p(t_{k_n}|k_1^n)$. As discussed before, the tempo has a Gaussian distribution (drawn besides the nodes in the first four frames in Figure 4), given the path leading to this node. A Kalman filter keeps track of the tempo down the path, and updates its distribution when and only when the path chooses a right branch (drawn with thicker lines), i.e., whenever it observes a note onset (discussed in Section 3.1).

The probability of arriving at a node, $p(k_1^n)$, according to the frame-wise generative model, can be iteratively calculated by $p(k_1^n) = p(k_1^{n-1})p(k_n|k_1^{n-1})$. Thus, $p(k_1^n)$ can be calculated from two parts: the probability of arriving at its parent node, $p(k_1^{n-1})$, and the probability of choosing the left or the right branch when transitioning from frame $n-1$ to frame n, $p(k_n|k_1^{n-1})$. We can use either Equation 11 or Equation 12 to calculate the latter, and both equations require the distribution of the tempo at the parent node, $p(t_{k_{n-1}}|k_1^{n-1})$—or equivalently, $p(t_{k_{n-1}}|o_1^{k_{n-1}})$.

Adopting the iterative nature of the calculation, we can compute the probability of (arriving at) every node and its

tempo distribution, frame by frame starting from the root. Since the tree includes every possible label sequence, those probabilities give us $p(k_1^n)$ for all $\{k_1^n\}$, $n = 1, \ldots, N$.

4.2 Conditioning on data

This section continues to focus on calculating the probability of arriving at a node in the tree, but now *conditioned* on the observed audio data up to the current frame—$p(k_1^n|y_1^n)$. Considering y_1^n ensures that sequences more consistent with the observed data would receive higher probabilities than the rest, helping identify more likely sequences. On the other hand, the tempo will not be affected by the observed data since the tempo distribution at a node depends only on the corresponding label sequence, i.e., $p(t_{k_n}|k_1^n, y_1^n) = p(t_{k_n}|k_1^n)$, as used later in Equation 13.

The audio frame data $y_1, \ldots, y_n$ are assumed to be conditional independent from each other given the frame labels $k_1, \ldots, k_n$, so we can have

$$p(k_1^n|y_1^n) = \frac{1}{Z_n}p(k_1^n, y_1^n)$$
$$= \frac{1}{Z_n}p(k_1^n)p(y_1^n|k_1^n)$$
$$= \frac{1}{Z_n}p(k_1^n)\prod_{i=1}^{n}p(y_i|k_i)$$
$$Z_n = p(y_1^n) = \sum_{\{k_1^n\}}p(k_1^n, y_1^n)$$

The joint probability $p(k_1^n, y_1^n)$ can be calculated iteratively from $p(k_1^{n-1}, y_1^{n-1})$ by

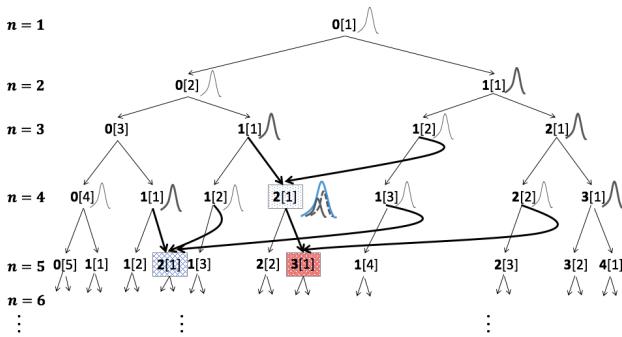
$$p(k_1^n, y_1^n) = p(k_1^{n-1}, y_1^{n-1})p(k_n|k_1^{n-1})p(y_n|k_n)$$

The calculation of the middle factor $p(k_n|k_1^{n-1})$ is discussed in Equations 9, 11, and 12, which involve using the tempo distribution of $p(t_{k_{n-1}}|k_1^{n-1})$. The third factor $p(y_n|k_n)$ is the data likelihood of the nth frame, discussed in Section 2. Therefore, we can calculate $p(k_1^n, y_1^n)$ for every node in the tree iteratively from frame 1 to frame N. To get the filtered probability of $p(k_1^n|y_1^n)$, we simply normalize $p(k_1^n, y_1^n)$ with Z_n at every frame. In sum, with the help of the data model factors $\prod_{i=1}^{n}p(y_i|k_i)$, we should be able to distinguish the sequences better by using $p(k_1^n|y_1^n)$ instead of $p(k_1^n)$: hypothesized sequences that are closer to the true sequence should have larger values of $p(k_1^n|y_1^n)$ than those of sequences further from the truth.

4.3 Filtering with Approximation

The task of filtering is to compute $p(k_n, t_{k_n}|y_1^n)$: the joint distribution of the last hidden states in the sequence, given the sequence of observed data so far. Writing $\mathcal{K}(k_n)$ as the set of all label sequences in Figure 4 that are n-label long and end with k_n, this filtered probability is:

$$p(k_n, t_{k_n}|y_1^n) = \sum_{k_1^n \in \mathcal{K}(k_n)}p(k_1^n, t_{k_n}|y_1^n)$$
$$= \sum_{k_1^n \in \mathcal{K}(k_n)}p(k_1^n|y_1^n)p(t_{k_n}|k_1^n) \quad (13)$$

This is a Gaussian mixture distribution with $|\mathcal{K}(k_n)|$ components. Without approximation, the computation is intractable because $|\mathcal{K}(k_n)|$ grows exponentially with n.


In Figure 4, there are duplicated nodes in terms of "label[age]" at every level (except for the first three levels), and these duplicates have the same subtree. The idea for simplifying the computation is to merge any duplicates at the same level into one node, as in Figure 5. The merged node then has the summed probability:

$$p(\text{merged node}) = \sum\nolimits_{\text{nodes}} p(\text{node}_i)$$

Each node in the frame-wise model also carries a Gaussian distribution for the tempo. The merged node would then carry a Gaussian mixture distribution:

$$p(t_{\text{merged}}) = \sum\nolimits_{\text{nodes}} \frac{p(\text{node}_i)}{p(\text{merged node})} p(t \mid \text{node}_i)$$

As more and more merging operations happen over time, the number of components in a tempo distribution grows exponentially, with each component corresponding with a possible label sequence, and the problem remains intractable. We can solve this by using *moment matching*: approximating a Gaussian mixture with a single Gaussian that has the same mean and variance as the mixture. This is proven to be the optimal approximation in the sense of Kullback-Leibler distance [18]. This approximation is reasonable if the components with larger weights are close to each other (agreeing with each other) in terms of mean and variance, and if those further away have smaller weights, thus could be ignored anyway. It's reasonable to believe that reality more often reflects this case, because unlikely nodes tend to have smaller probabilities and thus smaller weights in the mixture (thus should be ignored anyway), while more likely nodes tend to have more similar opinions about the tempo because they lean towards the truth.

Figure 5. Limiting tree growth by merging nodes with the same label and age. The first merge happens at frame #4, when the right child of 1[1] and the right child of 1[2] (at frame #3) merges into one node. This merged node's tempo has a Gaussian mixture distribution with two components from the two copies of the 2[1], and is approximated by a single Gaussian (thicker blue line). The two merges at frame #5 have similar approximations.

Under this strategy, it's guaranteed that a left child has no duplicates at a frame. All left children's ages are

at least two (frames), because they represent continuing notes. Merging nodes are always the right children of their parent nodes, and these nodes always have the age of 1. For nodes identified as $k_n[1]$ at frame n, their parent nodes must have the label of $k_n - 1$ and could have the age of 1, 2, $\ldots$, $n - k_n$ from frame $n - 1$. Therefore, there are $n - k_n$ copies of nodes $k_n[1]$ being merged together at frame n. It's worth noting that the size of the merging group, $n - k_n$, could be 1, which means there is no merging happening.

Distinguishing those two cases, we can iteratively approximate the discrete filtered probability of the label and the age, $p(k_n, a_n | y_1^n)$, and the continuous filtered probability of the tempo, $p(t_{k_n} | k_n, a_n, y_1^n)$. From previous discussions, we know that $p(t_{k_n} | k_n, a_n, y_1^n)$ is always a single Gaussian (after approximation), and we write its mean and variance as $\mu_n = \mu(k_n, a_n, y_1^n)$ and $\sigma_n^2 = \sigma^2(k_n, a_n, y_1^n)$.

The discrete and the continuous filtered probabilities can be iteratively calculated as follows in two cases. In the case where it stays in the same note, so $k_n = k_{n-1}$ and $a_n > 1$, there is only one parent node (without merging):

$$p(k_n, a_n | y_1^n) = \frac{1}{W_n} p(k_n, a_n, y_n | y_1^{n-1})$$
$$= \frac{1}{W_n} g(k_{n-1}, a_{n-1}, k_n, a_n, y_1^n) \quad (14)$$

$$g(k_{n-1}, a_{n-1}, k_n, a_n, y_1^n) = \quad (15)$$
$$p(k_{n-1}, a_{n-1} | y_1^{n-1}) p(k_n, a_n | k_{n-1}, a_{n-1}, y_1^{n-1}) p(y_n | k_n)$$
$$W_n = p(y_n | y_1^{n-1}) = \sum_{\{k_n, a_n\}} p(k_n, a_n, y_n | y_1^{n-1})$$

The middle factor in Equation 15 has been discussed in Equations 9 and 12, and the third factor is the data model. The filtered tempo in this case doesn't change, i.e.,

$$p(t_{k_n} | k_n, a_n, y_1^n) = p(t_{k_{n-1}} | k_{n-1}, a_{n-1}, y_1^{n-1}) \quad (16)$$

In the other case where it transitions to the next note, so $k_n = k_{n-1} + 1$ and $a_n = 1$, the only difference for the discrete filtered probability is that there is a merging process represented by the summation operation:

$$p(k_n, a_n | y_1^n) = \frac{1}{W_n} \sum_{\substack{1 \le a_{n-1} \\ \le n - k_n}} g(k_{n-1}, a_{n-1}, k_n, a_n, y_1^n) \quad (17)$$

The filtered tempo becomes a Gaussian mixture:

$$p(t_{k_n} | k_n, a_n, y_1^n) \quad (18)$$
$$= \frac{1}{p(k_n, a_n | y_1^n) W_n} \sum_{\substack{1 \le a_{n-1} \\ \le n - k_n}} g(k_{n-1}, a_{n-1}, k_n, a_n, y_1^n) \cdot$$
$$p(t_{k_n} | o_{k_n} = n, o_{k_{n-1}} = n - a_{n-1}, \mu_{n-1}, \sigma_{n-1}^2)$$

The last term can be calculated by the Kalman filter in Section 3.1. We further approximate the above Gaussian mixture using a single Gaussian with the mean as μ_n and the variance as σ_n^2. Putting Equations 14-18 together, we can iteratively calculate $p(k_n, a_n, t_{k_n} | y_1^n)$ by

$$p(k_n, a_n, t_{k_n} | y_1^n) = p(k_n, a_n | y_1^n) \, p(t_{k_n} | k_n, a_n, y_1^n)$$

5. PRELIMINARY EXPERIMENTS

5.1 Data Set

In score-following , the ground truth is the note onset times in the performance audio. This is usually difficult to obtain without tedious work of hand labeling or correction. One idea is to record the performances on pianos that capture movements of the keys, hammers and pedals, and store the information in MIDI files (e.g., *Disklavier* pianos). We can infer the note onsets from a MIDI file fairly easily. The MAESTRO data set by [19] contains such audio and MIDI data from 172 hours of piano performances from the International Piano-e-Competition [20].

The preliminary experiments contained 50 excerpts of real performances from 14 solo-piano pieces, as shown in Table 1. A typical excerpt lasted from 40 sec. to 90 sec., making the entire data set 48 min. of music. About 33 min. of it was from the MAESTRO, and the rest from the publicly available music recordings on the Internet. In the former case, we matched the performance MIDI data with the digital score according to the minimum-edit-distances criterion, with some minor manual corrections. For the latter case, we ran an offline audio-to-score algorithm which generated "close to perfect" results, and then manually corrected them. The audio data, along with a detailed description of the measures in these pieces are available at http://music.informatics.indiana.edu/papers/ismir20/.

Composer	Piece	#Excerpts
Mozart	Piano Concerto No. 17 in G major, mvmt1	3
Schumann	Piano Concerto in A minor, mvmt1	3

Haydn	Piano Sonata No. 24 in D major, mvmt2&3	3

Table 1. Piano music used in the experiments.

5.2 Evaluation Method

Write $\kappa_1, \ldots, \kappa_N$ as the ground truth index labels of all audio frames. At any frame, the probability of recognizing the truth note is then the sum of the filtered probabilities with the correct label (regardless of age), as in Equation 19. The overall accuracy on an excerpt is the average across all frames. This is called the *frame-wise accuracy* [14], accounting for the accuracy of every frame.

$$Acc_n = \sum_{\substack{k_n = \kappa_n \\ 1 \le a_n \le n - \kappa_n + 1}} p(k_n, a_n | y_1^n) \quad (19)$$

$$Acc = \sum_n Acc_n / N \quad (20)$$

5.3 Results

The baseline algorithm for comparison was Music Plus One [21], a state-of-the-art score-following systems, based on a hidden Markov model. Both algorithms used $8kHz$ sampling, 512-sample frame size (64 ms), and 128-sample hop size. Both algorithms also deployed the *beam search* technique to limit hypotheses at each frame to $\le$200.

Out of the 50 excerpts, 12 excerpts had "very low" accuracies ($< 40\%$) by at least one of the two algorithms. Very low accuracy can either exemplify a fatal error, in which the program got lost at certain frames, and never found its way back, or it can mean high uncertainty among neighboring chords. As shown in Table 2, the proposed method failed exactly two times fewer than the baseline, and it also had higher average accuracy among the failed excerpts.

	baseline	proposed
# failed excerpts	11	9
average accuracy	15.1%	22.1%

Table 2. Counts of low-accuracy excerpts.

Excluding those 12 excerpts, we calculated the average overall accuracy across all of the other 38 excerpts, as shown in Table 3. The proposed method achieved 4.1% higher accuracy than the baseline. A p-value of .0096 ($\alpha <$ .01) on a paired t-test indicates that the proposed method is measurably better than the baseline.

	baseline	proposed
average accuracy	65.0%	69.1%

Table 3. Average accuracies of 38 excerpts.

6. DISCUSSION AND CONCLUSION

Piano music is one of the most challenging cases in the score-following realm, as the preliminary experiments indicate: the baseline algorithm failed on 22% of excerpts. Further investigation suggests that the proposed method is more robust than the baseline: fewer fatal errors, easier recovery from mistakes, and successful following even when the performance tempo was far from the default tempo. With this evidence and significantly improved accuracy on successfully followed excerpts, we can speculate that treating the tempo as a variable helps the program adapt to unpredictable performance variations, and that modeling the tempo as smooth helps discriminate among hypotheses.

Although the dataset is not large enough to draw general conclusions, the preliminary experiments showed strong promise in the direction of tracking tempo while following a score. The presented method here is general and can be applied to a variety of instruments, monophonic or polyphonic. The tracked tempo information is also meaningful for anticipating the next note in automatic accompaniment systems, and is scalable to analyze the timing aspects of large numbers of performances.

In conclusion, this paper presents an interesting new method for improved score-following, and suggests a promising direction for future research endeavors.

ABSTRACT

Disentangling factors of variation aims to uncover latent variables that underlie the process of data generation. In this paper, we propose a framework that achieves unsupervised pitch and timbre disentanglement for isolated musical instrument sounds without relying on data annotations or pre-trained neural networks. Our framework, based on variational auto-encoders, takes as input a spectral frame, and encodes pitch and timbre as categorical and continuous variables, respectively. The input is then reconstructed by combining those variables. Under an unsupervised training setting, a major challenge is that encoders are tasked to capture factors of interest with distinct latent representations, without access to the corresponding ground-truth labels. We therefore introduce auxiliary tasks and objectives which leverage pitch shifting as a strategy to create surrogate labels, thereby encouraging the disentanglement of pitch and timbre. Through an ablation study we analyze the impact of the proposed objectives. The evaluation shows the efficacy of the proposed framework for learning disentangled representations, and verifies its applicability to unsupervised pitch classification and conditional spectral synthesis.

1. INTRODUCTION

The generative process from observed data can be described as having multiple latent factors of variation to explain the observations. For example, we may consider that a musical instrument sound consists of its pitch and timbre characteristic as the major underlying factors of variation. The concern of representation learning is to learn a model that captures such explanatory factors which are expected to be transferable to downstream tasks [1].

Disentanglement is said to be crucial for a good representation [1]. A disentangled representation allocates distinct factors of variation into separate dimensions of the representation, which facilitates an interpretable structure. Interventions along certain dimensions thereby only affect the corresponding latent factors, leading to a sparse change to the observation. In this paper, we propose a framework for learning disentangled representations of pitch and timbre, the two dominant factors of an isolated musical instrument sound. Unlike the supervised frameworks that address similar tasks [2, 3], we do not rely on data annotations or networks pre-trained on any form of supervision.

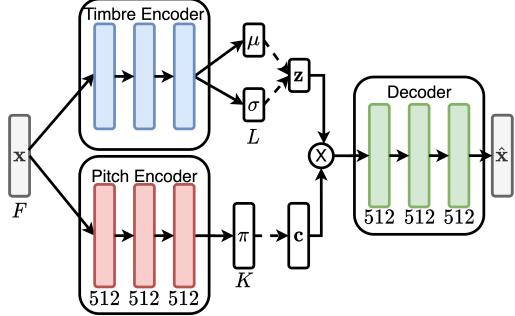
Many of the recent endeavors to achieve disentangled representation learning in an unsupervised setting are based on variational auto-encoders (VAEs) [4]. VAEs depict a data-generating process $p(\mathbf{x}, \mathbf{z}) = p(\mathbf{x}|\mathbf{z})p(\mathbf{z})$, where a multivariate latent variable $\mathbf{z}$ is first sampled from a prior distribution $p(\mathbf{z})$, and the observation $\mathbf{x}$ is sampled from the conditional distribution $p(\mathbf{x}|\mathbf{z})$ parameterized by a neural network; a variational distribution $q(\mathbf{z}|\mathbf{x})$, also parameterized using a neural network, is introduced to approximate the true posterior $p(\mathbf{z}|\mathbf{x})$.

In order to achieve disentanglement without access to data annotations, recent studies have proposed to impose regularizations on the latent space to promote a factorized aggregated posterior distribution $q(\mathbf{z})$ [5–7]. These works, however, demand further probes (e.g., traversal of latent space) to identify the semantics of the learned representations. One can also leverage prior knowledge of data structure and inject specific constraints [8–11]. For example, factors of variation of speech or video data are categorized as sequence-level (e.g., speakers) and segment-level (e.g., phonetic contents) latent variables [9, 10]. The mentioned prior knowledge, however, is not trivially applicable to factors of interest lacking of structural hierarchy (e.g., an isolated musical instrument sound with a constant pitch has both timbre and pitch as the sequence-level variable).

Given the challenge of disentangled representation learning in the unsupervised setting, literature has also assumed the accessibility to implicit or weak supervision in the form of grouped or paired data [12–14]. Our proposed framework, in contrast, does not require such a form of supervision; instead, we leverage pitch-shifting to create paired data, thereby introducing auxiliary objective functions to enhance feature disentanglement.

The underlying assumption of the proposed framework

is that a moderate shift of pitch does not alter the timbre of the original musical instrument sound; we can thereby consider the original and its pitch-shifted version as a pair, and introduce several constraints to promote disentanglement of pitch and timbre. In particular, we adapt the contrastive learning method [15] to our framework, and maximize the similarity measure of the paired data. We also employ cycle-consistency loss [16, 17] to further improve the disentanglement. Moreover, we propose an objective function that explicitly accommodates the information of pitch difference that arises from pitch-shifting [18], which plays a key role for performance improvement. An ablation study is conducted to evaluate the efficacy of the introduced objective functions.

We consider a generative process that samples a categorical and a continuous latent variable, referred to as pitch and timbre, respectively, and samples the data conditioned on both the variables. This manifests the discrete nature of pitch and introduces a strong inductive bias crucial to the success of unsupervised disentanglement [19], which is made feasible as each sample in this study corresponds to a pitch class in the equal tempered scale.


For evaluation, classifiers are built to predict ground-truth pitch and instrument labels, which take as input the learned timbre representation. The low accuracy for pitch, and the high accuracy for instrument indicate a disentangled timbre representation. We also evaluate the pitch latent variable in terms of the metrics used for clustering tasks, which demonstrates the model's capability of unsupervised pitch classification. Attributed to the interpretability of the disentangled representation, we can achieve pitch-conditioning spectral synthesis whereby disentanglement is evaluated through the lens of conditional generation. We also propose a metric that accounts for consistency and diversity of pitch of the generated data. Our main contributions can be summarized as follows:

- Propose a framework based on VAEs to tackle unsupervised disentanglement of pitch and timbre.

- Leverage pitch-shifting which enables the auxiliary objectives that further introduce inductive biases to improve disentanglement.

- Design a metric that accounts for pitch consistency and diversity which quantifies the performance of disentanglement.

We present the proposed framework and the auxiliary objective functions in Section 2, and detail the implementation along with the experimental setup in Section 3. The evaluation methods and the proposed metric are elaborated in Section 4, followed by experimental results and discussions in Section 5. The paper is concluded in Section 6.

2. METHOD

In this section, we describe the proposed framework, and present the auxiliary objective functions that are introduced to further enhance the model.

Figure 1: The proposed framework. The dashed lines denote sampling, and the cross denotes concatenation.

2.1 Overview

Figure 1 illustrates the proposed framework, which depicts a data-generating process of $\mathbf{x} \in \mathbb{R}^F$ being sampled from a conditional distribution $p_\theta(\mathbf{x}|\mathbf{z}, \mathbf{c})$, referred to as a decoder, where $\mathbf{c} \in \mathbb{R}^K$ is a categorical latent variable for pitch, and $\mathbf{z} \in \mathbb{R}^L$ is a continuous latent variable for timbre. θ denotes the parameters of the decoder. Variational distributions $q_\phi(\mathbf{c}|\mathbf{x})$ and $q_\phi(\mathbf{z}|\mathbf{x})$, referred to as the pitch and timbre encoder, are introduced to approximate the true posterior distributions. The parameters of the two encoders are collectively denoted as ϕ. Under the framework of variational inference, the generative model is optimized through the evidence lower bound (ELBO) of $p_\theta(\mathbf{x})$:

$$\mathcal{L}(\theta, \phi; \mathbf{x}) = \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})q_\phi(\mathbf{c}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z}, \mathbf{c})] \\ - \mathcal{D}_{\mathrm{KL}}\big(q_\phi(\mathbf{z}|\mathbf{x})\|p(\mathbf{z})\big) - \mathcal{D}_{\mathrm{KL}}\big(q_\phi(\mathbf{c}|\mathbf{x})\|p(\mathbf{c})\big). \tag{1}$$

For the continuous latent variable $\mathbf{z}$, we follow the literature [4] assuming $p(\mathbf{z}) = \mathcal{N}(0, I)$ and $q_\phi(\mathbf{z}|\mathbf{x}) = \mathcal{N}(\mu_\phi(\mathbf{x}), diag(\sigma_\phi^2(\mathbf{x})))$. For the categorical latent variable $\mathbf{c}$, we let $p(\mathbf{c}) = U(0, 1)$, a standard uniform distribution over number of categories K, and $q_\phi(\mathbf{c}|\mathbf{x}) = Cat(\mathbf{c}|\pi_\phi(\mathbf{x}))$. We can treat the pitch encoder as a pitch classifier that can be trained altogether with the entire network without pitch labels.

A major challenge for the unsupervised disentanglement is that the pitch encoder and timbre encoder are tasked to capture pitch and timbre features, respectively, without access to the corresponding labels. The presented model manifests the discrete nature of pitch with the categorical variable, thereby encouraging the pitch encoder to leave timbral information to the timbre encoder.

2.2 Gumbel-Softmax Distribution

In particular, we let $\mathbf{c}_k$ be a one-hot encoding of pitch, indexed at k, that is sampled from the $q_\phi(\mathbf{c}|\mathbf{x})$. To enable back-propagation through sampling of the discrete node, a common technique is to approximate $\arg\max$ with the Gumbel-Softmax distribution [20]. We specifically employ the straight-through estimator, which forward-passes the one-hot vector $\mathbf{c}_k$, and approximates its gradient with that of the Gumbel-Softmax distribution.

2.3 Auxiliary Objective Functions

Based on the underlying assumption that a moderate shift of pitch does not change the timbre of a musical instrument sound, we exploit pitch-shifting, thereby enabling the following auxiliary objective functions to enhance the model. We refer to $\mathbf{x}$ and $\mathbf{x}'$ respectively for the original sample and the pitch-shifted version throughout, and $(\mathbf{z}, \mathbf{c})$ and $(\mathbf{z}', \mathbf{c}')$ are the corresponding latent variables.

2.3.1 Latent Regression

One obvious auxiliary loss function enabled by pitch-shifting would be $\mathcal{L}_{\text{regression}} = \|\mathbf{z} - \mathbf{z}'\|_2^2$, which we include in the ablation study for comparison.

2.3.2 Contrastive Learning

We adapt SimCLR [15], a discriminative approach for representation learning [15, 21, 22], to our generative framework. Particularly, each sample in a minibatch of size N is pitch-shifted randomly upward or downward to a number of semitones, resulting in an augmented minibatch of size $2N$. A positive pair of data is defined as $(\mathbf{x}, \mathbf{x}')$, and the other $2(N-1)$ pairs are treated as negative ones, instead of being explicitly defined. The loss function for a positive pair, indexed as (i, j), is then defined as

$$\mathcal{L}_{i,j} = -\log \frac{\exp(\text{sim}(\mathbf{z}_i, \mathbf{z}_j)/\tau)}{\sum_{m=1}^{2N} 1_{[m \neq i]} \exp(\text{sim}(\mathbf{z}_i, \mathbf{z}_m)/\tau)}, \quad (2)$$

where $1_{[m \neq i]} \in \{0, 1\}$ is an indicator function evaluated as 1 if and only if $m \neq i$, and τ is a temperature parameter. The final loss $\mathcal{L}_{\text{contrast}}$ is obtained by aggregating $\mathcal{L}_{i,j}$ across all positive pairs. Following SimCLR [15], the cosine similarity is used as the similarity measure $\text{sim}(\cdot, \cdot)$.

Intuitively, the loss function attracts $\mathbf{z}$ and $\mathbf{z}'$ and repels the other negative pairs that are possibly derived from different instruments, which is expected to encourage the timbre encoder to extract pitch-invariant latent variables whereby the disentanglement is improved.

2.3.3 Cycle-consistency Loss

Cycle-consistency has been proposed to address unpaired image-to-image translation between different domains [16], which has been incorporated with VAEs to learn disentangled representations for images [17, 23].

We adopt the approach to further constrain the model and encourage disentanglement. Specifically, let E_p, E_t, and D denote the pitch encoder, the timbre encoder, and the decoder, respectively; whereby the cycle-consistency loss is defined as

$$\begin{aligned} \mathcal{L}_{cycle} =& \|E_t(D(\mathbf{z}, \mathbf{c}'_k)) - \mathbf{z}\|_2^2 + \|E_t(D(\mathbf{z}', \mathbf{c}_k)) - \mathbf{z}'\|_2^2 \\ &+ \text{CE}(E_p(D(\mathbf{z}, \mathbf{c}'_k)), k') + \text{CE}(E_p(D(\mathbf{z}', \mathbf{c}_k)), k), \end{aligned}$$
$$(3)$$

where $k = \arg\max_k q_\phi(\mathbf{c}|\mathbf{x})$ (similar for k'), and $\text{CE}(\cdot, \cdot)$ refers to cross-entropy loss.

Intuitively, given $(\mathbf{z}, \mathbf{c}'_k)$, D should generate a sample embodying timbre $\mathbf{z}$ and pitch category k', such that E_t and E_p can correctly predict $\mathbf{z}$ and k' in order to minimize

the loss (similar for $(\mathbf{z}', \mathbf{c}_k)$). The objective function is expected to enforce D to faithfully render the given conditioning signals, and to further encourage E_t and E_p to encode the respective factors. Empirically, we freeze the weights of E_t and E_p when back-propagating $\mathcal{L}_{cycle}$ as suggested in the literature [24].

2.3.4 Surrogate Label Loss

We also propose to exploit the information of the shifted amount of semitones. Specifically, we minimize $\mathcal{L}_{\text{surrogate}} = \text{CE}(E_p(\mathbf{x}'), y')$. The surrogate label for $\mathbf{x}'$ is $y' = k + \delta$, where $k = \arg\max_k q_\phi(\mathbf{c}|\mathbf{x})$, $\delta \in [-S, S]$ denotes the shifted number of semitones, and S is the maximum amount of shift. This enforces E_p to acknowledge the pitch difference. As shown in Section 5, this loss term plays a key role in reaching the best-performing model.

To sum up, based on the underlying assumption that moderate shift of pitch does not alter timbre characteristics, all the objective functions are made possible thanks to the pitch-shifting strategy. The aggregated objective function to be maximized thereby becomes

$$\begin{aligned} \mathcal{L} = \mathcal{L}(\theta, \phi; \mathbf{x}) - (&\lambda_1 \mathcal{L}_{\text{regression}} + \lambda_2 \mathcal{L}_{\text{contrast}} \\ &+ \lambda_3 \mathcal{L}_{\text{cycle}} + \lambda_4 \mathcal{L}_{\text{surrogate}}), \end{aligned} \quad (4)$$

where λ_1, λ_2, λ_3, and λ_4 denote the weights of each loss term. We conduct an ablation study to investigate the efficacy of each auxiliary objective in terms of the metrics elaborated in Section 4.

3. EXPERIMENTAL SETUP

In this section, we describe the dataset used to evaluate our framework along with the implementation details.

3.1 Dataset

We train the framework using a subset of Studio-On-Line (SOL) [25], which includes 1,885 samples of 12 musical instruments and 82 possible pitches. We resample all the recordings to 22,050Hz, after which they are converted to short-time Fourier transform (STFT) with a 92ms of Hann window and 11ms of hop size. Mel-spectrograms with 256 filterbanks are then derived from power magnitude spectrum of the STFT. The dataset is split into a training set (90%) and validation set (10%), both of which have a same distribution of instruments. The magnitude of the Mel-spectrogram is logarithmically scaled, and min-max normalized within $[-1, 1]$ using the minimum and maximum values in the training set. The normalization is performed corpus-wide to preserve the variety of dynamics.

As a preliminary study, we extract the spectral frame at 200ms from the processed spectrograms, a time instant that usually displays the sustained part of a musical note; a datum is therefore referred to as a spectrum $\mathbf{x} \in \mathbb{R}^{256}$ of a Mel-spectrogram. To facilitate the timbre encoder to extract pitch-invariant features, we further derive 30-dimensional Mel-frequency cepstral coefficients (MFCCs) from the Mel-spectrograms. Therefore, the inputs to the timbre and pitch encoder are $\mathbf{x}_{\text{MFCC}} \in \mathbb{R}^{30}$ and

$x_{\text{Mel-spec}} \in \mathbb{R}^{256}$, respectively. For convenience, we refer x to input data and do not distinguish x_{MFCC} and $x_{\text{Mel-spec}}$ in the text and Figure 1. Note that the reconstruction target for evaluating $p_\theta(x|z, c)$ remains as the Mel-spectrum.

As mentioned in Section 2, pitch-shifting is employed to augment the model by enabling the auxiliary objective functions. This is performed by stretching or shrinking an audio waveform with linear interpolation, which results in pitch-shifting in the frequency domain.

3.2 Implementation Details

Both the pitch and timbre encoders are comprised of three 512-unit fully-connected (FC) layers. They differ in the parametric layer; the pitch encoder outputs a categorical distribution $q_\phi(c|x)$ through a FC layer with number of units equal to $K = 82$, i.e., the number of possible pitches. We henceforth refer c to *pitch category*, which differentiates from the pitch labels y. The timbre encoder, on the other hand, contains a Gaussian parametric layer, which outputs two L-dimensional vectors, $L = 8$, representing mean $\mu_\phi(x)$ and variance $\sigma_\phi^2(x)$.

$c \sim q_\phi(c|x)$ and $z \sim q_\phi(z|x)$ are concatenated as the input to the decoder for reconstructing x. The straight-through Gumbel-Softmax estimator [20] and the reparameterization trick [4] enable gradients to back-propagate through the parametric layers with stochastic gradient descent. The decoder is also composed of three 512-unit FC layers, which finally outputs $\hat{x} \in \mathbb{R}^{256}$. Except for the two parametric layers, we use `tanh` as the activation function, and batch normalization follows thereafter.

All the experiments are conducted with a batch size of 256, and the model parameters are optimized using Adam [26] with a learning rate of 10^{-4}. The model stops training if the objective function (Equation (4)) does not improve over 300 epochs, i.e., we do not use any of the metrics presented in Section 4 as the stopping criteria, which assures absence of leakage of label information. We conduct an ablation study of the loss terms in Equation (4); however, we do not perform an exhaustive search for the corresponding weights, and instead evaluate $\lambda_i \in \{0, 1\}$ to investigate their effects. Fine-tuning the weights is left for future work.

4. EVALUATION METRICS

Our evaluation protocol relies on the properties of disentangled representations. From the synthesis point of view, the pitch of the synthesized spectrum should be invariant to perturbations in the timbre space as much as possible; from the perspective of analysis, the timbre space (pitch space) should mostly accommodate timbre information (pitch information) while minimizing clues for pitch (timbre). Accordingly, we consider the following metrics. Note that ground-truth annotations and pre-trained classifiers are employed only for evaluation purpose.

4.1 Classification Accuracy

We train logistic regression models which take as input the learned timbre latent variable z and predict labels of instrument and pitch. A well disentangled timbre representation should yield high accuracy for instrument, and low accuracy for pitch.

4.2 Clustering Accuracy (ACC)

During testing, the pitch encoder outputs a categorical distribution $q_\phi(c|x)$ from which a pitch category of x can be assigned as $k = \arg\max_k q_\phi(c|x)$. We can thereby consider it as a clustering task and calculate ACC [27] using pitch labels. Furthermore, since we do not train our model with pitch labels, the mapping from the inferred pitch categories to the pitch labels is unknown. For each category, we thus assign a pitch label that occurs the most within that category, and pitch classification accuracy can be calculated accordingly. This approximated pitch mapping is termed PM. Both ACC and PM are served to evaluate the unsupervised pitch classification.

4.3 Fréchet Inception Distance (FID)

We exploit FID [28] to quantitatively measure the quality of the synthesized spectrum. The metric measures the distributional difference between two multivariate Gaussians, which are fit to features derived from the real and generated samples, respectively. In our case, the features are extracted from a pre-trained instrument classifier, using the identical training data, which shares the same architecture with the encoder.

4.4 Consistency-Diversity Score (CDS)

In order to assess the model's capability of pitch-conditional generation, we propose a metric, termed CDS, to account for consistency of $p_k(y|\hat{x})$ and diversity of $\mathbb{E}_k[p_k(y|\hat{x})]$, where $p_k(y|\hat{x}) = p(y|D(z, c_k))$ is the posterior distribution of a pre-trained pitch classifier given the generated samples $\hat{x}$; and $\mathbb{E}_k[\cdot]$ denotes marginalization over k, where $k \in \{1, 2, \ldots, K\}$. Note that we can not simply measure pitch classification accuracy given the generated samples, as the true mapping from categories to pitch labels is unknown under the unsupervised setting.

Intuitively, the pre-trained pitch classifier should consistently output similar posterior distribution $p_k(y|\hat{x})$, if the generated samples $\hat{x}$ are synthesized conditioned on a fixed c_k regardless of z; and the aggregated distribution $\mathbb{E}_k[p_k(y|\hat{x})]$ should be uniformly distributed over y, which indicates that the generated samples $\hat{x}$, when conditioned on different c_k's, are predicted as having different pitches. Formally, CDS combines the two indicators as follows:

$$\begin{aligned} \text{CDS} &= -\mathbb{E}_k[H(p_k(y|\hat{x}))] + H(\mathbb{E}_k[p_k(y|\hat{x})]) \\ &= \mathbb{E}_k[\mathcal{D}_{\text{KL}}(p_k(y|\hat{x})\|\mathbb{E}_k[p_k(y|\hat{x})])], \end{aligned} \tag{5}$$

namely, the marginal KL-divergence of the per-category and the aggregated posterior. A higher CDS thus hinds toward better consistency and diversity of pitch manifested by the generated pitch-conditioning spectrum.

λ_1	λ_2	λ_3	λ_4		Pitch	Instrument	Combine	ACC	PM	$\text{FID}_{\text{recon}}$	FID_{rand}	CDS
				♭	8.81±3.47	87.68±1.09	89.43±1.85	95.14±0.98	96.04±0.71	21.80±1.05	23.78±1.47	24.33±0.71

1	1	1	1	M6	**14.57±2.29**	86.44±2.55	**85.93±2.06**	79.88±1.84	80.90±2.18	**13.76±1.07**	**19.18±1.90**	**13.46±1.64**

Table 1: The ablation study. For simplicity, we focus more on examining individual effects and do not exhaust all combinations. Each model (per row) is evaluated over all the evaluation metrics. For *Pitch* and *FID*, lower numbers indicate better performance, while the rest suggest the otherwise. The best-performing *unsupervised* models (♯, M0-M6) are highlighted.

Note that CDS bears resemblance to Inception Score (IS) [29]; the latter, however, was originally proposed to evaluate visual quality of synthetic images, whereas CDS evaluates the extent to which the model faithfully renders the conditional signal and enables correct classification.

5. EXPERIMENTS AND RESULTS

We train the framework with different configurations of the objective function $\mathcal{L}$ (Equation (4)), and quantify the performance of disentanglement with the metrics detailed in Section 4. For each model configuration, we initialize the model parameters with five random seeds, and report an averaged score along with standard deviation for each metric.

The results are summarized in Table 1, where we highlight the best-performing *unsupervised* models for each metric. Each row represents a model configuration; the symbol ♭ denotes the pitch-supervised model, which is trained to minimize an additional cross-entropy loss between the categorical distribution $q_\phi(\mathbf{c}|\mathbf{x})$ and the pitch labels, and is treated as a reference. The symbol ♯ denotes the unsupervised model trained without pitch-shifting. The rest M0-M6 are all unsupervised, utilizing pitch-shifting with maximum two semitones upward or downward.

For convenience, E_p, E_t, and D denote the pitch encoder, the timbre encoder, and the decoder, throughout.

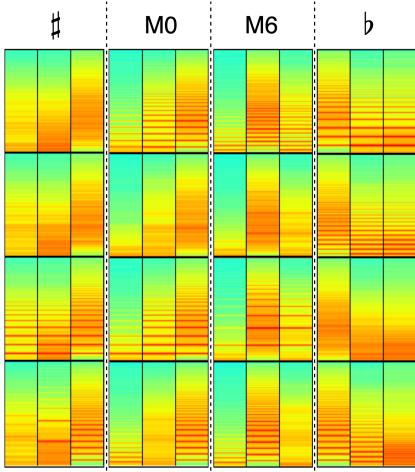
5.1 Timbre Space Classification

Using the learned timbre representation $\mathbf{z}$, which we replace with $\mu_\phi(\mathbf{x})$ (μ in Figure 1) as the input feature to the logistic regression models, we obtain a relatively low accuracy for pitch classification, and a high accuracy for instrument classification, as shown in columns *Pitch* and *Instrument* in Table 1. As mentioned previously, low and high accuracy of pitch and instrument, respectively, indicate disentanglement of the timbre representation; we thereby aggregate the two metrics by $\frac{1}{2}(1-a_{\text{pitch}}+a_{\text{instrument}})$ shown in column *Combine*, where a_{pitch} and $a_{\text{instrument}}$ are the classification accuracy.

The pitch-supervised (reference) model attains the best aggregated score, as E_p is explicitly trained to classify pitch, thereby preventing pitch leak to E_t. Among the proposed models, M6 outperforms in terms of the aggregated

score contributed by low a_{pitch}, which implies that combining all the auxiliary loss terms helps prevent pitch from leaking into the timbre space. Pitch-shifting alone improves the baseline unsupervised model significantly; this might be due to the rather imbalanced pitch distribution of the data. The high score attained without additional losses implies the efficacy of the proposed architectural design on disentangling pitch and timbre, given the augmented data.

Individually adding the auxiliary objective functions does not contribute much to the performance. For example, while M1-M4 degrade the aggregated score, combining M1-M3 (M5) approaches the best-performing model (M6). Notably, we can see that the proposed surrogate label loss further improves the performance of M5, which similarly applies to other metrics that follow.

5.2 Unsupervised Pitch Classification


As described in Section 4.2, we can consider E_p as a pitch classifier trained without labels as in our proposed models. We thus evaluate the performance with ACC.

We also report the pitch classification accuracy derived by the approximated mapping from pitch categories to pitch labels, which is the PM described in Section 4.2.

The supervised model can therefore be treated as the upper bound of pitch classification accuracy attained by the unsupervised E_p. M3 is the best model in terms of both ACC and PM, which could be attributed to the cycle-consistency that acknowledges the pitch-swapping scheme during training. This however promotes pitch leak to the timbre space as shown in column $Pitch$, which implies that an accurate E_p does not guarantee the absence of pitch leak, and, without supervision, more constraints are necessary to maintain both the pitch accuracy and timbre disentanglement, as demonstrated by M6.

5.3 Spectral Synthesis

We now turn our attention to the evaluation of generative tasks. In particular, we first evaluate the timbre representation by FID between the synthesized spectrum and the real one. To be more specific, the synthesized data are generated by D which takes as input $\mathbf{z}$ and $\mathbf{c}_k$, where $\mathbf{z} \sim p(\mathbf{z})$ and $k = \arg\max_k q_\phi(\mathbf{c}|\mathbf{x})$; that is, we first infer $\mathbf{c}_k$ of the

Figure 2: Pitch-conditioning spectrum generation. Each column represents a model, the bottom row refers to seed samples, and the top three rows correspond to generated samples conditioned on different pitch categories.

validation set, which is then combined with the randomly sampled **z** for decoding.

FID$_{recon}$ measures between the real and the reconstructed data, while FID$_{rand}$ is for the real and the synthesized data. FID$_{recon}$ can thus be treated as a lower bound of the metric. From Table 1, it is clear that M6 prevails. As discussed earlier, adding the proposed $\mathcal{L}_{surrogate}$ to M5 makes the best model in terms of FID.

Interestingly, the supervised model does not achieve satisfying performance, which implies that the discriminability gain of E_p does not correlate well with the generative quality of timbre features. This similarly applies to the model that employs only the contrastive loss (M2).

5.4 Pitch-Conditioning Synthesis

Next we evaluate the disentanglement through the lens of conditional generation. Particularly, we first infer $\mathbf{z} \sim q_\phi(\mathbf{z}|\mathbf{x})$ from the validation set, which we directly take the mean $\mu_\phi(\mathbf{x})$ as the representative latent variable. We then enumerate all possible pitch categories $k \in \{1, 2, ..., K\}$, each of which is converted to a one-hot vector and concatenated with the inferred **z**. D consumes the pitch-conditioned latent vector, and generates samples $\hat{\mathbf{x}}$ which are then classified by a pre-trained pitch classifier. This computes $p(\mathbf{y}|D(\mathbf{z}, \mathbf{c}_k))$, and CDS is derived by Equation (5). We report $\exp(\text{CDS})$ to restrict the value in $\{1, K\}$.

The supervised model performs well, due to the available pitch labels during training. M6 outperforms all the unsupervised models. Notably, $\mathcal{L}_{surrogate}$ alone (M4) outperforms M0, and, once again, the loss term further improves M5 to reach the best model M6.

The proposed $\mathcal{L}_{surrogate}$ synergizes with other loss terms, as evidenced by comparing M5 and M6 in terms of most metrics. This is probably attributed to the extra information from the amount of pitch-shift, which enables the model to explicitly account for the pitch difference [18].

Among all metrics, the t-test only yields a significant difference between the bold and M0 in terms of FID. Apart from the relatively high variances obtained by M0, this could be due to the small sample size (five random seeds) and the suboptimal configuration of values of loss weights, which we will investigate in future work.

5.5 Qualitative Study

We conclude our evaluation with a qualitative study on pitch-conditioning synthesis, as demonstrated in Figure 2. For each model (column), the bottom row refers to three reconstructed samples (with corresponding **z**'s) which are the seed spectrums sampled from the validation set. Each of the rest of the rows corresponds to generated samples conditioned on the same **z**'s but a different **c**.

As a result, for each model (column), a good performance is indicated by a matched harmonic pattern across all three frames in a row (consistency), and diverse harmonic patterns across the top three rows (diversity). Note that the seed samples (bottom row) and the three conditioning pitches are not fixed across the four models, thus a direct comparison is not available. Nonetheless, we can have a rough idea that model ♯ does not perform as well as others, as harmonic patterns do not clearly appear aligned except for the one at the third row. This to some extent verifies the proposed CDS, in terms of which model ♯ attains the worst performance, although a study of larger scale is required for a faithful verification.

We can also observe that the overall timbre, characterized by the spectral energy distribution, stays rather consistent along each frame of each column despite the change of the pitch condition, which verifies the disentanglement.

6. CONCLUSION AND FUTURE WORK

We have proposed a VAE-based framework for unsupervised learning of disentangled pitch and timbre representation. The framework accommodates a categorical and a continuous latent variable, with the former embodying the discrete nature of pitch. We exploit pitch-shifting which enables the auxiliary objective functions, that are shown to potentially enhance the performance in terms of the quantitative evaluation.

A major challenge for future research is to infer pitch values from the categorical assignment, without access to ground-truth annotations. Furthermore, the proposed model imposes a strong inductive bias to the pitch encoder, by restricting degree of freedom through a one-hot encoded categorical pitch variable. This might pose a challenge when a tuning difference among instruments is present in the dataset. Increasing the capacity of the pitch representation while maintaining enough constraints for disentanglement is a direction for future work. We also aim to train the framework on a larger and more structured dataset [30], and to evaluate the method on data with larger time scale, for which we aim to learn dynamical latent factors on top of the global variables that we have studied.

ABSTRACT

Machine learning is challenging the way we make music. Although research in deep generative models has dramatically improved the capability and fluency of music models, recent work has shown that it can be challenging for humans to partner with this new class of algorithms. In this paper, we present findings on what 13 musician/developer teams, a total of 61 users, needed when co-creating a song with AI, the challenges they faced, and how they leveraged and repurposed existing characteristics of AI to overcome some of these challenges. Many teams adopted modular approaches, such as independently running multiple smaller models that align with the musical building blocks of a song, before re-combining their results. As ML models are not easily steerable, teams also generated massive numbers of samples and curated them post-hoc, or used a range of strategies to direct the generation, or algorithmically ranked the samples. Ultimately, teams not only had to manage the "flare and focus" aspects of the creative process, but also juggle them with a parallel process of exploring and curating multiple ML models and outputs. These findings reflect a need to design machine learning-powered music interfaces that are more decomposable, steerable, interpretable, and adaptive, which in return will enable artists to more effectively explore how AI can extend their personal expression.

1. INTRODUCTION

Songwriters are increasingly experimenting with machine learning as a way to extend their personal expression [12]. For example, in the symbolic domain, the dance punk band Yacht used MusicVAE [59], a variational autoencoder type of neural network, to find melodies hidden in between songs by interpolating between the musical lines in their back catalog, commenting that *"it took risks maybe we aren't willing to"* [46]. In the audio domain, Holly Herndon uses neural networks trained on her own voice to produce a polyphonic choir. [15, 45]. In large part, these human-AI experiences were enabled by major advances in machine learning and deep generative models [18, 65, 67], many of which can now generate coherent pieces of long-form music [17, 29, 38, 54].

Although substantial research has focused on improving the algorithmic performance of these models, much less is known about what musicians actually need when songwriting with these sophisticated models. Even when composing short, two-bar counterpoints, it can be challenging for novice musicians to partner with a deep generative model: users desire greater agency, control, and sense of authorship vis-a-vis the AI during co-creation [44].

Recently, the dramatic diversification and proliferation of these models have opened up the possibility of leveraging a much wider range of model options, for the potential creation of more complex, multi-domain, and longer-form musical pieces. Beyond using a single model trained on music within a single genre, how might humans co-create with an open-ended set of deep generative models, in a complex task setting such as songwriting?

In this paper, we conduct an in-depth study of what people need when partnering with AI to make a song. Aside from the broad appeal and universal nature of songs, songwriting is a particularly compelling lens through which to study human-AI co-creation, because it typically involves creating and interleaving music in multiple mediums, including text (lyrics), music (melody, harmony, etc), and audio. This unique conglomeration of moving parts introduces unique challenges surrounding human-AI co-creation that are worthy of deeper investigation.

As a probe to understand and identify human-AI co-creation needs, we conducted a survey during a large-scale human-AI songwriting contest, in which 13 teams (61 participants) with mixed (musician-developer) skill sets were invited to create a 3-minute song, using whatever AI algorithms they preferred. Through an in-depth analysis of survey results, we present findings on what users needed when co-creating a song using AI, what challenges they faced when songwriting with AI, and what strategies they leveraged to overcome some of these challenges.

We discovered that, rather than using large, end-to-end models, teams almost always resorted to breaking down their musical goals into smaller components, leveraging a wide combination of smaller generative models and recombining them in complex ways to achieve their creative goals. Although some teams engaged in active co-creation with the model, many leveraged a more extreme, multi-

stage approach of first generating a voluminous quantity of musical snippets from models, before painstakingly curating them manually post-hoc. Ultimately, use of AI substantially changed how users iterate during the creative process, imposing a myriad of additional model-centric iteration loops and side tasks that needed to be executed alongside the creative process. Finally, we contribute recommendations for future AI music techniques to better place them in the music co-creativity context.

In sum, this paper makes the following contributions:

- A description of common patterns these teams used when songwriting with a diverse, open-ended set of deep generative models.

- An analysis of the key challenges people faced when attempting to express their songwriting goals through AI, and the strategies they used in an attempt to circumvent these AI limitations.

- Implications and recommendations for how to better design human-AI systems to empower users when songwriting with AI.

2. RELATED WORK

Recent advances in AI, especially in deep generative models, have renewed interested in how AI can support mixed-initiative creative interfaces [16] to fuel human-AI co-creation [27]. *Mixed initiative* [32] means designing interfaces where a human and an AI system can each "take the initiative" in making decisions. *Co-creative* [43] in this context means humans and AI working in partnership to produce novel content. For example, an AI might add to a user's drawing [20, 49], alternate writing sentences of a story with a human [14], or auto-complete missing parts of a user's music composition [4, 33, 37, 44].

Within the music domain, there has been a long history of using AI techniques to model music composition [22, 30, 52, 53], by assisting in composing counterpoint [21, 31], harmonizing melodies [13, 42, 50], more general infilling [28, 34, 40, 60], exploring more adventurous chord progressions [26, 36, 48], semantic controls to music and sound generation [11, 23, 35, 62], building new instruments through custom mappings [24], and enabling experimentation in all facets of symbolic and acoustic manipulation of the musical score and sound [3, 7].

More recently, a proliferation of modern deep learning techniques [8, 9] has enabled models capable of generating full scores [39], or producing music that is coherent to both local and distant regions of music [38, 54]. The popular song form has also been an active area of research to tackle modeling challenges such as hierarchical and multi-track generation [51, 56, 63, 69].

Despite significant progress in deep generative models for music-making, there has been relatively little research examining how humans interact with this new class of algorithms during co-creation. A recent study on this topic [44] found that deep learning model output can feel non-deterministic to end-users, making it difficult for users to steer the AI and express their creative goals. Recent

work has also found that users desire to retain a certain level of creative freedom when composing music with AI [25, 44, 64], and that semantically meaningful controls can significantly increase human sense of agency and creative authorship when co-creating with AI [44]. While much of prior work examines human needs in the context of co-creating with a single tool, we expand on this emerging body of literature by investigating how people assemble a broad and open-ended set of real-world models, data sets, and technology when songwriting with AI.

3. METHOD AND PARTICIPANTS

The research was conducted during the first three months of 2020, at the AI Song Contest organized by VPRO [66]. The contest was announced at ISMIR in November 2019, with an open call for participation. Teams were invited to create songs using any artificial intelligence technology of their choice. The songs were required to be under 3 minutes long, with the final output being an audio file of the song. At the end, participants reflected on their experience by completing a survey. Researchers obtained consent from teams to use the survey data in publications. The survey consisted of questions to probe how teams used AI in their creative process:

- How did teams decide which aspects of the song to use AI and which to be composed by musicians by hand? What were the trade-offs?

- How did teams develop their AI system? How did teams incorporate their AI system into their workflow and generated material into their song?

In total, 13 teams (61 people) participated in the study. The teams ranged in size from 2 to 15 (median=4). Nearly three fourths of the teams had 1 to 2 experienced musicians. A majority of teams had members with a dual background in music and technology: 5 teams had 3 to 6 members each with this background, and 3 teams had 1 to 2 members. We conducted an inductive thematic analysis [2, 5, 6] on the survey results to identify and better understand patterns and themes found in the teams' survey responses. One researcher reviewed the survey data, identifying important sections of text, and two researchers collaboratively examined relationships between these sections, iteratively converging on a set of themes.

4. HOW DID TEAMS CO-CREATE WITH AI?

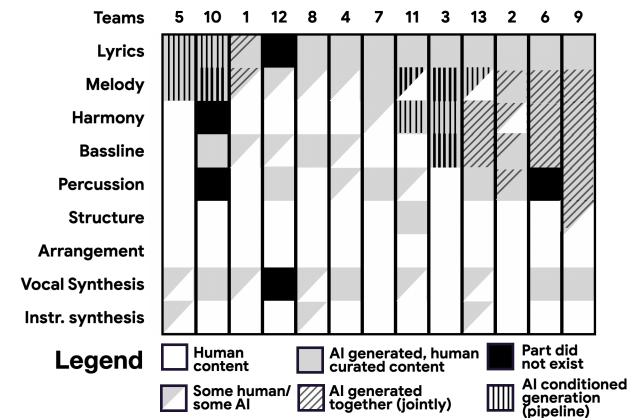
The vast majority of teams broke down song composition into smaller modules, using multiple smaller models that align with the musical building blocks of a song, before combining their results: *"So my workflow was to build the song, section by section, instrument by instrument, to assemble the generated notes within each section to form a coherent whole"* (T12). A few teams first attempted to use end-to-end models to generate the whole song at once, such as through adversarial learning from a corpus of pop song audio files (T6) or through generating an audio track using SampleRNN [47] (T13). However, they

Music building blocks	Models & techniques
Lyrics	GPT2, LSTM, Transformer
Melody	CharRNN, SampleRNN, LSTM + CNN, WaveNet + LSTM, GAN, Markov model
Harmony	LSTM, RNN autoencoder, GAN, Markov model
Bassline	LSTM + CNN, WaveNet + LSTM, GAN
Drums	DrumRNN, Neural Drum Machine, SampleRNN, Markov model
Multi-part	MusicVAE trio (melody, bass, drums), MiniVAE trio, Coconet/Coucou (4-part counterpoint), MusicAutobot (melody, accompaniment), Transformer (full arrangement)
Structure	Markov model
Vocal synthesis	WaveNet, SampleRNN, Vocaloid, Sinsy, Mellotron, Emvoice, Vocaloid, custom vocal assistant
Instrument synthesis	SampleRNN, WaveGAN, DDSP

Table 1. Overview of musical building blocks used by teams.

quickly learned that they were unable to control the model or produce professional quality songs, and thus turned to the modular approach instead. In the following sections, we summarize how teams used modular building blocks, combined and curated them, and in some cases more actively co-created with AI to iterate on the outcomes.

4.1 Leveraging modular musical building blocks

Overall, teams leveraged a wide range of models for musical components such as lyrics, (vocal) melody, harmony, bassline, drums, arrangement, and vocal and instrument synthesis. Table 1 shows an overview of models used for each song component, and Figure 1 illustrates how the 13 teams co-created with AI along these different components. The number of unique model types used by teams ranged from 1 to 6 (median 4). Some teams used the same type of model for modeling different song components.


All teams used AI to generate lyrics and melodies, and more than half of the teams synthesized vocals for parts of the song. Some of these decisions were due to model availability and existing levels of model performance. For example, teams almost always generated lyrics using AI because high-performing models like GPT-2 [55] along with a fine-tuning script were readily available.

Teams with professional musicians often chose to only generate lyrics and melodic lines, in order to leave enough creative space to musicians to decide how the various lines can be put together and to arrange the song in their own style (T5, 8). One exception is T3 who generated a lead sheet with lyrics, melody and harmony.

Teams with more ML and less music expertise opt for minimal arrangements (T10, 6, 9), and often used multi-part models because they could generate melody, harmony, bass, drums together in a coherent way, providing teams with larger building blocks to work with. In one extreme case, the team was able to generate all sections of their song by traversing the latent space of MusicVAE (T9) (see "Bridging sections through latents" below for more detail).

4.2 Combining building blocks

Teams leveraged many strategies for combining outputs of smaller models, piecing together the musical building

Figure 1. An overview of how 13 teams co-created with AI in songwriting. Each column shows whether each song's component was musician composed, AI generated then human curated, or both. Nearly all teams manually aligned AI generated *lyrics* and *melody*, except teams in the first three columns. T5 used a two-stage pipeline by first generating *lyrics* and *melody* separately, then algorithmically matching them up using their stress patterns. T10 first generated *lyrics*, and then conditioned on *lyrics* to generate *melody*. T1 jointly modeled *lyrics* and *melody*, generating syllables and notes in an interleaving fashion. T12, 8, 4, 7 all generated *melodic lines* first, and then manually **stitched** them together by layering them vertically as *melody* and *bassline* to yield *harmony*. In contrast, T11, 3 first generated *chords*, then conditioned on *chords* to generate *melody* (and *bassline* separately) in a **pipeline**. T13 iterated between conditioning on *melody* to jointly generate the other parts and vice versa. T2, 6 and 9 focused on models that could **jointly** generate multiple parts at once.

blocks to form a coherent song. These ranged from manually combining individual components, to using heuristics to automatically pair them up, to creating a pipeline between models, to adopting models that jointly model multiple components at once.

Stitching Many teams manually "stitched" together machine generated material, with the result informing the manual composition of other musical components. In

one team, a musician *"selected, tweaked, and weaved AI-generated melody, chords and drum parts into a ballad song form"*, while another musician wrote the bassline *"that seemed more or less implied by the AI materials"* (T7). This is echoed by another team, who composed the accompaniment *"based on chordal movements predicted by the melodic fragments"* (T5). Several teams layered melodic lines to yield harmony (T1, 12, 8, 4).

Pipelines Several teams leveraged model pipe-lining, feeding the output of one model into the input of another model. To generate melody that aligns well with lyrics, one team first used GPT-2 to generate lyrics, then a lyric-conditioned model to generate melody [68] (T10). One team decomposed melody generation into two steps, first using a LSTM to generate rhythm as note onset patterns, and then a CNN to assign a pitch to each onset (T8). While many teams "stitched" together melodic lines to create harmony, two teams first generated chords and then melody (and bassline) (T11 and T13). Pipeline approaches allowed teams to refine the output at each intermediate stage before passing content into the next model.

Joint modeling To generate multiple parts together, several teams adopted models such as MusicVAE trio [56], Coconet [34], MusicAutobot [61] or Transformers that are trained to jointly model multiple instrumental parts (T13, 2, 6, 9). One team experimented with jointly modeling notes and syllables from pairs of melodies and lyrics, but found it *"very hard to concurrently generate semantically meaningful lyrics and a melody that is not aimless"* (T1).

4.3 Generate then curate

A common approach was to generate a large quantity of musical samples, followed by automatically or manually curating them post-hoc. Teams took a range of approaches to curating the large quantity of results, ranging from brute-force manual curation, to a two-stage process of first filtering with AI, then curating manually.

Generation Often, teams used models to generate a large volume of samples to choose from. For instance, one team used their pipeline LSTM + CNN model to generate over 450 melodies and basslines (T8). Another team generated 10K lines of death metal lyrics (T13).

Manual curation While curating, teams were often looking for the key musical themes or motifs to use for their song. For example, one team used MusicVAE to generate several combinations of lead, bass, and drums, and *"handpicked the most appealing"* version to serve as their verse (T2). Another team was looking for a small, catchy snippet or *"earworms"* to flesh out the music (T11).

Two-stage curation A few teams first used automated methods to narrow down the choices, before manually selecting what would fit best in their song. For example, one team used a *"catchiness"* classifier trained on rankings of songs to filter melodies before handing them to an artist (T8). Another team curated their generated material by first algorithmically matching up the stress patterns of lyrics and melodies to make sure the material could be more immediately useful (T5).

Several teams found the process of generating and curating painstaking, or similar to a difficult puzzle (T1). However, one team described this massive generation process as exhilarating, or like *"raging with the machines"* (T5). They most appreciated the unexpected surprises, and actively engaged with this firehose of raw, AI-generated material: *"We couldn't resist including as much of the good and quirky machine output as possible...makes it much less repetitive than much of the music we might produce as humans. We really enjoyed having this firehose of generative capability...its constantly moving nature"* (T5).

4.4 Active co-creation

Some teams co-created music with AI in a more blended manner, where the model outputs influenced human composing and vice versa, similar to how human musicians might work together to write a song.

A few teams used AI-generated output as an underlying foundation for composing on top of, such as improvising a melody over AI-generated chords: *"we played the chords, and all of us around the table hummed along until we got to a simple and catchy melody"* (T11). Others took the AI output as raw material generated in a predefined structure, and manually composed an underlying beat (T8).

Others took AI output as an initial seed for inspiration and further elaboration. For example, one team trained SampleRNN on acappellas, which generated nonsensical output similar to babbling. A musician then tried to "transcribe" the words and the melody, and sang along with it. *"She found sections that sounded like lyrics. She wrote those lyrics down and sang them. She spent a day riffing on those lyrics, building a dialogue"*. These riffs and words fueled the formation of the larger story and song (T13).

For one participant, working with the AI was like jamming with another musician, an active back and forth process of priming the AI with chord progressions, hearing AI output, riffing on that output, then using those new ideas to seed the AI again (T12).

One team described making some deliberate decisions about how much agency to provide the AI vs. themselves as artists. To preserve the AI's content, an artist tried to only transpose and not "mute" any of the notes in two-bar AI-generated sequences, as he chose which ones to stitch together to align with lyrics. However, to bring the artist's own signature as a rapper, he decided to compose his own beat, and also improvise on top of the given melodies freely with a two-syllable word that was made up by ML (T8).

5. TEAMS OVERCOMING AI LIMITATIONS

In the previous section, we described the ways in which participants co-created with AI. Although teams made some headway by breaking down the composition process into smaller models and building blocks, we observed a wide range of deeper challenges when they attempted to control the co-creation process using this plethora of models. In this section, we describe participants' creative coping strategies given these challenges, and the strategies

they used to better direct the co-creation process.

5.1 ML is not directly steerable

Due to the stochastic nature of ML models, their output can be unpredictable. During song creation, teams leveraged a wide range of strategies in an attempt to influence model output, such as through data during fine-tuning, or through input or conditioning signals during generation. Below, we describe the most common patterns observed:

Fine-tuning   After experimenting with a model, many teams tried to influence the mood or style of the generated content by fine-tuning models on a smaller dataset. For example, teams fine-tuned GPT-2 with lyrics from uplifting pop songs to German death metal (T13), in order to steer the generation towards phrase structures more common in lyrics and also sub-phrases that reflect the desired sentiment and style.

Priming   While co-creating, teams often desired to create musical content in a particular key, chord, contour, or pitch range. To do so, many attempted to reverse engineer the process by priming the model's input sequence using music containing the desired property, in the hopes that it would produce a continuation with similar characteristics: *"I found that I could control the generation process by using different kinds of input. So if I wanted a sequence that is going upward, I would give that kind of input. If I wanted the model to play certain notes, I would add those notes in the input pattern"* (T12). This seemingly simple way of requesting for continuations led to a wide range of controls when used creatively.

To further direct content in lyrics, a team used specific words to start off each sentence (T5). Another team wondered *"can pop songs convey insightful messages with only two words?"*, and put together a verse with frequent bigrams from that dataset, such as *"my love"*, *"your heart"*. They entered this verse through the TalkToTransformer [41] web-app interface as context for GPT-2 to generate the next verses (T11).

Interpolating   Models such as MusicVAE provide a continuous latent space that supports interpolating between existing sequences to generate new sequences that bear features of both [58]. Some teams leveraged this latent space as a way to explore. For example, one participant found by chance that *"interpolating between really simple sequences at high temperatures would end up giving me these really cool baseline sequences"* (T12).

5.2 ML is not structure-aware

Because large, end-to-end models were not easily decomposable into meaningful musical structures, most teams used multiple smaller, independent models. Yet, these smaller, independent ML models are not able to take into account the holistic context of the song when generating local snippets. To address this, users created their own workarounds to fill in this contextual gap, by arranging and weaving these independent pieces into a coherent whole.

Creating an overall song structure   To create a backbone for the song, some teams used their musical knowledge to first curate chord progressions that can serve well for each song section (i.e. verse, chorus). One team then used a conditioned model (pretrained to be conditioned on chord progressions) to generate melody and basslines that would go well with those chords (T3).

Creating contrast between sections   The verse and chorus sections of a song often carry contrast. However, participants did not have a direct way to express this desire for structured contrast while preserving overall coherence between verse and chorus. To address this, one team used their verse as a starting point to generate various continuations to the melody and bass lines, and finally chose a variation for the chorus section (T2). Another team used similar priming approaches but used different temperatures to generate the verse and chorus in order to *"add some randomness into the generation"* (T12). These approaches gave users a way to manually create structured variety.

Rewriting to add variation   Rewriting allows one to generate new material while borrowing some structure from the original material. For example, one team was able to generate a *"darker version"* of the chorus of another song by rewriting it multiple times, alternating between regenerating the melody conditioned on the accompaniment, and then re-generating the accompaniment conditioned on the melody. To create a coherent song structure, the team initially attempted to *"repeat the same rave section twice"*, but later *"realized that was boring"*. The team then decided to vary how the second section ended by reharmonizing the melody with a new flavor: *"Coconet is great at reharmonizing melodies with a baroque flavor. We entered in the notes from our rave chorus. After a few tries, it made this awesome extended cadence"* (T13).

Bridging sections through latents   One team devised an unusual strategy for connecting different sections of a song in a meaningful way (T9). They first trained multiple miniVAEs [19], one for each section of the song (e.g. intro, verse, chorus or genre such as rock and pop). They then composed the song by computing the *"shortest path"* through these latent spaces, allowing the sections to share elements in common with each other, despite each being distinctive. The genre miniVAEs also made style transfer possible by interpolating an existing trio towards their latent areas, allowing them to tweak the style of each section.

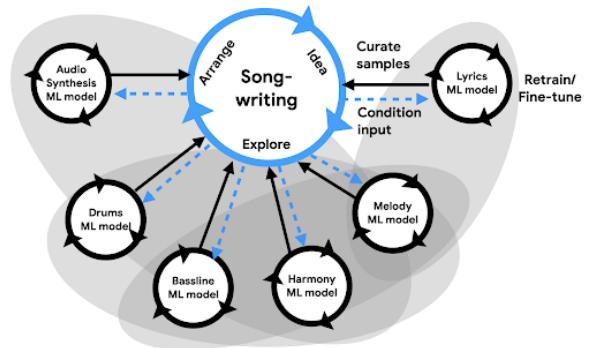
5.3 ML setup can interfere with musical goals

A logistical hurdle faced by teams was the significant setup and customization issues encountered to even start composing with a model. Aside from musical considerations, many teams chose or abandoned models based on what was available out-of-the-box, such as pre-trained checkpoints, fine-tuning scripts, scripts for retraining on a different dataset, data pre-processing scripts. In addition, different models expected different types of music representation as input (e.g. MIDI, piano roll, custom), adding additional pre-processing overhead to begin experimenting with them. To decrease time spent model wrangling, large teams sometimes divide-and-conquered, exploring several models in parallel to see which worked best. Ultimately,

teams' co-creation process involved navigating not only their musical goals, but also the logistical costs and benefits of using one model or another.

6. DISCUSSION

6.1 Decomposeable and context-aware modeling

Writing a song involves composing multiple sections, and multiple vocal and instrumental parts that all need to work well together as a whole. Because end-to-end models lacked meaningful hierarchical structures, and because smaller models lacked global awareness, participants often needed to reverse engineer a multitude of models, applying heuristics and domain knowledge to approximate high-level structure or to achieve desired musical effects. To ameliorate this process, one approach could be to infuse smaller models with more context-awareness, and exposing the common ways that they can be customized through user-facing controls. For example, a melody model could allow users to express whether they are creating a verse as opposed to a chorus, or whether they would like it to contrast with the next section. Another possibility is to design end-to-end models to have intermediate representations that align with the musical objects that musicians already know how to work with. The sweet spot is probably a hybrid that combines the flexibility of smaller models with the benefits of global context in end-to-end modeling.


6.2 AI-defined vs. User-defined building blocks

The design of ML models for music involves a series of upstream decisions that can have a large impact on how musicians think about music when they co-create with these models downstream. Whereas regular songwriting often starts with an initial spark of a human idea, in this work we found that the practical availability and limitations of AI tools were instead key drivers of the creative process, defining the scope of what's musically legitimate or possible. For example, most teams broke down songwriting into lyrics, melody, chords, etc., in part because these models were readily available. Yet, there are also other music building blocks that do not have corresponding, ready-made generative modsels (e.g. motif, verse, chorus, coda, etc.) or that currently are not treated as separate, first-class building blocks in deep models (e.g. rhythm, pitch). Likewise, a musician's creative thought process can be unintentionally influenced by the order of steps taken to fine-tune, condition, prime, and apply a model. In the future, the design of ML models should be coupled with a more careful consideration of what workflows and building blocks end-users already use in their existing practice, and perhaps start with those as first-class principles in guiding the design of AI systems.

6.3 Support for parallel music and ML exploration

A central aspect of the creative process involves a "flare and focus" [10] cycle of ideating, exploring those ideas, selecting ideas, then rapidly iterating. We found that a key

challenge of human-AI co-creation was the need to juggle not only this *creative* process, but also the *technological* processes imposed by the idiosyncrasies and lack of steerability of learning algorithms. For instance, while ideating motifs for a song, participants needed to carry out a large additional burden of sub-tasks, such as selecting which combination of models to use, re-training or conditioning them as necessary, chaining them together, and "gluing" their outputs together. In essence, the typical "flare and focus" cycles of creativity were compounded with a parallel cycle of having to first explore and curate a wide range of models and model outputs (Figure 2). While some of these model-wrangling tasks led to new inspiration, many interfered with the rapid-iteration cycle of creativity.

Figure 2. Parallel music and ML feedback loops in human-AI co-creative songwriting.

These issues raise important questions around how best to support users in juggling the dual processes of creative and technological iteration cycles. One approach is to have ML models readily available to musicians in their natural workflows. For example, Magenta Studio [57] makes available a suite of model plug-ins to music production software such as Ableton Live [1], and Cococo [44] allows users to semantically steer a model directly in its user interface. Beyond this, human-AI interfaces could scaffold the *strategic* part of the model exploration and selection process by surfacing effective model combinations (e.g. using general infilling models for rewriting or to reharmonize another generated melody) or fruitful workflows (e.g. matching lyric and melody stress patterns), so that new users can benefit from past users' experiences. Reducing this overhead of model-based decisions could empower users to more easily prototype their creative ideas, accelerating the feedback and ideation cycle.

7. CONCLUSION

We conducted an in-depth examination of how people leverage modern-day deep generative models to co-create songs with AI. We found that participants leveraged a wide range of workarounds and strategies to steer and assemble a conglomeration of models towards their creative goals. These findings have important implications for how human-AI systems can be better designed to support complex co-creation tasks like songwriting, paving the way towards more fruitful human-AI partnerships.

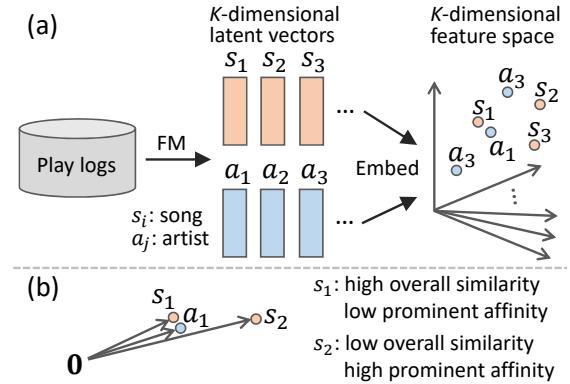
ANALYSIS OF SONG/ARTIST LATENT FEATURES AND ITS APPLICATION FOR SONG SEARCH

Kosetsu Tsukuda   **Masataka Goto**

National Institute of Advanced Industrial Science and Technology (AIST), Japan

`{k.tsukuda, m.goto}@aist.go.jp`

ABSTRACT


For recommending songs to a user, one effective approach is to represent artists and songs with latent vectors and predict the user's preference toward the songs. Although the latent vectors represent the characteristics of artists and songs well, they have typically been used only for computing the preference score. In this paper, we discuss how we can leverage these vectors for realizing applications that enable users to search for songs from new perspectives. To this end, by embedding song/artist vectors into the same feature space, we first propose two concepts of artist-song relationships: overall similarity and prominent affinity. Overall similarity is the degree to which the characteristics of a song are similar overall to the characteristics of the artist; while prominent affinity is the degree to which a song prominently represents the characteristics of the artist. By using Last.fm play logs for two years, we analyze the characteristics of the concepts. Moreover, based on the analysis results, we propose three applications for song search. Through case studies, we demonstrate that our proposed applications are beneficial for searching for songs according to the users' various search intents.

1. INTRODUCTION

Embedding songs into a feature space is beneficial for realizing various applications for music information retrieval (MIR). For example, by using tags of each song, songs can be embedded into a tag-based feature space [1]; this enables a user to search for similar songs of her favorite song. In another example, by embedding songs into the Arousal-Valence space [2] according to their audio features [3], a user can search for the song with the highest Arousal value from her favorite artist's songs. The same can be said for artists; by embedding artists into a feature space based on the topics of lyrics, artists similar to a user's favorite artist in terms of topic similarity can be retrieved [4].

Embedding heterogeneous data into a feature space is also useful for MIR tasks: song recommendations for playlists by embedding tags and songs [5, 6], computing tag similarity by embedding artists and tags [7], etc.

Figure 1. Overview of our proposed ideas: (a) embedding artists' latent vectors and songs' latent vectors into the same feature space and (b) concepts of overall similarity and prominent affinity.

In spite of the potential to embed heterogeneous data, there have been few studies that have embedded songs and artists [8]. If both songs and artists are embedded into the same feature space, greater variety of MIR applications can be realized. For example, given an artist, we can search for songs that have similar characteristics to those of the artist (i.e., songs whose feature vectors are close to the feature vector of the artist).

To realize this, we use Factorization Machines (FM) [9], which is an item recommendation technique. By using FM, each song, user, and artist can be represented by K-dimensional latent vectors. Although such vectors are usually used to compute a user's preference toward a song, we leverage the latent vectors of songs and artists to embed songs and artists into the same feature space (Fig. 1 (a)).

In the embedded feature space, we propose two concepts of artist-song relationships: overall similarity and prominent affinity. Suppose the vector's direction of artist a_1 in Fig. 1 (b) represents the sadness. The length of the vector indicates the degree of sadness. In this case, song s_1 has almost the same degree of sadness and s_1 is similar overall to a_1. On the other hand, song s_2 has a higher degree of sadness. This means that s_2 prominently represents a_1's characteristics and has a higher prominent affinity with a_1 in terms of sadness. We can recommend s_1 and s_2 to a user as a_1's characteristic songs because of the high overall similarity and the high prominent affinity, respectively. Such a recommendation would be useful when the user listens to one of a_1's songs for the first time because she can decide whether to listen to a's other songs after listening to a characteristic song of a_1. By using these concepts, we can realize not only such song recommendations

but also various applications for MIR, as in Section 5.

Our main contributions in this paper are as follows.

- We propose the concepts of overall similarity and prominent affinity between an artist and a song by leveraging their latent vectors learned through FM (Section 3).

- By using Last.fm play logs for two years, we show various characteristics of overall similarity and prominent affinity. For example, we reveal that an artist's popular songs tend to have high prominent affinity with the artist (Section 4).

- We demonstrate that the concepts of overall similarity and prominent affinity can be used to realize various applications for MIR. Specifically, we show three applications: familiarity-oriented search, typicality-oriented search, and analogy search (Section 5).

2. RELATED WORK

2.1 Matrix Factorization for Song Recommendations

Matrix Factorization (MF) [10] has been widely used for item recommendations. In the context of song recommendations, too, the effectiveness of MF has been reported [11–14]. One of the characteristics of MF for song recommendations is that each user and song are represented by K-dimensional latent vectors. This enables the model to learn a user's latent preference toward songs. Although MF typically considers interactions between users and songs, Factorization Machines (FM) [9] can include side information in addition to information about users and songs. Side information can be an artist, category of a song, and even the weather when a user listens to a song. Because of such flexibility, FM has also been used for song recommendations [15–18]. The idea of using artist information in FM for song recommendations has already been proposed [15, 16]; in this case, each user, song, and artist are represented by K-dimensional latent vectors.

Although such latent vectors in FM represent the characteristics of users, songs, and artists well, they have typically been used for computing a user's preference score toward a song and generating a personalized ranked list of songs for each user. Different from existing studies, we analyze latent vectors of songs and artists based on new relationships between artists and songs (overall similarity and prominent affinity) and show their potential to implement MIR applications.

2.2 Heterogeneous Embedding for MIR

The usefulness of embedding heterogeneous data into a feature space has been reported in various MIR tasks, where data has been embedded by a Markov-model-based method [5, 19], co-occurrence-based method [20], etc. For example, by embedding tags and songs, song recommendations for playlists have been realized [5, 6]. Other examples include computing tag similarity by embedding artists and tags [7], retrieving songs by words by embedding songs and words in playlist titles [20], and visualizing

the time-dependent listening preferences of a population by embedding users and songs [19]. Our study is different from theirs in that we embed artists and songs into a feature space.

The study closest to ours is that by Weston *et al.* [8]. They proposed a method for embedding artists and songs into a feature space and solved tasks such as predicting songs for a given artist and retrieving similar songs for a given song. To embed songs, their method requires audio data for all songs. In contrast, we use users' play logs. Although comparing the embedding accuracy of these two approaches is beyond the scope of this paper, our approach using play logs has an advantage over their approach in terms of the applicability of insights into the MIR community because various kinds of large play logs are easily accessible [21–27] compared to the accessibility of large audio data.

2.3 MIR Applications for Song Search

In the MIR community, various kinds of applications for song search have been proposed. These applications have enabled users to more easily find their desired songs and search for songs from a new perspective. For example, query by humming [28–34] and query by singing [35–38] enable users to search for songs even when they do not know the song title. Similarity-based song search is also beneficial for searching for new songs that are similar to a user's favorite song, where similarity between songs is measured by low-level acoustic features [39, 40], voice timbres of vocals [41], tags [1], and a combination of these characteristics [42]. When a user has a specific search intent, searching for songs using metadata [43,44] and words in lyrics [45] is also helpful to find her desired songs.

In this paper, we propose two concepts of artist-song relationships. These concepts can be used to search for an artist's characteristic songs, as we will show in Section 4.3. In addition, in Section 5, we demonstrate application examples that can be realized by leveraging these concepts and latent vectors of artists and songs. Our proposed applications are also helpful for searching for users' desired songs and new songs. We believe our study is beneficial for other researchers to implement MIR applications based on our proposed concepts.

3. OVERALL SIMILARITY AND PROMINENT AFFINITY

In this section, we first describe how to generate latent vectors of artists and songs through FM. We then propose the concepts of overall similarity and prominent affinity.

3.1 Notation

Let $\mathcal{U}$, $\mathcal{I}$, and $\mathcal{A}$ denote the sets of users, songs, and artists, respectively. $\mathcal{I}_u^+$ represents the set of songs preferred by user $u \in \mathcal{U}$. Following Lim *et al.* [46], we define the songs played $\geq \mu$ times by u as the preferred songs of u. By using the data, we first aim to accurately generate a per-

sonalized ranked list of songs for each user u from $\mathcal{I} \setminus \mathcal{I}_u^+$, which is a set of songs not included in u's preferred songs.

3.2 FM for Song Recommendation

FM [9] is a method for predicting a user's preference toward an item based on MF [10]. A typical MF deals with only interactions between users and items; while in FM, side information (e.g., the artist or category of a song) can also be included in the model. By considering artist information, we can extract new relationships between artists and songs, as we will describe in Section 3.3. Below, we describe FM considering artist information.

In FM, user u, song s, and artist a have K-dimensional latent vectors $\boldsymbol{\nu_u}$, $\boldsymbol{\nu_s}$, and $\boldsymbol{\nu_a}$, respectively. The preference score of user u toward song s based on the second-order estimator of FM is computed with the following model:

$$\widehat{x}_{us} = \alpha + \beta_u + \beta_s + \beta_{a_s} + \langle \boldsymbol{\nu_u}, \boldsymbol{\nu_s} \rangle + \langle \boldsymbol{\nu_u}, \boldsymbol{\nu_{a_s}} \rangle + \langle \boldsymbol{\nu_{a_s}}, \boldsymbol{\nu_s} \rangle,$$
(1)

where α is the global offset, a_s is the artist of s, and β_u, β_s, and β_{a_s} are the user/song/artist bias terms. As can be seen in the model, the preference score is computed by a user's affinity with a song ($\langle \boldsymbol{\nu_u}, \boldsymbol{\nu_s} \rangle$), user's affinity with an artist ($\langle \boldsymbol{\nu_u}, \boldsymbol{\nu_{a_s}} \rangle$), and artist's affinity with a song ($\langle \boldsymbol{\nu_{a_s}}, \boldsymbol{\nu_s} \rangle$). Regarding the last term $\langle \boldsymbol{\nu_{a_s}}, \boldsymbol{\nu_s} \rangle$, if artist a_s tends to sing calm songs and song s is also calm, the value of $\langle \boldsymbol{\nu_{a_s}}, \boldsymbol{\nu_s} \rangle$ becomes high; while if s is exciting music, the value becomes low. Note that because a song's popularity is reflected in β_s (i.e., more popular songs tend to have higher values of β_s), popular songs do not always have high values of $\langle \boldsymbol{\nu_{a_s}}, \boldsymbol{\nu_s} \rangle$. Rather, the value of $\langle \boldsymbol{\nu_{a_s}}, \boldsymbol{\nu_s} \rangle$ is determined purely by the affinity between a and s.

Note that although we use *simple* FM just by adding artist information, our goal in this paper is not to improve recommendation accuracy. Rather, we aim to study how to leverage latent vectors of songs and artists. Although this simple FM can learn reliable latent vectors because it can achieve high enough recommendation accuracy, as we will report in Section 4.2, we can adopt more sophisticated FM (e.g., FM considering song co-occurrence [47] and audio information [11]); we leave this for future work.

We adopt Bayesian Personalized Ranking (BPR) [48] to learn latent vectors. BPR is a pairwise ranking optimization framework and is designed to deal with users' implicit consumption behaviors such as playing a song rather than explicit ones such as rating. In BPR, the training set $\mathcal{D}$ used for optimizing parameters is defined as follows:

$$\mathcal{D} = \{ (u, i, j) \mid u \in \mathcal{U} \wedge i \in \mathcal{I}_u^+ \wedge j \in \mathcal{I} \setminus \mathcal{I}_u^+ \}.$$

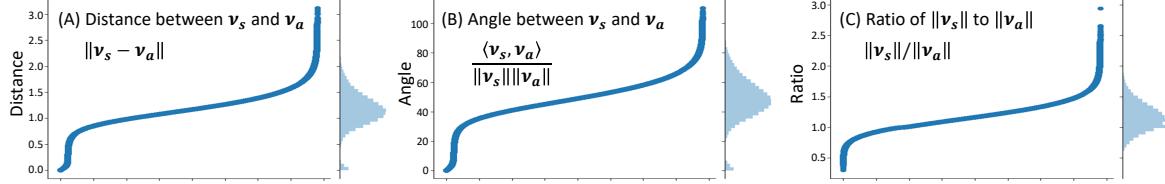
That is, a triad (u, i, j) means that user u prefers song i to song j. The optimization criterion for $\mathcal{D}$ is given by:

$$\sum_{(u,i,j) \in \mathcal{D}} \ln \sigma(\widehat{x}_{uij}) - \lambda_\Theta \|\Theta\|^2,$$
(2)

where σ is the sigmoid function, $\Theta = \{\beta_s, \beta_a, \boldsymbol{\nu_u}, \boldsymbol{\nu_s}, \boldsymbol{\nu_a}\}$ represents all model parameters, and λ_Θ is a regularization hyperparameter. $\widehat{x}_{uij}$ represents the difference between u's preference for i and that for j, which is defined as $\widehat{x}_{uij} = \widehat{x}_{ui} - \widehat{x}_{uj}$. Finally, we learn the parameters by using TensorFlow [49] with Adam optimizer [50].

3.3 Overall Similarity and Prominent Affinity

The learned model parameters are usually used for computing a user's preference score toward a song by using Eq. 1. In this paper, we propose using the learned model parameters (i.e., latent vectors) $\boldsymbol{\nu_a}$ and $\boldsymbol{\nu_s}$ for capturing the relationships between artists and their songs. In Eq. 1, because the affinity between $\boldsymbol{\nu_a}$ and $\boldsymbol{\nu_s}$ is considered, the nth ($1 \leq n \leq K$) dimension of $\boldsymbol{\nu_a}$ and that of $\boldsymbol{\nu_s}$ have the same meaning. For example, if the first dimension of $\boldsymbol{\nu_a}$ represents the calmness, the first dimension of $\boldsymbol{\nu_s}$ also represents the calmness of the song. Hence, we can embed $\boldsymbol{\nu_a}$ and $\boldsymbol{\nu_s}$ into the same feature space, as shown in Fig. 1 (a). In the feature space, the angle and length of a vector represents its qualitative and quantitative aspects, respectively. Specifically, the difference of the angle between two vectors represents the difference of their characteristics as a song or artist because each dimension represents a characteristic of songs and artists. While the length of a vector represents the degree of its characteristics: if the value of $\boldsymbol{\nu_s}$'s nth dimension is large, $\boldsymbol{\nu_s}$ represents nth characteristic well. By using the embedded feature space, we propose two concepts of the relationships between artists and songs: overall similarity and prominent affinity.

3.3.1 Overall Similarity


Suppose artist a_1's song s_1 is mapped fairly close to a_1 in the feature space, as shown in Fig. 1 (b). In this case, we can say that s_1 is similar overall to a_1. Thus, we define the closeness between an artist and a song in the feature space as the overall similarity between them. More formally, given artist a and song s, the overall similarity between a and s is computed based on the Euclidean distance between them: $f_{os}(a, s) = \frac{1}{\|\boldsymbol{\nu_a} - \boldsymbol{\nu_s}\| + 1}$.

The concept of overall similarity can be used to search for an artist's song that represents the artist's characteristics well. Searching for such a song and listening to it is useful to quickly understand the artist's characteristic songs. In particular, when a user listens to an artist's song for the first time, it might be helpful for her to listen to the artist's characteristic song and then decide if she wants to listen to the artist's other songs.

3.3.2 Prominent Affinity

Now suppose a_1's song s_2 is mapped fairly close to the extended position of a_1 as shown in Fig. 1 (b). This means that s_2 prominently represents a_1's characteristics because the degree of each characteristic of s_2 is higher than that of a_1. Thus, we define the inner product of an artist vector and a song vector as the prominent affinity between them. More formally, given artist a and a's song s, the prominent affinity between a and s is given by $f_{pa}(a, s) = \langle \boldsymbol{\nu_a}, \boldsymbol{\nu_s} \rangle$.

The concept of prominent affinity can be used to search for an artist's song that strongly represents the artist's characteristics. Similar to the overall similarity, searching for such a song would be helpful when a user listens to an artist's song for the first time.

Figure 2. Distributions of (A) distance between ν_s and ν_a, (B) angle between ν_s and ν_a, and (C) ratio of $\|\nu_s\|$ to $\|\nu_a\|$. Each dot represents a song where songs are sorted in ascending order of the y-values in each graph.

Number of users ($|\mathcal{U}|$)	84,708
Number of songs ($|\mathcal{I}|$)	390,158
Number of artists ($|\mathcal{A}|$)	32,448
Sum of preferred songs ($\sum_{u \in \mathcal{U}} |\mathcal{I}_u^+|$)	18,478,304

Table 1. Dataset statistics.

4. ANALYSIS

In this section, we analyze the characteristics of overall similarity (OS) and prominent affinity (PA).

4.1 Dataset

We use the LFM-1b dataset that includes music listening logs on Last.fm [21]. Each listening log consists of user ID, song ID, artist ID, and timestamp. The dataset also includes data for converting song ID and artist ID to song name and artist name, respectively. We use logs for two years (between 1/1/2012 and 12/31/2013). The μ in Section 3.1 is set to five, where μ is the threshold to determine that song s is included in $\mathcal{I}_u^+$ when u listens to s equal to or more than μ times. To increase the reliability of learned model parameters, songs and artists that have been listened to by less than 10 different users and users who have listened to less than 10 different songs are discarded. Table 1 shows the dataset statistics after the preprocessing.

4.2 Model Development

For each user, we split $\mathcal{I}_u^+$ into training/validation/test sets. To this end, we randomly select one preferred song (i.e., $i \in \mathcal{I}_u^+$) for validation $\mathcal{V}_u$ and another for testing $\mathcal{T}_u$ [51]. All the remaining songs are used for training $\mathcal{R}_u$. The recommendation performance is evaluated by the AUC (Area Under the ROC Curve), which is widely used to evaluate whether model parameters are appropriately learned [52, 53]: $AUC = \frac{1}{|\mathcal{U}|} \sum_{u \in \mathcal{U}} \frac{1}{|\mathcal{D}_u|} \sum_{(i,j) \in \mathcal{D}_u} \delta(\hat{x}_{ui} > \hat{x}_{uj})$, where $\mathcal{D}_u = \{(i,j) \mid i \in \mathcal{T}_u \land j \in \mathcal{I} \setminus \mathcal{I}_u^+\}$, and $\delta(z)$ is 1 when z is true and 0 otherwise. The AUC value ranges between 0 and 1, and a higher value represents better performance (i.e., the model parameters are appropriately learned). The hyperparameters (i.e., λ_Θ in Eq. 2 and the learning rate) are tuned on a validation set in terms of the AUC, where the hyperparameters are selected from {0.0001, 0.001, 0.01, 0.1, 1}. We set the latent dimensionality K to 50. [1] We emphasize that our goal here is not to evaluate the recommendation accuracy of FM by comparing with other methods. Rather, we aim to evaluate whether the parameters in FM developed by our dataset are

---

[1] We evaluated the AUC on the validation dataset by changing K from 10 to 100 in increments of 10. The AUC saturated when $K = 50$.

Rank	OS	PA
1	I'm So Tired	Something
2	Get Back	All You Need Is Love
3	The End	Come Together
4	Sun King	Hey Jude
5	Here Comes the Sun	I Am the Walrus
6	She's Leaving Home	Lucy in the Sky with Diamonds
7	Glass Onion	Eleanor Rigby
8	You Like Me Too Much	A Hard Day's Night
9	You Never Give Me Your Money	I Want to Hold Your Hand
10	The Night Before	Golden Slumbers

Rank	OS	PA
1	Minor Thing	Californication
2	Police Station	Scar Tissue
3	If	Dani California
4	Can't Stop	Snow (Hey Oh)
5	Fortune Faded	By the Way
6	Annie Wants a Baby	The Adventures of Rain Dance Maggie
7	Happiness Loves Company	The Zephyr Song
8	Brendan's Death Song	Brendan's Death Song
9	Give It Away	Torture Me
10	Emit Remmus	Dosed

Table 2. Ranking results of songs in terms of OS and PA (top: "The Beatles," bottom: "Red Hot Chili Peppers").

appropriately learned by showing that the AUC is close to 1 after the learning process.

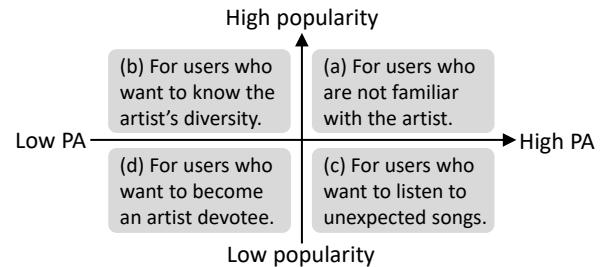
The AUC on the test set achieved a high value: 0.973. This result means that the model parameters and the embedded feature space are appropriately learned and the artist-song relations based on OS and PA are reliable. We also computed the Spearman rank correlation between the values of β_s and song popularities to evaluate if β_s correctly reflects song popularity, as mentioned in Section 3.2. The popularity of song s was measured by the number of different users who have played s. The popularity ranking of songs are obtained by sorting them in descending order of their popularities. For each artist, we compute the correlation between the popularities of the artist's all songs and their values of β_s. The average of the correlations over all artists was relatively high: 0.502. When we define the popularity of artist a as the number of different users who have played at least one of a's songs, the average of the correlations became high with increasing artist popularity: artists whose popularities are ≥ 100 and ≥ 300 had correlation values of 0.682 and 0.755 on average, respectively. From these results, we can say that the bias term β_s certainly reflects the song's popularity, and the value of $\langle \nu_{a_s}, \nu_s \rangle$ in Eq. 1 is determined mainly by the affinity between a_s and s especially for popular artists. Hereafter, the parameter values computed in this section are used for artist latent vectors and song latent vectors.

4.3 Analysis Results

Although we showed that the model parameters are appropriately learned, if most of an artist's songs are mapped

Rank	Area (a)	Area (b)	Area (c)	Area (d)
1	Gold on the Ceiling	Have Love Will Travel	Yearnin'	Can't Find My Mind
2	Lonely Boy	Same Old Thing	Keep Your Hands Off Her	Her Eyes Are A Blue Million Miles
3	Tighten Up	I Got Mine	Grown So Ugly	Howlin For You
4	Little Black Submarines	Run Right Back	Till I Get My Way	The Wicked Messenger
5	Everlasting Light	Your Touch	Just Got To Be	The Baddest Man Alive

Table 3. Ranking results of familiarity-oriented search for "The Black Keys" in terms of PA.

very close to the artist, it would be useless to rank songs according to the subtle difference of their positions. To confirm whether artists' songs are well distributed, we evaluate the distributions of (A) distance between ν_s and ν_a, (B) angle between ν_s and ν_a, and (C) ratio of $\|\nu_s\|$ to $\|\nu_a\|$. Fig. 2 shows the results. In all cases, the value distribution is close to the Gaussian distribution. These results indicate that songs are well distributed in the feature space and it is meaningful to rank songs according to OS, which is affected by (A), and PA, which is affected by (B) and (C).


Next, we analyze the ranked results of songs by OS/PA. Table 2 shows the top 10 songs of "The Beatles" and "Red Hot Chili Peppers." Since the top ranked songs are largely different between the two concepts, it would be meaningful to generate two ranked lists so that we can show one of them (or both of them) to a user according to her intent. We can also see that the top ranked songs in PA tend to be more popular than those in OS. To evaluate this, we compute the Spearman rank correlation between OS-based/PA-based song ranking and popularity-based song ranking. As expected, the correlation of PA-based ranking is high (0.577), while that of OS-based ranking is low (-0.147). As mentioned in Section 4.2, the effect of song popularity is eliminated by the bias terms β_s. Therefore, this high correlation of PA-based ranking is caused purely by the characteristics of the songs: songs strongly reflecting the artist's characteristics tend to be popular.

5. APPLICATIONS

In Section 4.3, we showed how to directly use the concepts of OS and PA to rank an artist's songs. In this section, by leveraging the concepts and learned parameters of ν_a and ν_s, we demonstrate three applications: familiarity-oriented search, typicality-oriented search, and analogy search. Through these demonstrations, we show that this paper brings reusable insights in that our proposed concepts can be used for various kinds of MIR applications.

5.1 Familiarity-oriented Search

By considering PA and song popularity, an application to search for songs according to a user's familiarity with an artist can be realized. As we mentioned in Section 4.3, songs with a high PA tend to be popular, but some of them are unpopular. Similarly, some popular songs have a low PA. Hence, according to the degree of PA and the degree of popularity, an artist's songs can be classified into four areas, as shown in Fig. 3. Searching for songs in area (a) would be beneficial especially for a user who listens to the artist's song for the first time because these songs are popular and represent the artist's typical characteristics well; she can decide if she wants to listen to the artist's other

Figure 3. Properties of songs classified by the degree of PA and the degree of popularity.

songs by listening to the searched songs. After listening to such songs, searching for songs in area (b) would be useful to let her understand the diversity of the artist because area (b) includes songs that are popular but different from the artist's typical characteristics. Moreover, searching for songs in area (c) enables her to listen to unexpected songs in terms of the fact that the searched songs match the artist's typical characteristics well but are not known by many people. Finally, searching for songs in area (d) would be helpful for her to become an artist devotee by listening to them.

In light of the above, given artist a, we rank all a's songs for each area in terms of PA as follows. For area (a), the score of song s is computed by $r_{ap}(s, \mathcal{I}_a) + r_{pop}(s, \mathcal{I}_a)$, where $\mathcal{I}_a$ is a set of all songs of a and $r_{ap}(s, \mathcal{I}_a)$ and $r_{pop}(s, \mathcal{I}_a)$ represent the ranks of s among $\mathcal{I}_a$ in terms of AP and popularity, respectively. The songs are then ranked in ascending order of score. For area (b), (c), and (d), the score is given by $r_{pop}(s, \mathcal{I}_a) - r_{ap}(s, \mathcal{I}_a)$, $r_{ap}(s, \mathcal{I}_a) - r_{pop}(s, \mathcal{I}_a)$, and $-r_{ap}(s, \mathcal{I}_a) - r_{pop}(s, \mathcal{I}_a)$, respectively. In these areas, the songs are also ranked in ascending order. Regarding OS, songs in each area has the same meaning as with PA and we can also make a song ranking for each area in the same manner as with PA.

Table 3 shows example results of the top five song rankings in each area for "The Black Keys" in terms of PA. It would be beneficial to show each ranking to a user according to her familiarity with "The Black Keys."

5.2 Typicality-oriented Search

Because the parameters of all artists and all of their songs are learned by using the same optimization criterion (Eq. 2), all artists and all songs can be embedded into the same feature space. This means that given artist a, all songs in the dataset can be ranked in terms of OS or PA. In other words, we can search for songs that represent a's typical characteristics well even if they were not a's songs. By showing such songs to a user who is a fan of a, she may be willing to listen to unfamiliar songs because they are highly related to her favorite artist. This is also benefi-

Rank	OS	PA
1	California Gurls / Katy Perry	Circus / Britney Spears
2	Racy Lacey / Girls Aloud	...Baby One More Time / Britney Spears
3	Gimme More / Britney Spears	I Wanna Go / Britney Spears
4	Cannibal / Ke$ha	Hung Up / Madonna
5	Piece of Me / Britney Spears	I Kissed a Girl / Katy Perry

Rank	OS	PA
1	Cymbal Rush / Thom Yorke	Untitled / Interpol
2	Atoms for Peace / Thom Yorke	The Clock / Thom Yorke
3	And It Rained All Night / Thom Yorke	I've Seen It All / Björk
4	Convergence / Jonny Greenwood	Svefn-g-englar / Sigur Rós
5	Quick Canal / Atlas Sound	Kingdom of Rust / Doves

Table 4. Ranking results of typicality-oriented search (top: "Lady Gaga," bottom: "Radiohead").

cial for online music streaming services because they can expand users' interests and let users listen to more songs.

Given artist a, when we generate a ranked list of all songs in $\mathcal{I}$ in terms of OS, we compute the score of each song by $f_{os}(a, s)$, which was defined in Section 3.3.1, and rank all songs in descending order of scores. Similarly, for PA, we use $f_{pa}(a, s)$, which was defined in Section 3.3.2, and rank all songs in descending order of scores.

Table 4 shows the top five song rankings for "Lady Gaga" and "Radiohead." Although we do not use acoustic features and metadata of songs, in the case of "Lady Gaga," all artists in the table are female artists. Similarly, in the case of "Radiohead," members of the band such as "Thom Yorke" and "Jonny Greenwood" are retrieved. In addition, because "Radiohead" is a rock band, rock bands such as "Interpol," "Sigur Rós," and "Doves" are ranked at higher positions. These results show the potential of this application to enable users to find new attractive songs.

5.3 Analogy Search

When a user searches for an object in an unfamiliar domain and obtains the desired search results, it is helpful to give an example object in her familiar domain to the search system. This kind of search is known as analogy search and its usefulness to search for persons [54] and restaurants [55] has been studied. An analogy search for MIR can also be an attractive application as follows. Suppose a user is a big fan of "Eminem" and likes his song "Not Afraid." She has recently become interested in "Lady Gaga." However, because she has little knowledge on "Lady Gaga" and there are too many "Lady Gaga" songs, she is at a loss as to which song she should listen to. In such a case, by using an analogy, she can ask something like "what Lady Gaga song corresponds to Not Afraid by Eminem?" If we can return search results for such a query, it would be helpful for her to try some songs of "Lady Gaga."

In an analogy search for MIR, given a query consisting of source artist a^s, source song s^s, and target artist a^t, our goal is to return a^t's song s^t where the relation between a^t and s^t corresponds to that between a^s and s^s. We compute the relation between an artist and a song based on the angle between their latent vectors and the ratio of their lengths because they respectively represent the qualitative and quantitative aspects of artists/songs as we described in Section 3.3. Intuitively, if the angle between a^s and s^s is similar to that between a^t and s^t, and the ratio of $\|\boldsymbol{\nu_{s^s}}\|$ to $\|\boldsymbol{\nu_{a^s}}\|$ is also similar to that of $\|\boldsymbol{\nu_{s^t}}\|$ to $\|\boldsymbol{\nu_{a^t}}\|$, we regard

Query			Rank	Song title
Source artist: Madonna			1	Yoü and I
Source song: Like a Prayer			2	Poker Face
Target artist: Lady Gaga			3	Telephone

Query			Rank	Song title
Source artist: Eminem			1	The Edge of Glory
Source song: Not Afraid			2	Bad Romance
Target artist: Lady Gaga			3	Yoü and I

Query			Rank	Song title
Source artist: The Beatles			1	Milk Cow Blues
Source song: That Means A Lot			2	Face
Target artist: Aerosmith			3	Temperature

Table 5. Ranking results of analogy search.

s^t as a good analogy search result of the query. However, because the degree of the scatter of songs in the feature space is different from one artist to another, we need to normalize the angles and ratios between an artist and its songs. Formally, given a^s, we first compute the angle between $\boldsymbol{\nu_{a^s}}$ and the vector of each of a^s's songs. The angles are then normalized to fit into the interval $[0, 1]$ by min-max normalization. Let θ_{s^s} denote the normalized angle of s^s. We also compute the ratio of the length of each of a^s's songs to $\boldsymbol{\nu_{a^s}}$'s length (i.e., $\|\boldsymbol{\nu_s}\|/\|\boldsymbol{\nu_{a^s}}\|$ where $s \in \mathcal{I}_{a^s}$). Again, min-max normalization is applied and let r_{s^s} be the normalized ratio of s^s. Similarly, we compute the normalized angles and ratios for each of a^t's songs. The score of $s^t \in \mathcal{I}_{a^t}$ for analogy search is then computed as follows:

$$f_{analogy}(a^s, s^s, a^t, s^t) = \gamma|\theta_{s^s} - \theta_{s^t}| + (1-\gamma)|r_{s^s} - r_{s^t}|,$$

where γ is a parameter to determine the weights on angle similarity and length-ratio similarity. Finally, a^t's songs are ranked in ascending order of $f_{analogy}(a^s, s^s, a^t, s^t)$.

In Table 5, we show example results where the top three songs are listed for each query. The value of γ is set to 0.5. In the top table, the source song is "Like a Prayer," which is a signature piece for "Madonna," and the target artist is "Lady Gaga." In this case, the signature pieces for "Lady Gaga" are ranked higher. Even when the source artist is "Eminem," whose music is largely different from that of "Lady Gaga," her signature pieces are retrieved for his signature piece "Not Afraid." When the source song is "That Means A Lot," which has a low PA with "The Beatles," songs with a low PA with "Aerosmith" are retrieved. From these results, we can say that this application can search for the target artist's songs that have a similar relationship between the source artist and the source song.

6. CONCLUSION

This paper analyzed song/artist latent features by embedding them into a same feature space. Based on the analysis results, we suggested three applications for song search. We acknowledge a limitation of this paper in that we did not quantitatively evaluate the search results of those applications. Nonetheless, we believe this study is worthwhile contribution as a first step toward leveraging latent vectors of songs and artists. In future work, we plan to quantitatively evaluate the usefulness of our proposed applications by conducting user studies. We also want other researchers to leverage the concepts of OS/PA and realize useful music information retrieval systems.

ABSTRACT

We analyze and identify collaboration profiles in success-based music genre networks. Such networks are built upon data recently collected from both global and regional Spotify weekly charts. Overall, our findings reveal an increase in the number of distinct successful genres from high-potential markets, pointing out that local repertoire is more important than ever on building the global music ecosystem. We also detect collaboration patterns mapped into four different profiles: *Solid*, *Regular*, *Bridge* and *Emerging*, wherein the two first depict higher average success. These findings indicate great opportunities for the music industry by revealing the driving power of inter-genre collaborations within regional and global markets.

1. INTRODUCTION

Artist collaborations are more popular than ever, as the landscape of the music industry becomes more complex. This widely adopted strategy is a strong force driving music nowadays, maintaining artists' presence and relevance in the market. Such connections usually help artists bridge the gap between styles and genres, overlapping new fan bases and consequently increasing their numbers. Figure 1 illustrates this phenomenon and highlights the growing trend in the number of collaborations within Billboard Hot 100 Charts. Although the general curve increases over time, genres such as *rap* and *hip-hop* present a collaboration rate higher than others (e.g., *pop* and *rock*). This contrast can be explained by the intrinsic nature of each music genre. For instance, *rap* and *hip-hop* artists frequently collaborate with the *pop* community, mainly as featured artists. Moreover, partnerships involving *pop* music may take place not only through intra-genre collaborations but also through inter-genres, bringing an additional dimension to their songs.

Musicians teaming up is nothing new but has risen far beyond the norm. Remaining an industry of creative growth, it is only natural for music (i.e., all musical scene members)

Figure 1: Historical frequency of collaborative hit songs for selected genres on Billboard Hot 100 Chart (1958 - 2020).

adapting to new conditions and redefining its layout. Not surprisingly, the Grammy categories were tightened (from 109 to 78, in 2012) as a result of its dynamic nature.[1] That is, the notion of categories and genres are blurred as never before. Through cross-genre collaboration, artists are naturally venturing into new domains and working outside of the category which they had originally been ascribed to. Such a collaboration phenomenon may be drastically reshaping music global environment, by challenging segments of certain genres to come up with something entirely new [1]. Moreover, this gradual revolution is becoming a driving force in creating a more collaborative scenario, making music one of the most innovative art forms.

As this creative market changes, it becomes more unpredictable; and doing both predictive and diagnostic analyses in such a context remains challenging. Still, we believe factors leading to an ideal musical partnership can be understood by exploring collaboration patterns that directly impact its success [1–3]. Hence, we aim to unveil the dynamics of cross-genre connections and collaboration profiles in success-based networks (i.e., connections formed by genres of artists who cooperate and create hit songs). We do so through the following research questions (RQ).

RQ1: *Does the regional aspect impact on popular genres and their hit songs?*

RQ2: *How has genre collaboration evolved over the past few years?*

---

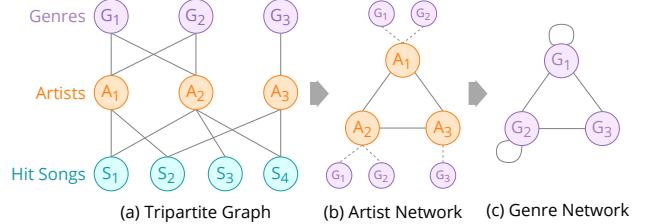
[1] Grammy Award: https://en.wikipedia.org/wiki/Grammy_Award

RQ3: *Which are the potentially intrinsic factors and indicators that influence the collaboration success?*

In order to answer such questions, we first model genre collaboration in the music scenario as success-based networks (Section 3.1). Then, we build a novel dataset with data from global and regional markets (Section 3.2) and present the network science concepts and metrics required for understanding the paper (Section 3.3). Overall, our analyses and experiments over the networks reveal that:

(1) Individually analyzing regional markets is fundamental, as local genres play a key role on determining hit songs and popular artists (Section 4.1).

(2) In general, genre collaborations are increasing, with emerging local genres hitting global success – despite the differences in the evolution of regional markets (Section 4.2).

(3) Genre collaborations analyses describe three significant factors (*Attractiveness, Affinity* and *Influence*, Section 5.1) to uncover four profiles (*Solid, Regular, Bridge* and *Emerging*, Section 5.3).


2. RELATED WORK

Genres are fundamental within the musical scenario by aggregating songs that share common characteristics. Hence, they are frequently used in the field of Music Information Retrieval (MIR), which aims to extract relevant information from music content. In fact, several tasks are genre-dependent or directly related to them, such as automatic genre classification, which has been largely studied by the MIR community over the years [4–8]. Nonetheless, there are also genre-aware studies assessing music source separation [9], genre modeling [10], preferences [11], disambiguation/translation [12, 13], new datasets [14] and ontologies [15]. Network science, the core of our methodology, has also been used to model genres into influence networks [2] and song communities [16].

Hit Song Science (HSS), which tackles the problem of predicting the popularity of a given song, is also an emerging field within MIR. Thus, different studies analyze the impact of acoustic and social features in musical success [17–20], some of them including genre information [21,22]. Moreover, Silva et al. [1] address collaboration as a key factor in success, using topological properties to detect relevant profiles in artist networks. Such an approach is novel and promising in HSS, but it is restricted to the artist and song levels. Therefore, studying collaboration from a genre perspective may reveal important information on how artists from different communities team up to make a new hit song. To the best of our knowledge, we are the first to build a success-based genre network and detect collaboration profiles within it, going deeper into the intrinsic factors that make up a successful collaboration.

3. METHODOLOGY

This work aims to detect collaboration profiles over music genre networks. Building a genre network (Section 3.1) re-

Figure 2: Reduction from the tripartite (a) to the one-mode Genre Collaboration Network (c). The intermediate step is an Artist Network with genre information (b). Artists and genres are linked when hit songs involve both nodes.

quires a proper dataset (Section 3.2), and finding its profiles needs different metrics (Section 3.3), as described next.

3.1 Genre Collaboration Network

A Collaboration Network is usually modeled as a graph formed by nodes (vertices) that may be connected through edges. For example, nodes represent artists and are connected by an edge if the respective pair of artists has collaborated in a song. Now, to analyze the interactions between genres, we model music collaboration as a tripartite graph, in which nodes are divided into three sets: genres, artists, and hit songs; i.e., the minimum elements to evaluate success. The building process of the genre network from the tripartite model is illustrated in Figure 2. Collaborative hit songs are sung by two or more artists, regardless of their participation (e.g., a typical *feat.* or a duet). We also equally consider all genres linked to an artist because they shape how such an artist is seen by fans and music industry.

For analyzing the interaction between musical genres, we reduce the tripartite model into a one-mode network in which nodes are exclusively genres. However, such a reduction is only possible by executing an intermediate step: building the artist collaboration network, Figure 2(b). In such a network, two artists are connected when both collaborate in one or more hit songs. The genres are not lost, as they are linked directly to the artists.

We may now build the final network by connecting the genres of artists who collaborate in the artist network. The edges are undirected and weighted by the number of hit songs involving artists from both genres, Figure 2(c). Also, self-loop edges are allowed, as there are hit songs from artists of the same genre. For example, the song *Old Town Road* [2] by Lil Nas X and Billy Ray Cyrus generates an edge between these artists in the intermediate network; and each of Lil Nas X's genres (*pop rap, country pop* and *hip hop*) is linked to Cyrus' only genre (*country*) with weight 1.

3.2 Dataset Building Process

Over recent years, the world has seen a dramatic change in the way people consume music, moving from physical records to streaming services. Since 2017, such services have become the main source of revenue within the global

---

[2] #1 Song of 2019 according to Billboard Year-End Hot 100 Chart: https://billboard.com/charts/year-end/2019/hot-100-songs

recorded music market. In fact, streaming revenues increased by 75.4% from then, reaching a total amount of US$ 11.4 billion by the end of 2019. [3] Thus, we build our dataset by using data from Spotify, the most popular global audio streaming service, with more than 286 million users across 79 markets. [4] It provides a weekly chart of the 200 most streamed songs in all its markets, and an aggregated global chart. We collect global and regional charts from January 2017 to December 2019, considering eight of the top 10 [5] music markets according to IFPI: United States, Japan [6], United Kingdom, Germany, France, Canada, Australia, and Brazil. We also use Spotify API [7] to gather information about the hit songs and artists present in the charts, such as all collaborating artists within a song (since the charts only provide the main ones) and their respective genres, which is the core of this work. Our final dataset contains 1,370 charts from 156 weeks, comprising 13,880 hit songs and 3,612 artists from 896 different music genres.

Then, a processing phase focuses on the artists' genres, because Spotify assigns a list of very specific genres to each artist. For example, Jay-Z (one of the most popular rappers) is assigned to both *east coast hip hop* and *hip hop* genres, which may be described only by *hip hop*. To simplify our modeling and further analyses, we choose to map all specific genres to more embracing and well-established *super-genres*. Note that the regional aspects are not lost in such a mapping, because our analyses are made separately for each considered market. Hence, the 896 existing genres are now mapped into 162 *super-genres*. The dataset and genre mapping are publicly available on our project page. [8]

3.3 Network Science Metrics

In this work, we use well-established network science metrics to analyze musical collaboration. Such metrics consider the network topological features, i.e., they relate to the network structure (nodes and edges) as follows. [9]

Degree and Weighted Degree. These metrics refer to the connectivity of each node in the network. The degree of a node is its amount of incident edges, and the weighted degree is the sum of the edges' weight. In our genre collaboration network, degree stands for the number of genre connections, and weighted degree represents the number of hit songs shared by both genres.

Clustering Coefficient (CC). Measures the tendency of neighbors of a node to be connected themselves. The higher its value, the more interconnected the node neighborhood.

Common Neighbors (CN). The number of neighbors that a given pair of nodes has in common in a network.

Neighborhood Overlap (NO). The ratio between the common neighbors of a given pair of nodes and the union set of their neighbors. Edges with low NO reveal local bridges in

Table 1: Most popular music genres in each considered market from 2017 to 2019.

	Genre	Songs	Arts.		Genre	Songs	Arts.		Genre	Songs	Arts.
Global	pop	1,715	424	**Canada**	pop	1,790	402	**UK**	pop	1,772	371

	sertanejo	565	82		hip hop	2,660	285		hip hop	1,719	241
	brazilian funk	559	156		rap	2,526	245		pop	1,704	340
	dance pop	415	101		francoton	1,097	82		pop rap	1,518	139
	electro	307	93		dance pop	391	119		trap	1,370	172

the network, i.e., nodes traveling in "social circles", having almost no common connection.

Preferential Attatchment (PA). The probability of a given pair of nodes connecting in the future. The intuition is the more neighbors they have, the more likely they are to connect in the future.

Edge Betweenness (EB). The fraction of shortest paths that go through an edge in the network. Edges with a high score represent a bridge-like connector between two parts of the network, and their removal may affect the communication between others due to the lost common shortest paths.

Resource Allocation (RA). For a pair of nodes, it represents the fraction of a resource (e.g., information) that a node can send to another through its common neighbors.

4. EXPLORATORY ANALYSIS

We perform an exploratory analysis of the data collected in two main steps. First, we analyze Spotify charts for each market to detect popular genres (Section 4.1). Then, we characterize the genre collaboration network to understand the evolution of each market (Section 4.2).

4.1 Music Genres Overview

To answer *RQ1*, we analyze charts of eight markets over three years (see Methodology) in Table 1. Each country has its own musical inclinations, although the predominant genres are mostly *pop/pop rap*, *hip-hop*, and *rap*. Such preference may be due to the increasing number of collaboration songs among artists from different musical genres, as revealed in Figure 1: growing collaborations of *pop*, *rap*, *hip-hop*, and *R&B* in recent years. Also, except for *R&B*, they are the main genres at the top-5 genre lists on most markets; i.e., such genres are among both the most collaborative ones and the most listened on the globe. Moreover, there are three markets with local genres on their top-5 list: Brazil with *sertanejo* and *brazilian funk*; France with *francoton*; and Japan with *j-pop* and *j-rock*. Although local, such genres are potentially good choices for record companies to encourage musical collaborations. Note local engagement shapes the global environment, ensuring that music culture within such countries can develop and progress.

4.2 Network Characterization

After analyzing the charts, we build the genre collaboration network for each market and year to find out how genres connect to answer $RQ2$. With nine markets (global and eight countries) during three years, we analyze 27 networks [10]. For each network, we calculate basic statistics on its nodes and edges, as well as structural metrics (Section 3.3). Table 2 shows the results for selected markets.

First, the global genre networks reveal the world is more open to new successful genres (number of nodes/genres growth). Also, the number of genre connections (edges) increased considerably, meaning more collaborative hit songs are coming from artists whose genres are not linked in prior networks, opening up new opportunities for those genres to acquire new listeners. The networks average degree remains stable, while its weighted value decreases over the years. This could reveal a growth in the number of collaborations of well-established genres with emerging ones, represented by edges with low weight values (few hit songs). Still, such low-degree emerging genres may become popular shortly, expanding their collaborations to other unexplored genres. For instance, *k-pop* connections double as it spreads worldwide, approaching genres such as *reggaeton* (e.g., the collaboration between J-Hope from BTS and Becky G in the song *Chicken Noodle Soup*, September 2019).

For regional markets, we classify the countries into three groups, according to the similarities in networks' evolution: *(i)* USA and Canada; *(ii)* Brazil, France, Germany and Japan; *(iii)* UK and Australia. As the global network, countries in the first group have an increasing average degree and a decreasing average clustering coefficient, thus indicating a stronger tendency to diversify the inter-genre collaborations. Then, the second group includes non-English speaking countries with decreasing connectivity metrics in 2019, after a peak in 2018. The last group has countries in which more genres are becoming successful, while the connections are not increasing in the same proportion.

Overall, considering regional markets individually becomes more important for producers and record labels, as they are delivering more global hits over time. Their distinct behavior emphasizes the strength of cultural aspects on determining how music is consumed and the success of a given genre or artist. In each market, genre connections may reveal distinct profiles, which are an important tool for analyzing successful genre collaborations.

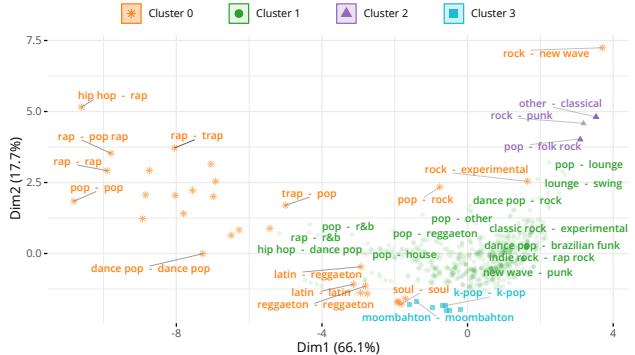
5. GENRE COLLABORATION PROFILES


This section presents our approach to uncover significant factors that compose a successful music genre collaboration. Inspired by Silva et al. [1], we first extract information from the success-based networks by evaluating six edge-dependent metrics (Section 3.3). We perform an Exploratory Factor Analysis on such metrics to define factors in Section 5.1, and then perform cluster analysis in Section 5.2. Finally, we organize the found clusters into collaboration profiles in Section 5.3, to investigate the key driving factors on successful collaborations and then answer $RQ3$.

5.1 Exploratory Factor Analysis

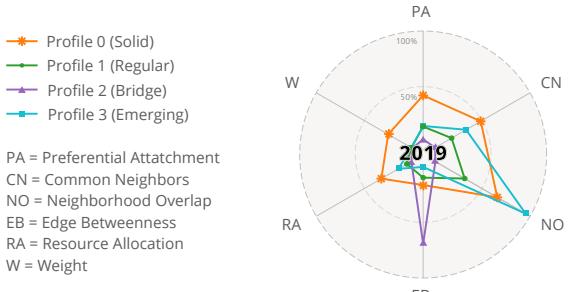
Exploratory Factor Analysis (EFA) [26] is a statistical method designed to underline patterns of correlations among observed variables and extract latent factors. Generally, EFA identifies the number of common factors and the pattern of factor loadings (correlations). It assumes and asserts that manifest (observed) variables are expressed as a linear combination of factors and measurement errors. Each factor explains a particular variance in the variables and may find hidden data patterns. There are two main issues when executing an EFA: *(i)* determining the number of factors to retain for analysis, and *(ii)* selecting the final structure for how the measured variables relate to the factors. For the former, we use the Parallel Analysis criteria [27], which is based on random data simulation. The suggested number of factors to extract is then provided and based on examining the *scree plot* [28] of factors of the observed data with that of a random data matrix of the same size as the original. Finally, the EFA is performed using the well known Ordinary Least Squares (OLS) factoring method and an oblique rotation, allowing factors to correlate with each other.

We use EFA to identify the common factors and the

Figure 4: Clustering result for the USA network, in 2019, with examples of some genre collaborations in each cluster.

Figure 5: Collaboration profiles for all markets (2019). For additional radar plots, see Supplementary Material.

relationships among the edge-dependent metrics of all 27 success-based networks. Overall, the analysis results suggest a three-factor structure within those six metrics. A graphical representation of the emerging structure is in Figure 3. As the three factors are conceptually coherent, we labeled them as follows.

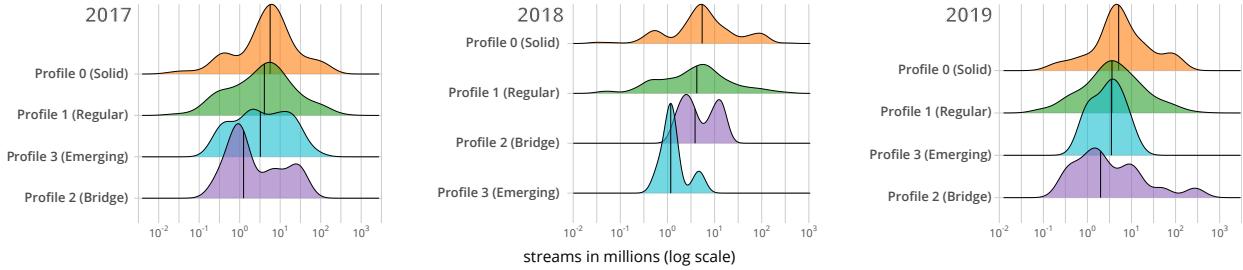
Attractiveness (F1). Factor 1 has high loads for both PA and CN metrics, with a positive correlation between them. Specifically, values close to 0 indicate that two nodes are not close and attracted, while higher values indicate closer nodes. Therefore, this factor corresponds to the predisposition of two nodes to connect in the future.


Affinity (F2). Factor 2 has high loads for both RA and W metrics, with a positive correlation between them. High values indicate strong social ties, and lower ones indicate weak ties. Hence, this factor measures both the frequency of collaboration between two nodes and the social strength.

Influence (F3). Factor 3 has high loads for both NO and EB metrics, with a negative correlation between them. Edges with low NO and high EB certainly consist of local bridges in the network. That is, they represent a bridge-like connector between two "social circles". Therefore, this factor corresponds to the importance level of an edge with access to different regions in the network.

5.2 Cluster Analysis

The second step of our approach is cluster analysis to group similar music genre connections based on the aforementioned factors. We use DBSCAN [29] as a clustering algorithm, which assigns data points to the same cluster if they are *density-reachable* from each other. Two important parameters are required for DBSCAN: ϵ defines the radius of neighborhood around a point x; and $MinPts$ (minimum points) is the minimum number of neighbors within the ϵ radius. To choose the optimal ϵ value, we use a method based on *k*-nearest neighbor distances, which calculates the average of the distances of every data point to its k nearest neighbors. In general, the value of k is specified by the user and corresponds to the $MinPts$ parameter. As a general rule, the $MinPts$ can be derived from the number of dimensions D in the dataset as $MinPts \geq D + 1$. Since we have six topological metrics, we set $MinPts = 7$.

Overall, four distinct clusters were detected in at least


one of the 27 collaboration networks. As an example including all clusters, Figure 4 shows the result of the US network in 2019, where Cluster 0 groups the outliers identified by DBSCAN (data points in low-density regions, i.e., not associated with any proper cluster). Clusters 1 and 2 are slightly overlapping, but each covers groups of high-density data points, which is successful information in this analysis. We can also certainly conclude Cluster 3 is separate from the others. Next, we describe each cluster.

5.3 Collaboration Profiling

Now that we have detected a set of predominant clusters on all modeled networks, the next step is to look at their characteristics for profiling them and defining proper identities. First, for each network, we calculate the mean of the normalized metrics values grouped by each cluster id. Then, for each year, we plot radar charts for each profile with the mean values of each market present in that profile. Figure 5 shows such radar charts, where each cluster is represented by a polygon that exhibits its identity. To compare the metric values' magnitude of each cluster, we adopt the following scale: *low* is the bottom 30th percentile; *medium* is between 30th and 80th percentile; and *high* is the top 20th percentile. Such scale is based on the annual general values, i.e., considering the grouped normalized features of all markets by year.

The differences among the three plots represent minimal changes over the years. However, the distinct shapes show each cluster is *high* or *low* in certain features. Particularly, Cluster 0 presents collaborations with *high* values for *Attractiveness* and *Affinity* factors, but *medium* values for *Influence*. With a similar shape, Cluster 1 presents *medium* values for all four factors. On the other hand, Cluster 2 presents *high* values only for *Influence*, with *low Attractiveness* and *Affinity*. Finally, Cluster 3 is the group with major differences over the years: in general, its collaborations have *medium Attractiveness* and *Affinity*, and *low Influence*. Overall, each curve depicts a distinct collaboration profile, acting as a class descriptor of a cluster.

With the collaboration profiles settled, we can now answer $RQ3$. First, we analyze the distributions of success rate, and then the number of *intra-* and *inter*-genre collaborations for each profile. Here, we define success rate as the average of total streams of songs belonging to the music

Figure 6: Density ridgeline plots of streams in millions for each cluster. Darker vertical lines represent median values.

genres that compose the collaboration (edge) in that year. Figure 6 shows the success density ridgeline plots for each profile, indicating that Profiles 0 and 1 are composed of the most successful music genre collaborations, on average. With results from Table 3, in general, the most successful profiles are those composed of more inter-genre collaborations. Such a result may indicate a strong correlation between musical success and inter-genre collaborations. Indeed, by teaming up with one (or more) person of a different musical style in a song, both artists may draw from one another's fan bases; i.e., they may promote themselves to new public who could increase their fan base and audiences.

To summarize the characteristics of the collaboration profiles, we name each as follows.

– Profile 0 is *Solid Collaboration (Solid)*, composed of well-established collaborations between most popular genres (super-genres), which have been going on for decades. Examples include: *rap* and *hip-hop*, whose collaborative albums are hugely popular; and *hip-hop* and *pop*, whose separating line (between both genres) has become completely blurred in the last decade, mainly in the USA;

– Profile 1 is *Regular Collaboration (Regular)*, composed of the most common collaborations in all markets, which are very similar to solid collaborations but not as engaged. For instance, collaborations between *hip-hop/rap/pop* and *jazz/blues/soul*, which can be typical in many markets, but not as consolidated when compared to *Solid* ones;

– Profile 2 is *Bridge Collaboration (Bridge)*, composed of collaborations with high influence, representing bridge-like connectors between two regions of a network (mostly between divergent music styles). Such collaborations may be possible sources of investment to increase connectivity and strengthen ties among different audiences. One example is collaborations between *gospel* and others, such as *rap* and *MPB* (*Brazilian Popular Music*); and

– Profile 3 is *Emerging Collaboration (Emerging)*, formed mainly of collaborations between regional genres. Such partnerships generally occur within the same genre; possibly between one (or more) unknown artist and one (or more) established artist; or maybe in order to easily reach that genre audience. We propose the term *emerging* because such a profile can be seen as a transition phase for beginners, until they establish their fan bases. Examples of regional genres here include *k-pop* (popular music from South Korea), *moombahton* (fusion genre of *house* music and *reggaeton* (from Washington, D.C.), and *forró* (a popular musical genre from Brazilian Northeastern Region).

Table 3: Total number of *intra-* and *inter-*genre collaborations in each profile, from 2017 to 2019.

Collab	Solid			Regular		
	2017	2018	2019	2017	2018	2019
Inter-genre	140 (49%)	125 (42%)	103 (51%)	1,828 (99%)	1,916 (98%)	2,165 (94%)
Intra-genre	145 (51%)	174 (58%)	99 (49%)	23 (1%)	34 (2%)	128 (6%)

Collab	Bridge			Emerging		
	2017	2018	2019	2017	2018	2019
Inter-genre	10 (100%)	7 (100%)	16 (100%)	3 (7%)	1 (17%)	0 (0%)
Intra-genre	0 (0%)	0 (0%)	0 (0%)	40 (93%)	5 (83%)	7 (100%)

6. CONCLUSIONS

In this paper, we analyze and identify collaboration profiles in success-based music genre networks. Our results suggest that analyzing regional markets individually is fundamental, as local genres play a key role in determining hit songs and popular artists. Besides the differences in the evolution of regional markets, genre collaborations are also increasing, with emerging local genres achieving global success. Moreover, the networks' structures reveal three main factors that describe a genre collaboration: *Attractiveness*, *Affinity* and *Influence*. Analyzing such factors uncovers four different collaboration profiles: *Solid*, *Regular*, *Bridge* and *Emerging*, which act as class descriptors of successful partnerships. Overall, our results contribute to the understanding of the relation between cross-genre collaboration and hit songs.

Indeed, detecting genre collaboration profiles is a powerful way to assess musical success by describing similar behaviors within collaborative songs from multiple angles. Our findings may act as base material for further research tasks, e.g., prediction and recommendation. The former enables predicting the success of a given song/artist/album, while the latter can be used to point out potentially successful genre/artist collaborations. This not only benefits the MIR community, but also the music industry as a whole. In fact, music industry CEOs may maximize expected success by properly investing in potential artist/genre collaborations. Finally, artists may also profit by identifying the most suitable partnerships to lead the album to early stardom. In conclusion, this work sheds light on the science behind the collaboration phenomenon, providing potential impact to the music industry.

Future Work. We plan to consider other data sources and to expand the time period in order to better understand the markets' behavior, enhancing further analyses.

ABSTRACT

Choral singing is a widely practiced form of ensemble singing wherein a group of people sing simultaneously in polyphonic harmony. The most commonly practiced setting for choir ensembles consists of four parts; Soprano, Alto, Tenor and Bass (SATB), each with its own range of fundamental frequencies (F0s). The task of source separation for this choral setting entails separating the SATB mixture into the constituent parts. Source separation for musical mixtures is well studied and many deep learning based methodologies have been proposed for the same. However, most of the research has been focused on a typical case which consists in separating vocal, percussion and bass sources from a mixture, each of which has a distinct spectral structure. In contrast, the simultaneous and harmonic nature of ensemble singing leads to high structural similarity and overlap between the spectral components of the sources in a choral mixture, making source separation for choirs a harder task than the typical case. This, along with the lack of an appropriate consolidated dataset has led to a dearth of research in the field so far. In this paper we first assess how well some of the recently developed methodologies for musical source separation perform for the case of SATB choirs. We then propose a novel domain-specific adaptation for conditioning the recently proposed U-Net architecture for musical source separation using the fundamental frequency contour of each of the singing groups and demonstrate that our proposed approach surpasses results from domain-agnostic architectures.

1. INTRODUCTION

Choir music is a well-established and long-standing practice involving a body of singers performing together. Such ensembles are usually referred to as choir and may perform with or without instrumental accompaniment. A choir ensemble is usually structured by grouping the voices into four different sections, each depicting different frequency ranges for the singers; "Soprano" (260 Hz-880 Hz), "Alto" (190 Hz-660 Hz), "Tenor" (145 Hz-440 Hz), and "Bass" (90 Hz-290 Hz) [1]. This type of structural setting is usually referred to as a SATB setting. Although different variants of this structure exist, the SATB is the most well documented, with several conservatories across Europe dedicated to the study and practice of the art form, highlighting its cultural significance. This will be the main focal point of our study.

The segregation of a mixture signal into its components is a well researched branch of signal processing, known as source separation. For polyphonic music recordings, this implies the isolation of the various instruments mixed together to form the whole. With applications such as music remixing, rearrangement, audio restoration, and full source extraction, its potential use in music is of great appeal. While the task remains similar independently of the type of setting involved, the nature of the sources (e.g.: speech, musical instrument, singing voice) and their relations may entail various challenges and, consequently, require different separation methodologies to be employed.

The most studied case of musical source separation focuses on pop/rock songs, which typically have three common sources; vocals, drums, bass along with other instrumental sources which are usually grouped together as others. A large body of research [2–4] has been published in this field over the last few years, beginning with the consolidation of a common dataset for researchers to train and evaluate their models on. In 2016, *DSD100* [5] was first introduced and made available to the public and was later extended to *MUSDB18* [6], which comprises 150 full-length music tracks for a total of approximately 10 hours of music. To this day, *MUSDB18* represents the largest freely available dataset of its kind.

While source separation for the pop/rock case has come leaps and bounds in the last few years, it remains largely unexplored for the SATB choir case, despite its cultural importance. This is partly due to the lack of a consolidated dataset, similar to the *MUSDB18*, and partly due to the nature of the task itself. The sources to be separated in pop/rock have distinct spectral structure; the voice is a harmonic instrument and has a distinct spectral shape, defined by a fundamental frequency and its harmonic partials

and formants. The bass element to be separated also has a harmonic structure, but lacks the formants found in the human voice and has a much lower fundamental frequency than the human voice. In contrast, the spectrum of a percussive instrument is generally inharmnoic and energy is usually spread across the spectrum. In contrast, the sources to be separated in a SATB choir all have a similar spectral structure with a fundamental frequency, partials and formants. This makes the task more challenging than its more studied counter part. However, the distinct ranges of fundamental frequencies in the sources to be separated can be used to distinguish between them, a key aspect that we aim to explore in our study.

We build on top of some recently proposed Deep Neural Network (DNN) models to separate SATB monoaural recordings into each of their respective singing groups and then propose a specific adaptation to one of the models. The rest of the paper is organized as follow: Section 2 presents and investigates some of the recently proposed high performance deep learning based algorithms used for common musical source separation tasks, such as the U-Net [7] architecture and its waveform-based adaptation, Wave-U-Net [8]. Section 3 goes over the dataset curation carried out for this experiment. Section 4 presents our adaptation of the conditioned U-Net model described in [9], with a control mechanism conditioned on the input sources' fundamental frequency (F0). Section 5 defines the evaluation metrics and methodology used in this experiment. In Section 5.2 we evaluate and compare how existing models and our proposed adaptation perform on the task of source separation for SATB recordings. We then present and discuss the results. Section 6 finally concludes with a discussion around our experiment and provide comments on future research that we intend to carry out.

2. RELATED WORK

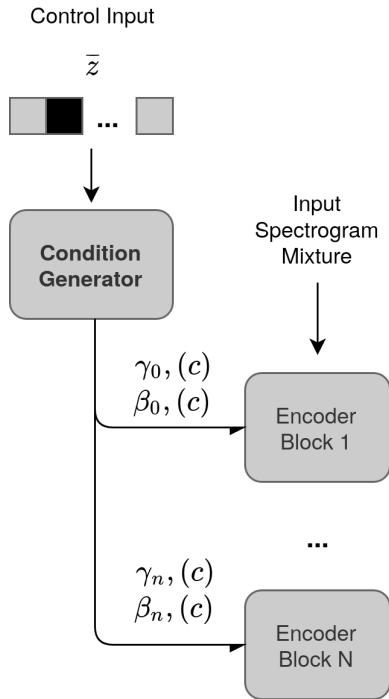
While source separation has remained relatively unexplored for the case of SATB choirs, a number of architectures have been proposed over the last few years for musical source separation in the pop/rock case. A comprehensive overview of all proposed models is beyond the scope of this study, but we provide a summary of some of the most pertinent models that we believe can easily be adapted to the case in study.

2.1 U-Net

The U-Net architecture [7], which was specifically developed to process and segment biomedical images, inspired many subsequent audio-related adaptations due to its unprecedented performance.

The original model includes an encoding path, which reduces the initial input into a latent representation (bottleneck) followed by a decoding path, which expends the channels' receptive field back into its original shape while concatenating the feature maps from the contracting path by the mean of skip connection layers.

One of the first paper to present a U-Net adaptation towards audio source separation was proposed by Jansson et al. [10], where they propose an architecture which specifically targets vocal separation performed on western commercial music (or pop music). The authors present an architecture directly derived from the original U-Net one, which takes spectrogram representations of the sources as input and aims at predicting a soft-mask for the targeted source (either vocal or instrumental). The predicted mask is then multiplied element-wise with the original mixture spectrogram in order to obtain the predicted isolated source. It is worth mentioning that for each of the given sources, a U-Net instance is trained in order to predict its respective mask. In the case of SATB mixtures, four U-Net instances are necessary in order to predict each of the four singing groups.

2.2 Conditioned-U-Net


Depending on the nature of the separation task, its underlying process can easily lead to scaling issues. The conditioned U-Net (C-U-Net) architecture, described in [9], aims at addressing this limitations by introducing a mechanism controlled by external data which govern a single U-Net instance. C-U-Net does not diverge much from the initial U-Net one; as an alternative to the multiple instances of the model, each of which is specialized in isolating a specific source, C-U-Net proposes the insertion of feature-wise linear modulation (*FiLM*) layers [11], which represents an affine transform defined by two scalars - γ and β, across the architecture. This allows for the application of linear transformations to intermediate feature maps. These specialized layers conserve the shape of the original intermediate feature input while modifying the underlying mapping of the filters themselves.

$$FiLM(x) = \gamma(z)x + \dot\beta(z) \qquad (1)$$

In eq. (1), x is the input of the *FiLM* layer, γ and β the parameters that scale and shift x based on an external information, $\overline{z}$ [9]. γ and β modulates the feature maps according to an input vector $\overline{z}$, which describes the source to separate. The condition generator block described in Figure 1 represents a neural network embedding the one-hot encoding input $\overline{z}$ into the most optimal values to be used by the *FiLM* layer.

2.3 Wave-U-Net

In [8], the authors present a time-domain adaptation of the U-Net architecture, which performs the separation operation on the waveform. As the input is a one-dimensional signal, the feature maps are computed directly from the waveform samples through 1D convolution operations. Because Wave-U-Net takes raw waveforms as input, the initial U-Net model has to be adapted accordingly in order to accommodate for the input's nature. Consequently, the feature maps along both contracting and expanding paths are computed by the means of single-dimensional convolution layers. Both paths contain twelve convolutional layers, each, for a total of 24 layers. In the down-sampling

Control Input

Figure 1: C-U-Net control mechanism with the vector $\bar{z}$, a one-hot representation of the source to separate, which dictates the N sets of γ and β values to be used by the *FiLM* layer at each of the block of the encoding path, 1 to N.

path, the receptive field is reduced in half after each layer while the input feature maps are increased by a factor of 24 every time. On the other hand, in the up-sampling path the time-context is doubled after every convolutional layer while the feature maps are reduced, again by 24, after every layers. By that mean, the receptive field and the number of channels of the original input signal will remain preserved at the output stage. Although Wave-U-Net has proven to deliver satisfying results on common musical source separation tasks, the fact remains that waveform-based architectures in general require more data than their spectrogram-based counter parts.

3. DATASET

The training data we have curated for this experiment are composed of the following two datasets:

- Choral Singing Dataset [12] (CSD). Three songs performed by 16 singers from the Anton Bruckner Choir (SATB) [1].

- A proprietary dataset with 26 Spanish SATB songs by 4 singers, one for each part.

There are very few publicly available choir music datasets, thus our choice remains limited. To this day and to the best of our knowledge, there isn't any existing dataset which is specifically suited to our task, thus one

---

[1] https://zenodo.org/record/1286570#.XyGcHy-z3yU

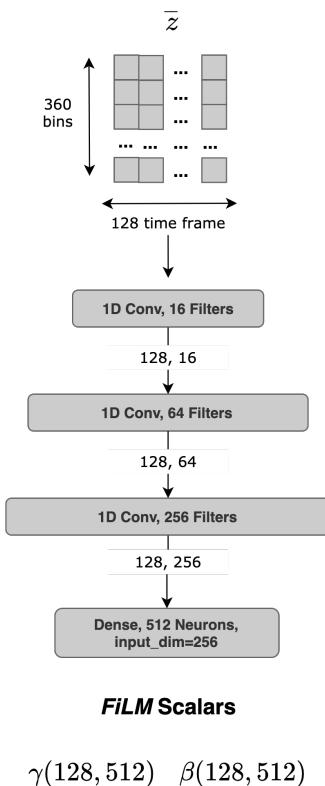
---

of the subsidiary work of this experiment revolves around curating a proper and complete dataset to train our various models. For our experiment, we take advantage of the CSD [12]. This dataset was recorded in a professional studio and contains individual tracks for each of the 16 singers of a SATB choir, i.e. 4 singers per choir section. It comprises three different choral pieces: *Locus Iste*, written by Anton Bruckner, *Nĩno Dios d'Amor Herido*, written by Francisco Guerrero, and *El Rossinyol*, a Catalan popular song; all of them were written for 4-part mixed choir. The dataset is very well suited for our experiment as the isolated track for each individual singer will allow us to proceed the same way as in [13], that is to create artificial mixes by combining various stems from different groups together. Using different combinations of all 16 singers, we created 256 SATB quartets for each piece, which represent all possible combinations of singers taking into account the voice type restriction (i.e. exactly one singer per voice is needed).

The second dataset we use is a proprietary one including 26 songs for exactly one singer per part (i.e. 4 stems per song), which is a well-suited format for our task as well. All songs offered as part of this dataset are performed in Spanish and their length revolves around two to three minutes, for a total of 58 minutes of audio data.

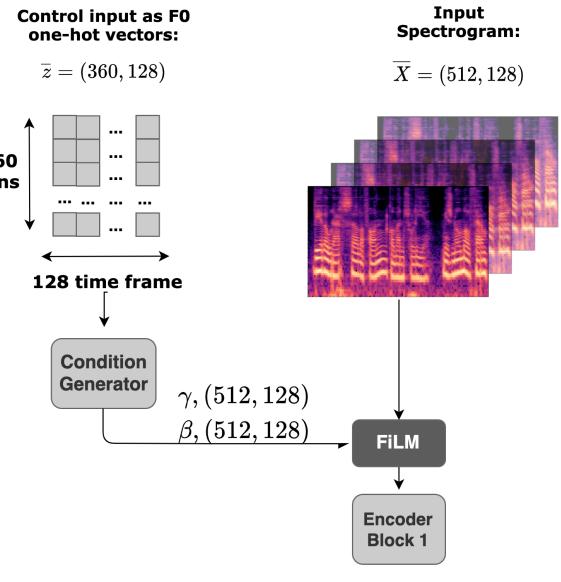
Our curation work consists in consolidating these two datasets and make sure all the data that we are using remain consistent and well-formatted across all the audio stems, which includes length and amplitude normalization, as well as properties standardization. Most of the files included as part of the initial datasets were presented as 10-seconds long snippets as opposed to full-length songs, which isn't an ideal format to work with. Hence, some additional efforts have been devoted to turn these files in a more convenient and consolidated format.

4. APPROACH

Injecting domain knowledge in DNNs has been proved to be an effective way to learn complex input-output relations with high accuracy when the available data happen to be scarce and limited [14], such as found in our case.


Each of the singing groups in a SATB recordings performs within its own respective frequency range, that is, the voices' F0 contour will rarely overlap across the various groups. This factor makes the sources' F0 a suitable discriminative feature, which could be injected in the DNN during the training stage and potentially improve the separation of the various singing groups in SATB recordings.

In this view, we propose to adapt the original C-U-Net architecture, which initially embeds the instruments to be separated, $\bar{z}$, in order to produce the various *FiLM* parameters (γ, β), and substitute the external control input data for the F0 track of the target source. The new control input vector $\bar{z}$ will thus hold time as well as frequency dimensions.

4.1 Control Input Representation


As previously mentioned, we use the frame-wise F0 as the external control data of our condition generator network. This entails that a few preliminary steps are required prior to proceeding to the training stage. We first automatically extract the sources' F0 track using the DIO algorithm [15]. Once the raw pitch tracks are obtained, we convert each time-step F0 into a one-hot encoded representation as postulated in [16], that is 60 frequency bins over 6 musical octaves, with a base frequency of 32.7 Hz Hertz, for a total of 360 frequency bins per time-step. As a result, for 128 time-steps, our control input will be in the shape of [128, 360].

Figure 2: Control model architecture. The convolution is performed across the frequency bins for each time-step. The dense layer provides a specific conditioning for each frequency bin.

4.2 Control Model

The control model used in our proposed architecture embeds the one-hot encoded CQT F0 representation for a given time-step into a set of transforms of identical shape as the spectrogram input. This is achieved by modeling the condition vectors as 1-D data with multiple feature channels. The condition vectors are then fed into a convolutional neural network (CNN) with a kernel of size 10 seizing contextual information from the adjacent time-steps. As a result, all input channels of the initial convolution contribute to all resulting feature maps in the output of the first convolutional layer. Finally a dense layer provides a

Figure 3: C-U-Net Control Mechanism adapted to our task, with the one-hot vector $\overline{z}$ depicting the various SATB singing groups' F0 contour.

specific conditioning for each frequency bin at each time-step, taking into account the contextual information previously captured by the CNN. Figure 2 shows the condition generator architecture in greater details.

As the temporal relation between the external control input data and the input spectrogram is crucial, it is important to apply these affine transformations while the receptive field of the input is still intact. Hence the *FiLM* layer is applied prior to the encoding path. Figure 3 shows the overall structure behind the proposed conditioning architecture.

We propose two variants of the architecture described above, each of which differs slightly in the way it embeds the control input data; the first variant applies a unique affine transform for each individual frequency bin at every input time-step. The resulting scalars in the output of the external CNN model will thus be in the shape [512, 128] for a given input spectrogram of the same time context. On the other hand, the second variant applies a single transform for all frequency bins at a given time-step, resulting in a set of scalars of shape [1, 128] for 128 spectrogram frames given in the input. We refer to the two approaches as "Domain-Specific Global" and "Domain-Specific Local", respectively and define them with the acronyms *C-U-Net D-S G* and *C-U-Net D-S L* in the rest of this paper. while the three models covered in Section 2 will be referred to as "Domain-Agnostic" models.

5. EVALUATION

To assess our proposed approach and show that injecting domain knowledge as control input data to the network improves its performance on SATB recordings, we evaluate the performances of three domain-agnostic state-of-the-art DNN models; U-Net, its waveform adaptation

Wave-U-Net, and the original C-U-Net. We then compare the results with the two domain-specific models proposed in Subsection 4.2. We evaluate the performance of a model by computing three metrics, SDR, SIR, and SAR [5], between the predicted and true audio sources. The three measurement metrics describe the overall quality of the separation, the level of interference with other sources as well as the amount of artifact added by the separation algorithm, respectively. The metrics are computed using the *mir_eval toolbox* [17] for each of the SATB singing groups.

5.1 Train - Test Split

Given the limited size of our data, we opted to set apart one song from the proprietary dataset as well as one singer per voice for each song from the CSD in order to build our first use-case test set. The rest of the data was used for training. This allowed us evaluate the model on unseen songs and singers. Our second test case contains unison singing, which was not seen at all during training. As such, we used the three songs from the CSD with all singers for evaluation.

5.2 Experiment Results

Subsections 5.2.1 and 5.2.2 present the performance results for the two test cases described earlier; that is, for the test set involving exactly one singer per part and the other involving exactly four singers per part, respectively. *C-U-Net D-A* refers to the domain-agnostic architecture while *C-U-Net D-S L* and *C-U-Net D-S G* refer to our two domain-specific adaptations. For testing, we use the oracle fundamental frequency of each of the sources, precomputed prior to model inference. In a complete source separation pipeline, we would complement our system with the multi-pitch algorithm proposed by [18].

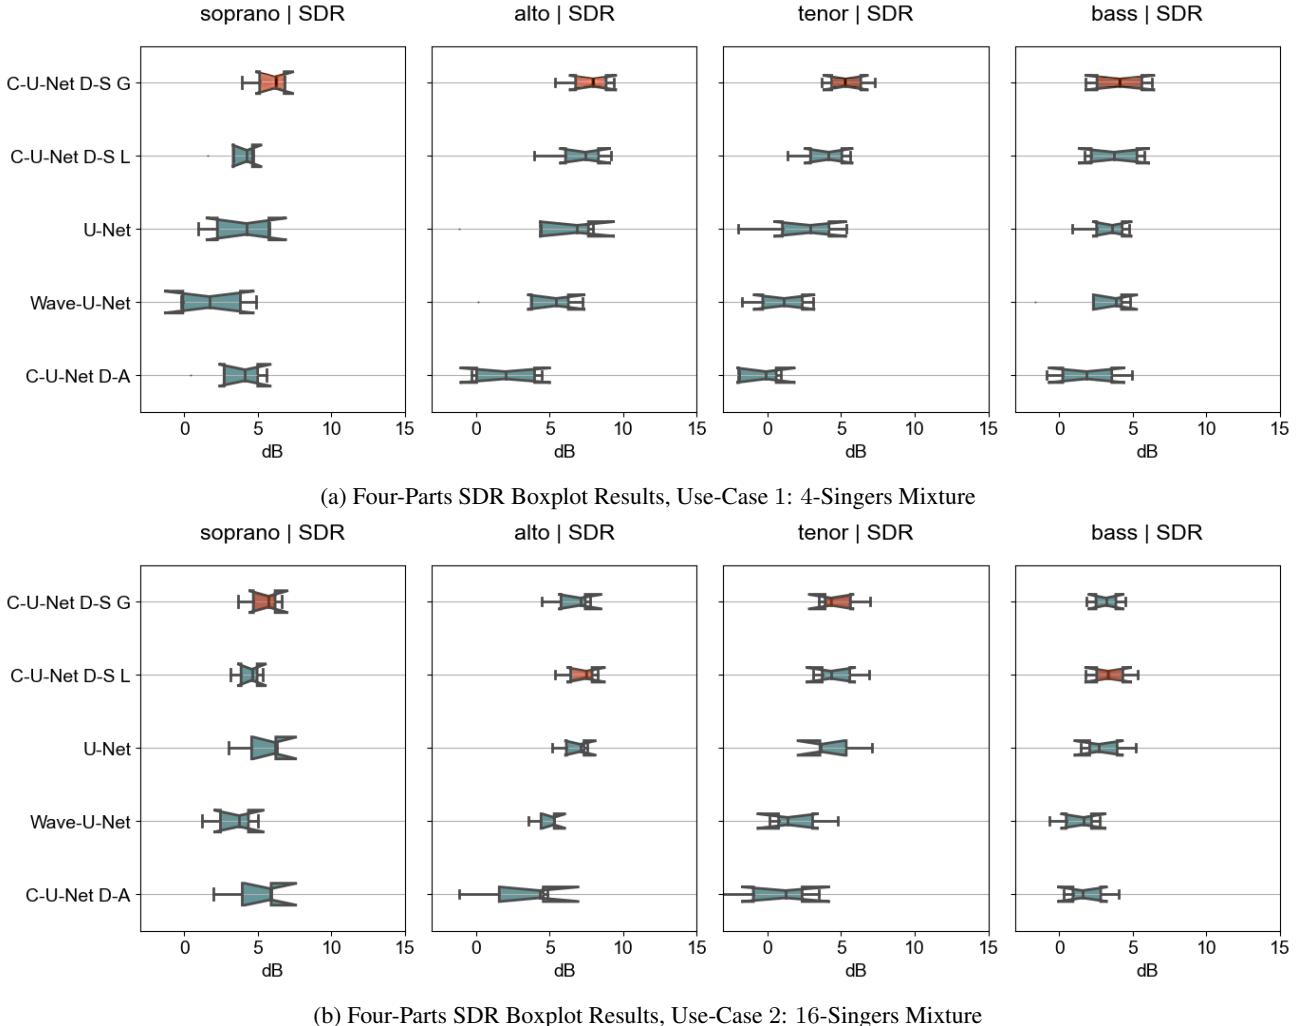
5.2.1 Use-Case 1:

Table 1 portrays the mean SIR and SAR results on all the SATB parts and average for all five models mentioned in previous sections. Figure 4a details the SDR score distributions on our first test set. We observe that our two adaptations, *C-U-Net D-S L* and *C-U-Net D-S G*, call attention to a significant score gap between domain-agnostic and domain-specific models, with an average increase of about 1dB SDR and 1.5dB SIR between the two different approaches. These improvements underline an overall better quality of the predicted sources (SDR) as well as a decline in interference between the various predictions. Our domain-specific architecture hence demonstrates a better ability to cope with the correlated nature of the various SATB sources and seem to predict an appropriate spectral mask for each of them. We also observe that our proposed adaptations return the lowest SDR, SIR and SAR performances for the Bass part, specifically. This could be due to the fact that the Bass group, among all SATB groups, shares the highest number of harmonics with its other source counter parts.

We also note that the mean SDR substantially drops for the Tenor singing group across nearly all domain-agnostic

models, reaching a negative result with the *C-U-Net D-A* architecture (−1.25dB SDR). We speculate that the reason behind such decline can be directly related to the close nature of the F0 contours of both Alto and Tenor singing groups, making it harder for domain-agnostic architecture to distinguish between the two sources. This limitation brings yet another justification for the conditioning approach we have taken in this paper.

5.2.2 Use-Case 2:

Figure 4b as well as the bottom portion of Table 1 presents the SDR, SIR and SAR scores on the second use-case test set. We observe that the introduction of more complex mixtures involving a higher number of singers (i.e.: 16 singers in this case) decreases the performance of our proposed models, with an average SDR barely surpassing U-Net's for our *C-U-Net D-S G* model and levelling it out for the *C-U-Net D-S L* model. This can be attributed to the use of the mean of the various pitches present in a singing group, to represent the pitch of the unison. Since domain-agnostic models, such as the plain U-Net, don't hold this assumption, these architectures are less prone to errors when exposed to these type of mixture settings [2].


6. CONCLUSIONS AND FUTURE WORK

In this work we have presented the task of musical source separation applied to SATB choir recordings. We first described the consolidated dataset that we've specifically curated for this experiment and its potential use and application for future related research. We then assessed how well recent domain-agnostic deep learning based architectures for musical source separation performed on this task, given two different use-cases; 4-singers mixture and 16-singers mixture separation. An adaptation of the U-Net architecture was then proposed, consisting in conditioning some of the network parameters on the fundamental frequency contour of each of the SATB mixture sources. The preliminary results showed that taking advantage of domain-knowledge during the training process improved the performance on both of our proposed use-cases. For the evaluation presented in this paper, we use the oracle F0 is currently used as external control input data to the network. In a complete source separation pipeline, we plan on combining the task of multi-pitch tracking [18] with the system presented in this paper. We also plan on validating our evaluation with perceptual listening tests and exploring applications of the SATB separation. including remixing, transcription and transposition combined with the work presented in [19, 20].

ABSTRACT

Labeling a music recording according to its genre is an intuitive and familiar way to describe its content. Music genres are valuable information especially for music organization, personalized listening experience, and playlist generation. Automatically classifying music genres is a challenging endeavor due to the inherent ambiguity and subjectivity. Most efforts on music genre classification consider the complete independence between labels. However, music genres typically respect a hierarchical structure based on the influences or origins of each style. Conversely, many of the methods available for hierarchical classification are based on assumptions about the class hierarchy, such as the need for multiple children in each hierarchy's node, which may limit their use in music applications. Also, the local classifier per node approach that would be the most suitable for this scenario is costly regarding time and memory. In this paper, we present two local hierarchical classification approaches and show how to combine them to obtain a single one that is more robust and faithful to the music genre classification scenario. We evaluate our proposal in a music dataset hierarchically labeled with 120 music genres. As shown, compared to state-of-the-art approaches, our approach has a lower computational cost and can achieve competitive performances.

1. INTRODUCTION

The music genre is a convention used by humans to categorize and organize pieces of music. Besides being essential metadata for large databases of music distribution, the music genre resides in one of the most common descriptors employed in studies involving storage, retrieval, and usage of music knowledge [1–3].

The major problem with music genre information is that it is usually fuzzy and inaccurate. At the core of this question is human subjectivity, closely related to the several criteria for labeling music in genres [4]. Because of subjectivity, the music genre classification task becomes even more challenging, since it needs to deal with differences in interpretation and an unavoidable intersection between genres.

Besides, as there is no standard for labeling music, some music platforms may present a high number of genres. For example, the streaming music service Spotify [1] catalogs its music in over 1500 genres, which will eventually be updated and increased in quantity in the future. Also, a song classified as, for instance, "gothic metal" on Spotify may be labeled as "alternative rock" and "indie rock" on other platforms, such as Google Play Music [2] and Apple Music [3]. Finally, some music genres overlap in these services, while others have subgenres. Although there is no unique way of determining an item's music genre, the literature covers distinct approaches and methods to support this complex and many-sided task.

So far, most of the work in music information retrieval is only concerned with music genres as a flat classification problem [5–8]. A flat classifier seeks to associate each example with a class that belongs to a finite, devoid of structural dependencies and usually small, set of classes. However, the music genre classification calls for a genre taxonomy, *i.e.*, a hierarchical set of categories to be mapped onto a music collection.

In hierarchical music genre classification, supervised machine learning algorithms are designed to induce a hierarchical decision model. Such a model links the features of the examples to a class hierarchy, generally represented as a tree or a direct acyclic graph with varying specificity and generality levels. An advantage in assigning examples to hierarchically organized classes is that the closer to the root of the hierarchy a linkage occurs, the smaller the classifier error rate tends to be. Conversely, the obtained classification will be less specific and, therefore, less informative [9, 10].

Having the genres structured into a class hierarchy helps users to not only browse and retrieve music pieces but also navigate the collection according to the similarity of its content.

Most of the methods available for hierarchical classification are based on the local classifier per node approach.

This approach resides in training a binary classifier for each node of the class hierarchy, except the root node, aiming to predict whether or not an example has the corresponding class [11]. The local binary dataset for a given node in the class hierarchy contains positive examples, those that have some relation to the class of the node in question, and negative examples, those related to the remaining classes. We can determine the sets of positive and negative examples in different ways; for instance, adopting heuristics based on set operations [12] or strategies based on nearest neighbors [13]. Depending on the number and disposition of the classes in the hierarchy, we may choose to use multiclass classifiers instead of binary ones. Thus, while the local classifier per parent node approach builds a multiclass classifier for each non-leaf class node of the hierarchy, the local classifier per level approach generates a multiclass classifier for each hierarchy level [11].

The multiclass approaches are much more efficient concerning time and memory than the binary one because they build fewer classifiers. On the other hand, they make some assumptions about the class hierarchy, such as the need for multiple children in each hierarchy's node. Although the assumptions help to avoid both the generation of one-class local datasets and class-membership inconsistency, they may limit the direct use of multiclass classifier-based hierarchical approaches in music applications.

In this paper, we combine the per node and per parent node approaches to obtain a single local hierarchical method that is more robust and faithful to the music genre classification scenario. We advocate using decision tree-based classification algorithms to build the local classifiers because they internally perform feature selection. As discussed throughout this work, this is a relevant consideration in hierarchical music genre classification since the features that most distinguish among classes tend to be different at each level of the class hierarchy.

We evaluate the proposed approach using a music dataset with 120 hierarchically organized music genres. Also, we compare our proposal with three well-known approaches in terms of performance and runtime. The results show that our proposal is computationally inexpensive and competitive against the traditional approaches.

The remainder of this paper is organized as follows: Section 2 gives a general view of the problem and summarizes research efforts in automatic music genre classification; Section 3 introduces the concepts of hierarchical classification; Section 4 describes our proposal, from the design of the hierarchical decision model to the prediction strategy adopted; Section 5 presents the experimental protocol, as well as the results and our discussion about them; Section 6 concludes this study and shows directions for future work.

2. RELATED WORK

Recognition of music genres is one of the most prominent research problems in music information retrieval. Studies point out that genre is the most chosen concept to guide the user browsing in music repositories [1, 14].

A music genre recognition system aims to categorize an audio signal with an unknown label into a previously known music genre from relevant features extracted from this audio. A classifier makes use of such characteristics to identify the music genre of the analyzed signal. The benefits of categorizing pieces of music in genres extend to many other tasks, such as organizing digital audio databases [15], building new search engines [16], and recommending songs [17].

Several approaches for audio-based music genre classification extract features associated with the timbral information, such as Mel-Frequency Cepstral Coefficients (MFCC), and sets of spectral and rhythmic characteristics [18].

There are three main categories of algorithms that can be applied in this context [19]. The first one represents the entire recording with one single set of features [5, 20]. The other two rely on classifying feature vectors extracted from short frames of the recordings and achieve the final result by an ensemble of these classifications. Some methods perform this approach directly on the frame-level features [21], while some other aggregate few consecutive frames, creating a new set of features usually given by the mean and standard deviations of the aggregated features [6, 22, 23].

More recently, researchers have used deep learning models to learn a feature representation that promises to advance the task of genre recognition significantly [24–27]. Although deep learning methods are computationally expensive, they allow the extraction of relevant audio features without having to depend on ad-hoc domain-dependent signal processing strategies [24].

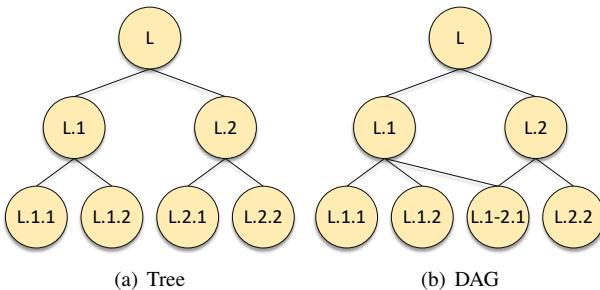
The literature has mostly treated the automatic music genre classification as a problem of flat classification. In other words, most papers in this domain consider all the genres in the same hierarchy's level [5–8]. However, the music genre classification problem is better modeled with a taxonomy of genres. We describe below some notable works that have used class hierarchies to support the task mentioned above.

A binary approach, which uses a feature selection method on each generated local dataset and a Gaussian Mixture Model as a base-level classifier, was proposed in [28]. In this same direction, the authors in [29] applied an ensemble of Feed Forward Neural Networks and k-Nearest Neighbors (kNN) over the local binary datasets. For the kNN classifier, they employed a genetic algorithm feature selection mechanism.

Two datasets with content-based features and a standard local approach using Support Vector Machines classifiers were explored in [30]. Differently, the authors in [31] developed a local approach that adopts feature selection, multiple representations from the same object, and enables hierarchically multi-label classifications by using a two-layer labeling process.

The study reported in [32] involved two selective multiclass hierarchical methods. The first one selects the best feature set instead of the best classifier, while the second

one selects both the best classifier and the best representation simultaneously.

The authors in [33] proposed a novel approach to building a classification tree through subspace cluster analysis. On the other hand, hierarchical analysis of spectrograms was investigated in [34] to help classify music in genres.


This paper presents a proposal that differs from the literature for having another point of view. Here we combine two local approaches to quickly and efficiently obtain a single hierarchical method that faithfully represents the music genre classification scenario.

3. HIERARCHICAL CLASSIFICATION

Flat classification differs from hierarchical one because in the latter the domain classes follow a logical organization. In flat classification, while the absence of interrelationships between classes characterizes some problems (single-label classification), the non-structural relationships between labels evidence others (multi-label classification). Structural dependencies, which express super or subclass relations, define hierarchical classification.

A dataset for hierarchical classification in the attribute-value table format comprises N pairs of examples $(\vec{x}_i, Y_i)$, where $\vec{x}_i = (x_{i_1}, x_{i_2}, x_{i_3}, \ldots, x_{i_M})$ and $Y_i \subset L = \{L, L.1, L.1.1, L.1.2, \ldots\}$. Specifically, each example $\vec{x}_i$ is represented by M predictive features (attributes) and has a set of labels Y_i for which there are relationships that obey a hierarchical class structure stipulated *a priori*. The class attribute, in turn, reflects the concept to be learned and described by the induced hierarchical models using supervised machine learning algorithms.

We can discern the hierarchical classification methods according to four central aspects [11]. The first one covers the type of hierarchical structure – tree or Direct Acyclic Graph (DAG) –, taken to depict the relationships among classes. In the tree structure (Figure 1(a)), each node, except the root node, is linked with at most one parent node. In the DAG structure (Figure 1(b)), each node, except the root node, can have one or more parent nodes.

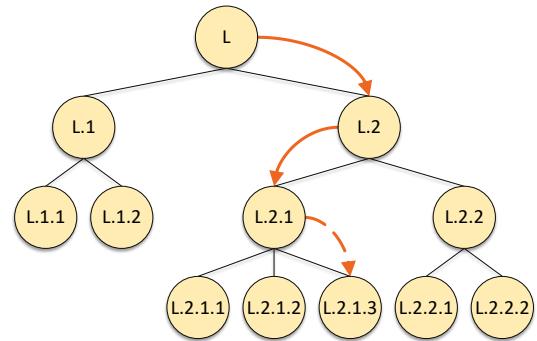
(a) Tree   (b) DAG


Figure 1. Hierarchical class structures.

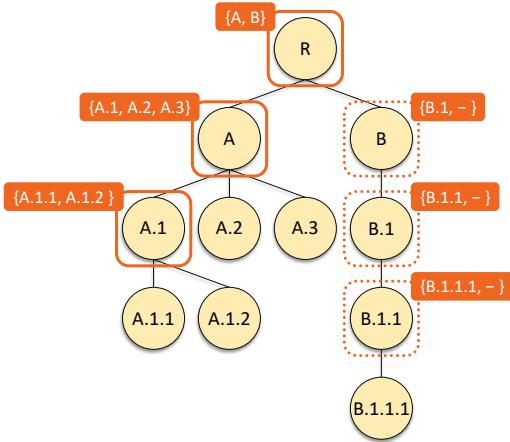
The second aspect determines whether the algorithm can predict classes in one or more paths in the hierarchical structure. For instance, in the class hierarchy tree of Figure 1(a), if the model is able to predict both classes L.1.1 and L.1.2 for a provided example, which refers to the

paths L→L.1→L.1.1 and L→L.1→L.1.2, then it can predict multiple paths – Multiple Path Prediction (MPP). Conversely, the method performs Single Path Prediction (SPP) when this type of association is invalid.

The third aspect involves the hierarchical level at which the classification takes place. An algorithm can predict using only classes represented by leaf nodes – Mandatory Leaf-Node Prediction (MLNP) – or by using classes denoted by any internal or leaf node within the hierarchical structure – Non-Mandatory Leaf-Node Prediction (NMLNP). Figure 2 illustrates these two prediction strategies; the path L→L.2→L.2.1 portrays the NMLNP strategy, and the path L→L.2→L.2.1→L.2.1.3 indicates the MLNP tactic. We need to highlight that the NMLNP strategy is convenient mainly in applications that opt for the freedom to conduct a more generic classification, but with greater reliability.

Figure 2. Hypothetical class hierarchy.


The fourth and final aspect concerns the way that machine learning methods deal with the hierarchical structure. We can group the approaches described in the literature into three broad categories: (i) flat approach, (ii) local approach, and (iii) global approach. Further details are available in [11].

4. PROPOSED APPROACH

One interesting research aspect that has been neglected by the music information retrieval and machine learning communities is the development and evaluation of the fusion of two or more hierarchical classification approaches. The motivation behind this idea arises because, unlike the global approach that generates a single classifier whose structure includes the entire class hierarchy [32, 35, 36], traditional approaches work with several local classifiers – binary or multiclass – to model the taxonomy of the problem's labels [9, 11].

Local approaches are generally preferred over the global ones due to the possibility of employing conventional supervised machine learning algorithms, which have been extensively tested and validated in flat classification tasks [37]. However, while some of the local approaches are computationally expensive in terms of time and memory, others make assumptions about the class hierarchy and, as a result, cannot be directly applied in some scenarios like the one treated here.

As aforementioned, the purpose of this paper is to combine the per node and per parent node local approaches to obtain a more efficient one. The justification for proposing a hybrid approach comes from the music genre classification problem, and we will explain it below using the class hierarchy tree of Figure 3.

Figure 3. Proposed approach: a hybrid local approach based on the per node and per parent node approaches. Squares with curved corners symbolize multiclass classifiers. Squares with dotted curved corners depict binary classifiers.

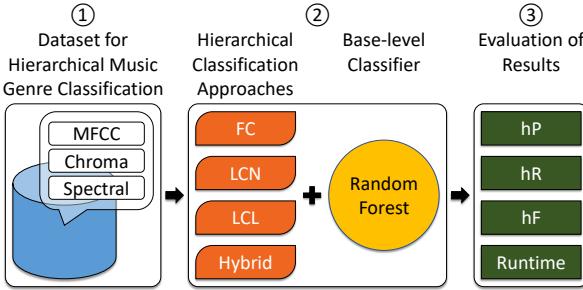
The class hierarchy of Figure 3 shows 11 classes that can be interpreted as music genres. A music genre can have one or more subgenres. If we adopted the local classifier per node approach, we would create a binary classifier for each class in the hierarchy, except for the root node, employing a set of positive examples – examples representing the current class – and a set of negative examples – examples that they are not associated with the current class. In this sense, to find the local training sets related to each class from the training dataset, several heuristics have been proposed [12, 13, 37]. The per node approach is suited to the task of music genre classification, but due to the construction of $|L| - 1$ classifiers, it is expensive regarding memory and processing.

On the other hand, if we were to use the local classifier per parent node approach, we would build, for each non-leaf node in the class hierarchy, a multiclass classifier to label new examples according to their subclasses. Therefore, in this approach, classifiers are also generated from sets of local training examples. Each local training set should be prepared so that the examples included therein are labeled only with the classes that will be differentiated by the multiclass classifier. The label of each example inserted in the training set selected for the classifier's induction must be generalized so that only the labels referring to the child classes of the analyzed node are present. Here a problem arises: if the approach were to encounter nodes B, B.1, and B.1.1 in Figure 3, it would generate one-class local datasets. Single paths like B→B.1→B.1.1→B.1.1.1 are essential in music genre classification since it demonstrates the evolution of the genre over time. Despite this

issue, the per parent node approach has better memory and processing than the per node one, and the resulting classifiers are less complex than the per level approach.

The local classifier per level approach, which creates a multiclass classifier for each level of the hierarchy, is not exempt from limitations. For the fourth level of the tree structure in Figure 3, such an approach would generate a local dataset containing only one class (B.1.1.).

In order to address the above issues, we propose a hybrid approach that represents the class hierarchy as a tree. We set up it as follows: for each internal node in the hierarchy with two or more children, we apply the local classifier per parent node approach and build a multiclass classifier with the children nodes, as indicated by the squares with curved corners in Figure 3. Otherwise, if the node has only one child, we apply the local classifier per node approach and generate a binary classifier, as symbolized by the squares with dotted curved corners in Figure 3. Note that we need to employ a strategy to choose the positive and negative examples from the local binary datasets. The literature shows that the more examples we consider in the learning phase, the better the induced classifier performs [12].

In this work, we suggest applying the "inclusive" heuristic to create local datasets [12]. This heuristic defines that the set of positive examples (S^+) is the most specific class and its descendants. In contrast, the set of negative examples (S^-) is all other classes except those in the set of positive examples and the ancestors of the most specific class. The output of the "inclusive" heuristic for node L.2.1 is: $S^+ = \{L.2.1, L.2.1.1, L.2.1.2, L.2.1.3\}$, and $S^- = \{L.1, L.1.1, L.1.2, L.2.2, L.2.2.1, L.2.2.2\}$.


At each level of the hierarchy, groups of music genres are distinguished by their differences. Intuitively, the acoustic features that discriminate gothic metal from pop music diverge from those that differentiate country from gospel music. Hence, we can affirm that the classification of distinct music genres, like many other objects, benefits from different representations at distinct levels of the hierarchy. For this reason, we advocate applying learning algorithms based on decision trees to induce the local classifiers since they internally perform feature selection.

Finally, the hierarchy of music genres has some peculiarities that allow the classification to stop at internal nodes or go down up to the leaf nodes. To avoid inconsistencies in the classification step, we recommend using the top-down prediction strategy. In this strategy, an example is initially classified – based on the classifier's reliability (classification score) – among the first-level classes, and the subtrees of interest are only used to classify the examples at the other levels. The classification procedure is interrupted when the current classifier's reliability is less than a predefined $threshold$.

5. EXPERIMENTAL EVALUATION

This section presents an empirical assessment of our proposal and its comparison with three well-known approaches (Figure 4). First, we describe the considered

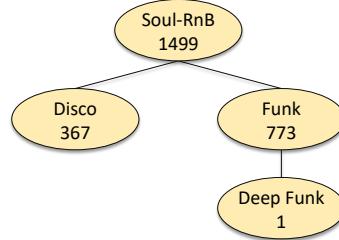
dataset. Next, we report the experimental setup regarding the adversary approaches, parameter setting, and evaluation measures. Then, we show and discuss the obtained results in terms of predictive performance and learning time.

Figure 4. High-level overview of the empirical evaluation.

5.1 Dataset

In our experiments, we used data from the Free Music Archive (FMA) [38]. This dataset contains 106,574 recordings, organized in 161 imbalanced genres.

We note that this paper's focus is not proposing novel features or comparing them in the classification scenario. For this reason, we considered the features available with the FMA dataset instead of extracting or learning features from the audios. Such a decision allowed us to compare the hierarchical classification approaches without relying on the gain provided by a better (or worse) feature set.

The features provided with the dataset, which we applied in our computational tests, are statistics from windowed MFCC, chroma, and spectral features extracted from 30 seconds in the middle of each recording using the LibROSA framework [39]. Specifically, these statistics are the mean, standard deviation, skew, kurtosis, median, minimum, and maximum.


As noted in Section 2, music genre classification is usually performed by timbre-related features, such as MFCC and spectral characteristics. However, we also included the chroma-based features in our experiments to evaluate both the contribution of this kind of feature in the genre classification and our proposal's behavior when dealing with distinct music characteristics.

The FMA dataset has a default training-validation-test split. As we did not use the validation set to tune parameters, we merged it with the test examples. This operation provided us a training set that comprises 80% of the examples. Consequently, 20% of the remaining recordings belong to the test partition. Besides, this split is stratified and is guaranteed that there is no artist in the test set that also appears in the training set.

The genre hierarchy is an interesting characteristic to observe in this dataset. As the FMA allows the artists to label their songs themselves, the dataset presents a complex hierarchy of genres.

Another challenging factor present in this dataset is the class imbalance – "unbalanced with 1 to 38,154 tracks per genre" [38].

Figure 5 illustrates one branch of the class hierarchy, which presents the stated issues. It has nodes with single and multiple children, as well as genres with a significant difference regarding the number of tracks.

Figure 5. Example of genre hierarchy for the top-level Soul-RnB genre.

To make the hierarchical classification of single paths feasible, we address some issues found in the FMA dataset. In so many cases, the associated genres belong to more than one path in the genre hierarchy tree. In these cases, we select the genre for which the leaf node is at the lowest level. In case of ties, we kept that one in which the genre in the lowest level of each path comprises the higher number of tracks. We also removed unlabeled examples and examples from the test set whose classes were not present in the training set. Therefore, the dataset evaluated in this paper has 82,374 training examples and 15,681 test examples. These examples are described by 461 features and are associated with 120 classes organized hierarchically. The class hierarchy has four levels, each with 21, 107, 17, and 2 classes.

5.2 Compared Approaches and Parameter Settings

We compared the hybrid approach with three other well-known ones: (i) Flat Classifier (FC), (ii) Local Classifier per Node (LCN), and (iii) Local Classifier per Level (LCL). For FC, we assume each possible path in the label tree to be a class. For LCN, we use the "inclusive" heuristic to generate local datasets.

We adopted Random Forest [40] as a symbolic base-level classifier with the number of variables available for splitting at each tree node ($mtry$) equal to $\sqrt{(M-1)}$.

We considered the NMLNP strategy with $threshold = 0.5$. This setting means that the classification at the deepest levels is interrupted when the classification score is less than 0.5 or, in the case of per node classifiers, the predicted class is negative.

The experimental protocol execution comprised the use of the programming language R[4] with the following packages: caret, data.table, data.tree, and doParallel.

5.3 Evaluation Measures

In hierarchical classification problems, classes belonging to the levels furthest from the root node are generally more difficult to predict than classes associated with levels closest to the root node. In view of this, we assessed the quality

---

[4] https://www.r-project.org.

of the hierarchical classification approaches according to three hierarchical performance measures: (i) hierarchical Precision (hP), (ii) hierarchical Recall (hR), and (iii) hierarchical F-measure (hF). They are defined as follows:

$$hP = \frac{\sum_i |Y_i \cap \hat{Y}_i|}{\sum_i |\hat{Y}_i|} \quad (1) \qquad hR = \frac{\sum_i |Y_i \cap \hat{Y}_i|}{\sum_i |Y_i|} \quad (2)$$

$$hF = \frac{(\beta^2 + 1) \times hP \times hR}{\beta^2 \times hP + hR} \quad (3)$$

In Eqns. 1 and 2, $\hat{Y}_i$ denotes the set of labels predicted for a test example i and Y_i corresponds to the set of classes correct for this example. During the *hP* and *hR* computations, we need to discard the root node of the label hierarchy since, by definition, it is common to all the examples. The summations, in turn, are calculated over all the test examples.

As for Eqn. 3, β belongs to $[0, \infty)$ and refers to the importance assigned to the hP and hR values. Here, we established $\beta = 1$.

We must emphasize that the described measures are extended versions of the well-known metrics of precision, recall, and F-measure but tailored to the hierarchical classification scenario.

5.4 Results and Discussion

In order to check the performance of the hybrid method, we made comparisons with three other hierarchical classification approaches: FC, LCN, and LCL.

Our first evaluation criterion to be analyzed is predictive performance. Table 1 exhibits the three hierarchical performance measures obtained in the FMA dataset for the proposed method, as well as for the approaches used as baselines.

Performance measure	Hierarchical approaches			
	FC	LCN	LCL	Hybrid
hP	67.62	72.36	69.86	75.79
hR	66.10	71.96	69.46	77.38
hF	66.88	72.16	69.66	76.57

Table 1. Hierarchical predictive performance in % of the traditional approaches from the literature compared to our approach.

As shown in Table 1, the hybrid approach provided the best results, surpassing by a margin of approximately 4% the LCN scheme that is widely applied in the related literature. The poorest results came from the flat classifier. We expected this since such a model completely ignores the problem class hierarchy and, consequently, does not use domain knowledge to decompose the feature space of the problem in question into subproblems with a smaller number of classes.

After the predictive performance, our second evaluation criterion is runtime. In this work, runtime refers to learning time, *i.e.*, the time spent in inducing hierarchical classifiers over a dataset. Table 2 presents the runtime results achieved in the FMA dataset using both our proposal and the baseline approaches. We performed the tests on a server running 2.10 GHz Intel Xeon E5-2620 v4 processor (32-core) with 92GB RAM and operational system Debian 4.9.130-2 (64 bits) under the same processing conditions for all measurements. The times are indicated in minutes (min) or hours (h).

	Hierarchical approaches			
	FC	LCN	LCL	Hybrid
Learning time	48 min	92.44 h	4.41 h	3.53 h

Table 2. Time costs of the traditional approaches from the literature compared to our approach.

In Table 2, we can see that the hybrid method had a relatively shorter execution time than the LCN and LCL approaches. While LCN built 119 binary models and LCL four multiclass classifiers, our approach induced 27 models, 16 of which are multiclass and 11 binaries. We highlight that although our proposal has generated more classifiers than LCL, the induced models involved fewer examples and classes.

Even though the flat classifier's learning time was shorter than that of the hybrid method, the latter provided the best results in terms of predictive performance.

6. CONCLUDING REMARKS

In this paper, we introduced a novel approach for hierarchical music genre classification. The proposed method is based on combining local approaches to adapt the genre classification to more realistic hierarchies of music genre. Our results showed that the designed approach is better than the traditional ones in terms of predictive performance and execution time.

As future work, we intend to extend our method to deal with multiple labels in distinct paths in the hierarchy. Also, we plan to evaluate the use of different features and learning algorithms for the local classifications.

Finally, this research covered one real music genre hierarchy. As mentioned, distinct music platforms organize their labels in different ways. Thus, it is also our interest to perform a broad study on other real music genre structures to find specific contrivances that may aggregate information to improve hierarchical classifications in the context of music data.

ABSTRACT

Music source separation is a core task in music information retrieval which has seen a dramatic improvement in the past years. Nevertheless, most of the existing systems focus exclusively on the problem of source separation itself and ignore the utilization of other —possibly related— MIR tasks which could lead to additional quality gains. In this work, we propose a novel multitask structure to investigate using instrument activation information to improve source separation performance. Furthermore, we investigate our system on six independent instruments, a more realistic scenario than the three instruments included in the widely-used MUSDB dataset, by leveraging a combination of the MedleyDB and Mixing Secrets datasets. The results show that our proposed multitask model outperforms the baseline Open-Unmix model on the mixture of Mixing Secrets and MedleyDB dataset while maintaining comparable performance on the MUSDB dataset.

1. INTRODUCTION

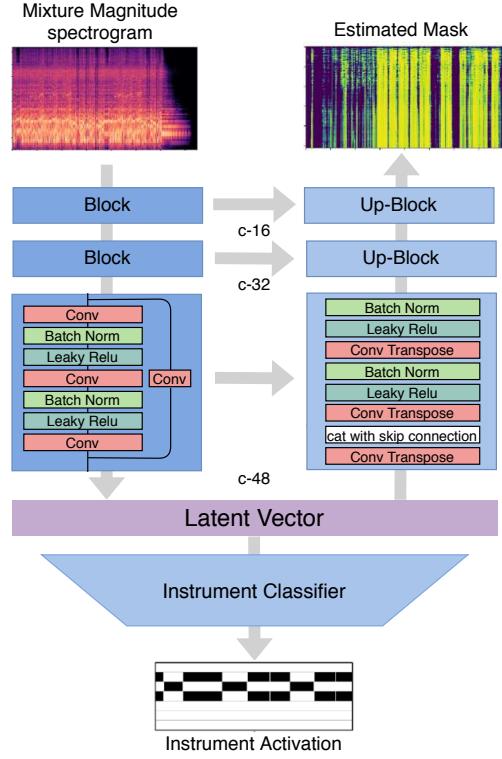
Music source separation has long been an important task for Music Information Retrieval (MIR) with numerous practical applications. By isolating the sound of individual instruments from a mixture of music, source separation systems can be used, for example, as a pre-processing tool for music transcription [22] or for audio remixing [37]. They also enable special applications such as the automatic generation of karaoke tracks by separating vocals from the accompaniment, stereo-to-surround upmixing, and instrument-wise equalization [1, 24].

Most of the current source separation systems use deep learning approaches to estimate a spectral mask for each independent instrument, then apply the mask to the mixture audio for separation. Although the utilization of deep learning has improved source separation performance dramatically, one problem of this approach is the limited amount of training data for the prevalent supervised learning approaches. More specifically, the datasets need to comprise

of the separated tracks of each instrument, which renders most easily accessible music data useless as it is already mixed. Multiple open-source datasets attempt to address this issue [5, 11, 17]. MUSDB [23] is nowadays the most frequently used dataset for the training and evaluation of source separation systems. In addition to the limited size, the main shortcoming of MUSDB is the limited number of instrument tracks: 'Bass,' 'Drums,' 'Vocals,' and 'Other.' Other datasets show other drawbacks, for instance, the iKala and MIR-1K datasets only contain short clips of music instead of complete songs [5, 11].

In addition to the data challenge, one potential issue with most existing music source separation systems is that they exclusively focus on the source separation task itself. Harnessing the information of other MIR tasks by incorporating them into source separation, however, has not been explored in-depth. For example, Instrument Activation Detection (IAD) can help determine which time frame contains the target instrument, while pitch detection can help determine which frequency bins are more likely to contain a harmonic series [13, 19]. This kind of multitask learning approach has been reported to be efficient for multiple other MIR tasks. Böck et al. achieve state-of-the-art performance for both tempo estimation and beat tracking by learning these two tasks at the same time [4]. Bittner et al. show that by estimating multi-f0, melody, bass line, and vocals at the same time, the system outperforms its single-task counterparts on all four tasks [2]. Similar results have been reported for simultaneously estimating score, instrument activation, and multi-f0 [12]. However, only recently was multitask learning successfully applied to source separation by combining it with pitch estimation [28].

In this paper, we propose a novel multitask learning structure to explore the combination of IAD and music source separation. By training for both tasks in an end-to-end manner, the estimated instrument labels can be used during inference as a weight for each time frame. The goal is both to suppress the frames not containing the target instrument and to correct a potentially incorrectly estimated mask. To increase the size of the available training data, we leverage two open-source large-scale multi-track datasets (MedleyDB [3] and Mixing Secrets [8]) in addition to MUSDB to evaluate on a larger variety of separable instruments. We refer to the combination of these two datasets as the *MM dataset*.

In summary, the main contributions of this work are


- the systematic investigation of the first multi-task source separation deep learning model that incorporates source separation with IAD in the spectral domain,

- the application of the IAD predictions during inference, and

- the presentation of the first open-source model that separates up to six instruments instead of the four tracks (3 independent instruments) featured by MUSDB.

2. RELATED WORK

State-of-the-art systems for music source separation are all based on deep learning due to proven superior performance. Uhlich et al. presented one of the pioneering works using a Deep Neural Network (DNN) architecture for music source separation [35], and Nugraha et al. used a DNN architecture and fully-connected layers for multichannel music source separation [21]. In the following years, more deep learning related systems were introduced. For example, Takahashi and Mitsufuji used recurrent neural networks to deal with temporal information [36], while others proposed the U-net structure for multiple separation tasks [14]. The U-net structure had been previously found useful for image segmentation [26] and treats the decomposition of a musical audio signal into the target and accompanying instrument tracks analogous to image-to-image translation. Takahashi et al. presented a dense LSTM that achieved the highest score in the SiSEC2018 [31] competition [34]. To preserve high resolution information, Liu and Yang introduced dilated 1-D convolution and a GRU network to replace pooling [16]. Different from other approaches using spectrograms as the input representation, Défossez et al. experimented on time-domain waveform source separation and showed that results comparable to spectrogram-based source separation systems are achievable [6]. "Spleeter," based on a U-net model structure, is currently regarded as one of the most powerful source separation systems [10]. It should be noted that —although the pre-trained model is freely available— Spleeter is trained on a proprietary, publicly unavailable dataset.

Stöter et al.'s "Open-Unmix" is frequently used as modern benchmark system on the MUSDB dataset [23]. It is a well documented open-source music source separation system with a recurrent architecture that achieves good separation results [32].

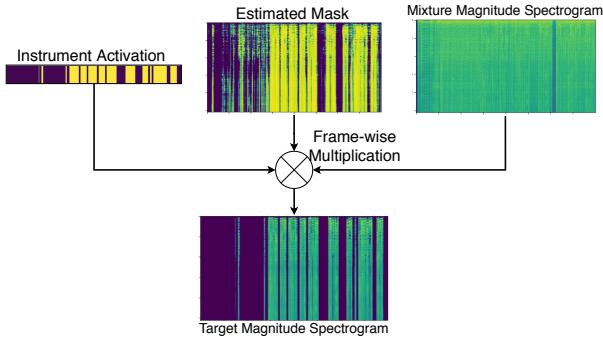
Most of the methods mentioned above are trained and evaluated on the open-source dataset used in SiSEC2018 competition [31]: MUSDB [23]. As mentioned above, one of the main problems of the MUSDB dataset is that it has only a limited amount of songs and instrument categories: it only includes three separable independent instruments. To include more separable instruments, Miron et al. proposed a score-informed system able to separate four classical instruments by training it on synthetic renditions [19]. However, their system is limited to classical music and requires the musical score for separation. While Spleeter is able to separate four independent instruments and Uhlich et al.


Figure 1. Multitask model structure for our proposed source separation system. Block is the residual block composed of convolutional layers while Up-Block is the residual block composed of transposed convolutional layers. "c" is the number of features.

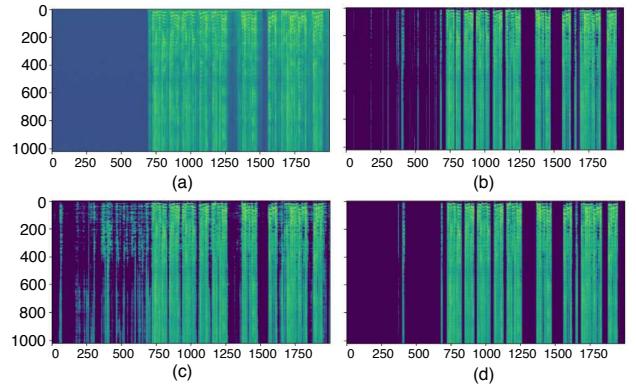
constructed a dataset which contains nine separable instruments [35], both their datasets are not publicly available.

To explore the possibility of separating unseen instruments, Seetharaman et al. proposed to use instrument class labels as a condition to cluster time-frequency bins for different instruments into the embedding space [28]. Their work showed that the system can also separate unseen instruments during testing by sampling from the learned embedding space. Lee et al. proposed to use audio queries for music separation [15]. The learned feature vector from the audio query acts as the condition to inform the separation of the target source. Manilow et al. introduced a multitask learning structure for source separation, instrument classification, and music transcription [18]. They showed that by jointly learning these three tasks, the source separation quality increased. Furthermore, the network seems to generalize better to unseen instruments. Other works such as [29, 33] combine instrument activity with source separation, however, they utilized either the predicted activity or ground truth as an input condition instead of learning in an end-to-end manner.

3. METHOD

We propose a U-net-based [27] multitask structure to incorporate instrument recognition with music source separation, which we refer to as Instrument Aware Source Separation (IASS) system. An overview of the model is shown in

Figure 2. Using instrument activation as a weight to filter the estimated mask, which will be used to multiply with the mixture of the magnitude spectrogram.

Figure 1. Although the multitask approach shows similarities with previous approaches (compare [18]), we design our model with a different goal: instead of just learning a joint representation using the multitask structure, our model uses estimated labels from multitask learning during inference to improve source separation estimation.


3.1 Model structure

The U-net structure has been found useful for image decomposition [26], a task with general similarities to source separation. The skip connections of U-net enable the model to learn from both high-level and low-level features leading to its success for music source separation [10, 14, 30].

Our model differs from previous U-net-based source separation systems by using a residual block instead of a CNN in each layer. The residual block allows the information from the current layer to be fed into a layer 2 hops away and deepens the structure. Each encoder and decoder contains three blocks with each block containing three convolutional or transposed convolutional layers, respectively, two batch normalization layers, and two leaky ReLU layers. The multitask objective is achieved by attaching a CNN classifier to the latent vector. This classifier predicts the instrument activity and has four transposed convolutional layers and three batch normalization layers in between. The last convolutional and transposed convolutional layers in each block feature a (3,1) filter size for up-sampling or down-sampling, while the others have a (3,3) filter size. During training, we use a Mean Square Error (MSE) loss for source separation and a Binary Cross-Entropy (BCE) loss for the prediction of the instrument activity. A hyperparameter α is manually tuned to balance these two loss functions:

$$L = L_{\text{MSE}} + \alpha L_{\text{BCE}}. \tag{1}$$

After successful training, the predicted instrument activity is used as a binary weight to multiply with the magnitude spectrogram along the time dimension. By doing so, the instrument labels are able to suppress the frames not containing any target instrument as shown in Figure 2. However, this binary instrument mask has two potential problems. First, false negatives of the predicted labels

Figure 3. First 2000 frames of the separated vocal track from the song *Angels In Amplifiers — I'm Alright* from the MUSDB-HQ dataset, visualizing different post-processing methods for applying instrument activity as a weight on the predicted magnitude spectrogram: (a) ground truth spectrogram, (b) predicted spectrogram without post-processing, (c) predicted spectrogram with raw predicted instrument labels as a weight, (d) predicted spectrogram with smoothed predicted instrument labels.

might mistakenly suppress wanted components in the spectrogram. Figure 3 (b) exemplifies that around frames 800 and 1000 with gaps caused by false negative prediction within a continuous sound. Even if the gaps have only a the length of a few milliseconds, it will have negative impact on the perceived quality. Second, the binary mask might cause repeated abrupt switching between silence and sound, which might lead to artifacts such as musical noise further decreasing the perceived quality. To address these problems, a median filter is applied to smooth the predicted instrument activities. The influence is discussed in Sect. 4.

An implementation of our system is publicly available online.[1]

3.2 Data representation

We extract magnitude spectrograms with a window length and hop size of 4096 and 1024 samples, respectively, at a sample rate of 44100 Hz for the input of our source separation model. The same magnitude spectrogram is extracted for the target audio reference. The instrument activity ground truth is at the frame level, meaning there is a binary label for each instrument to show whether the instrument is active or not in each time frame. Instrument labels have the same time resolution as the input spectrogram. We use the original activation probability computed by both datasets [3, 8], and binarize the activation with a threshold of 0.5 as suggested.

4. EXPERIMENT

To show the efficiency of our proposed model, we first compare our model with the baseline Open-Unmix model [32] on the MUSDB-HQ dataset. Note that we choose

Table 1. SDR score for IASS source separation performance with 3 and 4 residual blocks.

MUSDB-HQ instead of MUSDB because we want to obtain a high-quality separation system without potential coding artifacts. The audio of MUSDB is encoded in a lossy format while MUSDB-HQ provides the raw audio data. Other than that, there is no difference between the two datasets. However, since MUSDB-HQ is a newly released dataset it complicates comparing our results to other approaches directly as most of the previous systems have not been evaluated on the MUSDB-HQ dataset. Both the baseline and the proposed method are then evaluated on the MM dataset with six different instruments. For each source, a separate model is trained for both the baseline and our proposed method. Finally, an ablation study is conducted to investigate the impact of instrument labels and median filter on the source separation results. We train our models with the Adam optimizer with a learning rate of 0.001 and apply early stopping if the validation loss does not change for 100 epochs.

4.1 Dataset

Two open-source datasets, MUSDB-HQ [25] and the combination of Mixing Secrets [8] and MedleyDB [3] dataset (MM dataset) are used for the experiments. MUSDB is the most widely used dataset for music source separation and contains four separated tracks: 'Bass,' 'Drums,' 'Vocals,' and 'Others.' The dataset has 150 full-length stereo music tracks. We use the data split proposed by Stöter [32]: 86/14/50 songs for training, validation, and testing, respectively. Since data augmentation has been proven to be helpful [34], the following data augmentation is applied during the training. First, one track is randomly selected from each source and multiplied with a random gain factor ranging from 0.25 to 1.25. The starting point of each track is randomly chosen for chunking into a clip with length of 6 s. Finally, the chunked audio clips from each source are remixed for training. Since the original MUSDB-HQ dataset does not include instrument activation labels, we apply the energy tracking method proposed for MedleyDB [3] with a threshold of 0.5 to obtain the frame-level binary instrument activity labels.

The MM dataset contains 585 pieces of songs (330 from MedleyDB and 258 from Mixing Secrets) with more than 100 instruments and their individual tracks. We use the training and testing split proposed by Gururani et al. [9] for training (488 songs) and evaluating (100 songs) our system. The most frequently occurring 6 instruments are picked as target instruments: 'Bass,' 'Drums,' 'Vocals,' 'Electrical Guitar,' 'Acoustic Guitar,' and 'Piano.' One of the problems with this dataset is that not all of the songs provide parameters on how to remix the individual tracks into the mixture. Therefore, the volume of each track is adjusted

	Method	SDR	SIR	SAR	ISR
Vocals	Open-Unmix	6.11	13.21	6.75	12.43
	IASS	**6.46**	**14.70**	**6.98**	**14.30**
Bass	Open-Unmix	**4.48**	**8.23**	**5.40**	**10.29**
	IASS	4.18	7.30	4.52	6.85
Drums	Open-Unmix	5.02	10.17	6.05	10.55
	IASS	**5.56**	**10.74**	**6.86**	**10.92**
Other	Open-Unmix	**4.23**	**9.90**	3.88	7.34
	IASS	4.19	8.78	**4.70**	**9.32**

Table 2. BSS metrics for Open-Unmix and IASS on the MUSDB-HQ dataset.

to the same loudness (RMS) during training before applying the random gain as detailed above. In addition, each track is downmixed to a single channel. Furthermore, the data augmentation technique introduced above is applied to generate a large number of training samples from the MM dataset. We construct two separate groups of songs. One contains all the tracks including the target instrument, while another contains the tracks without the target instrument ("accompaniments"). There are total of 128 target tracks for 'Acoustic Guitar,' 189 for 'Piano,' 325 for 'Electrical Guitar,' 374 for 'Vocals,' 468 for 'Drums,' and 458 for 'Bass.' During training, we randomly select 1 to 5 tracks in the accompaniment pool to mix with the target instrument. By doing so, we can generate various combinations of training "songs." The random chunking approach applied to MUSDB-HQ is also applied on MM dataset. The testing set also balances the loudness of each track. We filter out the songs from the testing set which do not contain any of the 6 target instruments, resulting in 20 songs with 'Piano,' 23 songs with 'Acoustic Guitar,' 54 songs with 'Electrical Guitar,' 71 songs with 'Vocals,' 76 songs with 'Bass,' and 81 songs with 'Drums.'

4.2 Evaluation

To reconstruct the waveforms from the resulting magnitude spectrograms, we multiply the magnitude spectrogram with the phase of the original complex spectrograms and apply the inverse short-time Fourier transform on the complex spectrogram. We do not use any post-processing such as Wiener filtering here to focus on the raw result without potentially confounding quality gains in post-processing. Therefore, the Open-Unmix post-processing is disabled for the evaluation.

The quality of the source separation is evaluated with the four most frequently used objective metrics: source to distortion ratio (SDR), source to interference ratio (SIR), source to artifact ratio (SAR), and Image to Spatial distortion Ratio (ISR) [7]. We use the *museval* package for calculating the evaluation metrics [31].

4.2.1 Source separation on MUSDB-HQ

To allow for comparison with other systems trained on the MUSDB, the first experiment reports the result on MUSDB-HQ.

	Open-Unmix	IASS	IBM	input-SDR
Vocals	3.68	4.78	6.49	-6.24
Elecgtr	1.55	1.77	4.56	-5.90
Acgtr	0.95	1.29	3.38	-6.65
Piano	1.08	1.91	3.63	-6.31
Bass	4.04	5.26	5.34	-5.77
Drums	4.45	4.89	6.23	-6.05

Table 3. SDR score for Open-Unmix, IASS, an ideal binary mask and input-SDR.

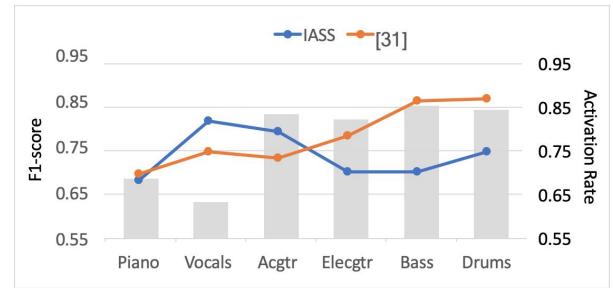
In a first preliminary experiment we investigate whether adding more residual blocks influences the performance of the proposed method. We report the SDR score for the four sources of the MUSDB-HQ dataset in Table 1. The performance with three residual blocks and with four residual blocks is comparable on all instruments. For training efficiency, we use three residual blocks in the following experiment.


Table 2 shows the results of our proposed model compared to Open-Unmix. Our model outperforms the Open-Unmix model on 'Vocals' and 'Drums', performs equally on 'Other', and slightly worse on 'Bass'. This might be because 'Bass' most likely to appear throughout the songs. As a result, the improvement of using the instrument activation weight is limited. The imbalanced activity might also impact the instrument classifier.

4.2.2 Source separation on MM

The results for the MM dataset are summarized in Table 3. We re-trained the Open-Unmix model on the MM dataset by using the default training setting provided with their code. The results for the Ideal Binary Mask (IBM) (source code [31]) represent the best case scenario. The worst case scenario is represented by the results for input-SDR, which is the SDR score when using mixture as the input. Compared to MUSDB-HQ, the MM dataset has a larger amount of training data. It can be observed from Table 3 that our proposed model generally achieves better source separation performance on six instruments. We can also observe a trend that both models have higher scores on 'Drums,' 'Bass,' and 'Vocals' than on 'Electrical Guitar,' 'Piano,' and 'Acoustic Guitar.' This might be attributed to the fact that 'Guitar,' 'Piano,' and 'Acoustic Guitar' have fewer training samples (cf. Sect. 4.1). Another possible reason is that the more complicated spectral structure of polyphonic instruments such as 'Guitar' and 'Piano' make the separation task more challenging.

4.2.3 Instrument activity detection

While our system's source separation performance was the primary concern, the accuracy of the instrument predictions is also of interest. Our classifier output is compared to the model proposed by Gururani et al. [9], which was trained and evaluated on the same MM dataset. Note that this comparison is still not completely valid as their system uses multi-label prediction while our model is single-label.

Figure 4. IAD result for both Gururani et al.'s method (orange) and our IASS (blue) with label aggregation. Indicated in gray is the activation rate (percentage of the training frames containing positive activity labels).

Still, it can provide some insights into how well our system predicts the instrument activity. As Gururani et al.'s system predicts instrument labels with a time resolution of 1 s, the output resolution of our prediction has to be reduced. For each second, all the estimated activations are aggregated by calculating their median. Furthermore, instrument subcategories from their work are combined. For example, female and male singers are combined into 'Vocals,' electrical bass and double bass are combined into 'Bass,' electrical and acoustic piano are combined into 'Piano' and clean and distorted electrical guitar are combined into 'Electrical Guitar.' We report the AUC score in Figure 4.

We can make the following observations. First, 'Piano,' 'Electrical Guitar,' and 'Bass' tend to have lower detection rates. This might be because all these instrument categories include both acoustic and electric instruments which the model might easily confuse with the background music. This might also influence the source separation performance. The result can explain that in Table 4, 'Vocals' have the highest increase in the average score when applying instrument labels since 'Vocals' has better instrument detection accuracy. In contrast, 'Bass' has a lower increase since it has poorer instrument detection results. Second, from Figure 4 we can observe that 'Vocals' and 'Piano' have a lower activation rate, which means the model has fewer sound samples containing 'Vocals' and 'Piano' during training. This aligns with the highest SIR score increase on 'Vocals' and 'Piano' in Table 4 when instrument activation is added, since instrument activation can help suppress the interference at the non-active frames. This also shows the potential of our model to be used on instruments which only appear in the song infrequently.

4.3 Ablation study

In this experiment, we investigate the impact of the instrument labels on our model. First, the IASS model is trained and evaluated without using instrument labels, i.e., as a standard U-net without instrument classifier on the latent vector. The model will only be updated by the MSE between the ground-truth magnitude spectrogram and predicted spectrogram ($\alpha = 0$). For testing, all instrument "predictions" are set to 1. Second, the IASS model is trained

Table 4. Ablation study for IASS source separation performance training and evaluating with (✓) or without (✗) instrument labels.

with instrument labels but evaluated without instrument labels. This is a traditional multitask scenario: the model will be trained with both the MSE and the BCE losses in Eq. (1). However, during evaluation, the output magnitude spectrogram is not weighted by the instrument activity (predictions equal 1). Third, we include the IASS results from Table 3 —computed with both losses and using the instrument predictions as mask weights— for convenience.

The results are shown in Table 4. It can be observed that using instrument labels as a weight generally leads to a better performance than without using instrument labels. The result also somewhat unexpectedly shows that training with instrument detection loss influences source separation performance, as the average quality score is often lower when training with the multitask loss. One possible reason for this is that adding the IAD sub-task forces more information to be passed to the bottom layers, where the resolution is compressed. We argue, however, that the multitask learning structure does bring an extra benefit to the system: using the instrument activity predictions as a weight leads to better separation quality. Figure 3 visualizes the effect on one of the songs from the MUSDB-HQ dataset. This song does not have any vocals before 16 s, which is around time frame 700. Subfigure (a) shows the ground truth magnitude spectrogram before applying instrument labels while (c) and (d) show the predicted spectrograms after applying the instrument activations or the smoothed instrument activations, respectively. Both the false positive predictions in the beginning before time frame 700 as well as the false negative predictions around frames 800 and 1000 have been repaired by using smoothed activations. This result is consistent with the results in Table 4 where SIR has the highest increase: interferences are more successfully suppressed.

Furthermore, we investigate the influence of median

Figure 5. Ablation study for IASS source separation performance with or without median filter on instrument labels. The orange bar shows the increase of the average score (average of SDR, SIR, and SAR) after applying median filtering. Gray shows the average score increase when using instrument ground truth labels instead of estimated labels.

filtering the predicted instrument activity on our results. Figure 5 shows the performance of our proposed source separation model with and without applying the median filter on the predicted instrument activities. Using the median filter generally increases performance across all instruments as it eliminates spurious prediction errors.

Finally we are using the oracle ground truth labels instead of the estimated labels as the weight. As we can observe from Figure 5, using the ground truth labels brings an average score increase in all instruments, especially for vocals and piano. This can be seen as the upper-bound best case scenario of our instrument-activity-weighted model and emphasizes the potential for improvement when combining instrument prediction with source separation.

5. CONCLUSION

In this paper, we proposed a novel multitask structure combining instrument activation detection with multi-instrument source separation. We utilize a large dataset to evaluate on various instruments and show that our model achieves equal or better separation quality than the baseline Open-Unmix model. The ablation study also shows that using instrument activation as a weight is able to correct the false estimation from the source separation task and improve source separation performance. In summary, the main contributions of this work are the proposal of a multitask learning structure combining IAD with source separation, and insights into using new open-source datasets to increase the number of separable instrument categories.

We have identified several directions for future extensions of this model. First, we plan to increase the number of target instruments by combining synthesized data with the MM dataset especially for underrepresented instrument classes. Second, we plan to incorporate other tasks, such as multi-pitch estimation, into our current multi-task structure [20]. Third, we will explore using multi-label instrument detection to separate multiple instruments at the same time. Lastly, we will explore post-processing methods such as Wiener filter to improve our system's quality.

ABSTRACT

Deep learning algorithms are increasingly developed for learning to compose music in the form of MIDI files. However, whether such algorithms work well for composing guitar tabs, which are quite different from MIDIs, remain relatively unexplored. To address this, we build a model for composing fingerstyle guitar tabs with Transformer-XL, a neural sequence model architecture. With this model, we investigate the following research questions. First, whether the neural net generates note sequences with meaningful note-string combinations, which is important for the guitar but not other instruments such as the piano. Second, whether it generates compositions with coherent rhythmic groove, crucial for fingerstyle guitar music. And, finally, how pleasant the composed music is in comparison to real, human-made compositions. Our work provides preliminary empirical evidence of the promise of deep learning for tab composition, and suggests areas for future study.

1. INTRODUCTION

Thanks to the cumulative efforts in the community, in recent years we have seen great progress in using deep learning models for automatic music composition [8]. An important body of research has been invested on creating piano compositions, or more generally keyboard style music. For instance, the "Music Transformer" presented by Huang *et al.* [19] employs 172 hours of piano performances to learn to compose classical piano music. Another group of researchers extends that model to generate pop piano compositions from 48 hours of human-performed piano covers [20]. They both use a MIDI-derived representation of music and describe music as a sequence of event tokens such as `NOTE-ON` and `NOTE-VELOCITY`. While the MIDI format works the best for representing keyboard instruments and less for other instruments (for reasons described below), Donahue *et al.* [14] and Payne [31] show respectively that it is possible for machines to learn from a set of MIDI files to compose multi-instrument music.

There are, however, many other forms of musical notation that are quite different from the staff notation assumed by keyboard music. For example, the tabulature, or "tab" for short, is a notation format that indicates instrument fingering rather than musical pitches. It is common for fretted stringed instruments such as the guitar and ukulele, and free reed aerophones such as the harmonica. It makes more sense for people playing such instruments to read the tabs, as they suggest how to move the fingers.

Figure 1. An example of fingerstyle guitar tab composed by human, along with the corresponding staff notation.

As shown in Figure 1, a tab contains information such as the fingering configuration on the fretboard (six strings for the case of the guitar) as well as usage of the left-hand or right-hand playing techniques. Such information is usually missing in the corresponding staff notation and MIDI files. Learning to automatically compose guitar music directly from MIDI files, though possible, has the limitation of ignoring the way people play these instruments. However, to our best knowledge, little has been done to use tabs to train a deep generative model.

To investigate the applicability of modern deep learning architectures for composing tabs, we compile a new dataset of 333 TAB files of "fingerstyle guitar" (including originally fingerstyle guitar music and fingerstyle adaptation) [3], and modify the data representation of the Music Transformer [19] to make the extended model learn to compose guitar tabs. With this model, we aim to answer three research questions (RQs):

- Whether the neural network learns to generate not only the note sequences but also the fingering of the notes to be played on a fretboard, from reading only the tabs (instead of, for example, watching videos demonstrating how people play the guitar)?

- Whether the neural network generates compositions with coherent "groove," or the use of rhythmic patterns over time [13, 32, 39]? It is generally assumed that the layers of a neural network learn abstractions of data on their own to perform the intended

task, e.g., to predict the next events given the history. However, in music, groove is usually indirectly implied according to the arrangement of notes along the time axis, instead of explicitly specified in either a MIDI or TAB file. Therefore, it remains to be studied whether the model can do better if it has to explicitly handle bar-level GROOVING events, inserted into the training data as a high-level information in some way, or if such a modification is not needed. This is in particular relevant in the context of fingerstyle composition, as in fingerstyle a guitarist has to take care of the melody, chord comping, bass line and rhythm simultaneously [3].

- Finally, how the compositions generated by the neural network compare with human-composed guitar tabs, when both rendered into audio waveforms and presented to human listeners? This gives us a direct evaluation of the effectiveness of the neural network in modeling guitar music.

We provide audio rendition of examples of the generated tabs (using a guitar synthesizer of a DAW called Ample Sound [1]) at `https://ss12f32v.github.io/Guitar-Transformer-Demo/`, along with a video recording of a guitarist playing a generated tab.

In what follows, we review some related work in Section 2, and then present the tab dataset in Section 3. After that, we describe in Section 4 the methodology for modeling and learning to compose guitar tabs. We present the result of objective and subjective evaluations addressing the aforementioned research questions in Section 5.

2. RELATED WORK

2.1 Guitar-related Research in MIR

In the music information retrieval (MIR) community, research concerning guitar is often related to automatic guitar transcription [5, 7, 9, 16, 18, 21, 22, 27, 34, 46] and playing technique detection [4, 10, 37, 38]. For example, Su *et al.* [38] built a convolution neural network (CNN) model for detecting the playing techniques associated with the string-pressing hand, and incorporated that for transcribing audio recordings of unaccompanied electric guitar performances. Rodríguez *et al.* [34] presented a model for transcribing Flamenco guitar falsetas, and Abeßer and Schuller [5] dealt with the transcription of solo bass guitar recordings. We note that, while automatic transcription concerns with recovering the tab underlying an audio guitar performance, our work deals with automatic composition of original guitar tabs in the symbolic domain, and therefore does not consider audio signals.

As there are multiple fret positions to play the same note on a guitar, it may not be easy for a novice guitar learner to play a guitar song without the corresponding tab. Automatic suggestion of the fingering given a human-made "lead sheet," a symbolic format that specifies the melody and chord sequence but not their fingering, has therefore been a subject of research. Existing work has explored the use of hidden Markov models, genetic algorithm, and

neural networks to predict the fingering by examining its playing difficulty for a guitarist, viewing the task as an optimal path finding problem [6, 28, 35, 40]. While such prior arts can be considered as performing a MIDI-to-TAB conversion, our work aims to model TABs directly.

Xi *et al.* developed the GuitarSet [45], a set of 360 audio recordings of a guitar equipped with the hexaphonic pickup. The special pickup is able to capture the sound from each string individually, making it possible for a model to learn to perform multipitch estimation and tabulature fingering arrangement at the same time. Using the dataset, Wiggins and Kim [43] built such a model with CNN, achieving 0.83 F-score (i.e., the harmonic average of precision and recall) for multipitch estimation, and 0.90 for identifying the string-fret combinations of the notes. While the dataset is relevant for guitar transcription, its recordings are all around 12–16 bars in length only, which seems to be too short for deep generative modeling.

McVicar *et al.* [24–26] used to build sophisticated probabilistic systems to algorithmically compose rhythm and lead guitar tabs from an input chord and key sequence. Our work differs from theirs in that we aim to build a general-purpose tab composition model using modern deep generative networks. An extra complexity of our work is that we experiment with fingerstyle guitar, a type of performance that can be accomplished by a single guitarist.

2.2 Transformer Models for Automatic Composition

The Transformer [41] is a deep learning model that is designed to handle ordered sequences of data, such as natural language. It models a word sequence $(w_1, w_2, \ldots w_T)$ seen in the training data by factorizing the joint probability into a product of conditionals, namely, $P(w_1) \cdot P(w_2|w_1) \cdot \cdots \cdot P(w_T|w_1, \ldots, w_{T-1})$. During the training process, the model optimizes its parameters so as to correctly predict the next word w_t given its preceding history $(w_1, w_2, \ldots w_{t-1})$, for each position t in a sequence.

Following some recent work on recurrent neural network (RNN)-based automatic music composition [29, 42], Huang *et al.* [19] viewed music as a language and for the first time employed the Transformer architecture for modeling music. Given a collection of MIDI performances, they converted each MIDI file to a time-ordered sequence of musical "events," so as to model the joint probability of *events* as if they are *words* in natural language (see Section 4.1 for details of such events). The Transformer with relative attention was shown to greatly outperform an RNN-based model, called PerformanceRNN [29], in a subjective listening test [19], inspiring the use of Transformer-like architectures, such as Transformer or Transformer-XL [12], in follow-up research [11, 14, 20, 31, 44]. [1]

There are lots of approaches to automatic music composition, deep learning- and non-deep learning based included [8, 15, 30]. We choose to consider only the Transformer architecture here, to study whether we can translate its strong result in modeling MIDIs to modeling TABs.

---

[1] We note that it is debatable whether music and language are related. We therefore envision that some other new architectures people will come up with in the future might do a much better job than Transformers in modeling music. This is, however, beyond the scope of the current work.

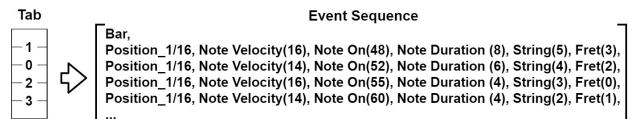
	# tabs	# bars	# bars per tab	# events per tab
training	303	24,381	80±41	5,394±3,116
validation	30	2,593	74±35	5,244±3,183

Table 1. Statistics of the dataset; the last two columns show the mean and standard deviation values across each set. Please see Table 2 for definitions of the events.

3. FINGERSTYLE GUITAR TAB DATASET

There have been some large-scale MIDI datasets out there, such as the Lakh MIDI dataset [33] and BitMidi [2]. The former, for example, contains 176,581 unique MIDI files of *full songs*. In contrast, existing datasets of tabs are usually smaller and shorter, as they are mainly designed for learning the mapping between tabs and audio (i.e., for transcription research), rather than for generative modeling of the structure of tabs. The tabs in the GuitarSet [45], for example, are performances of *short excerpts of songs*, typically 12–16 bars in length, which are not long.

For the purpose of this research, we compile a guitar tab dataset on our own, focusing on the specific genre of fingerstyle guitar. Specifically, we collect digital TABs of *full songs*, to facilitate language modeling of guitar tabs. We go through all the collected TABs one-by-one and filter out those that are of low quality (e.g., with wrong fingering, obvious annotation errors), or are not fingerstyle (e.g., have more than one tracks). We also discard TABs that are not in standard tuning, to avoid inconsistent mapping between notes and fingering. As shown in Table 1, this leads to a collection of 333 TABs, each with around 80 bars. This includes TABs of famous professional fingerstyle players such as Tommy Emmanuel and Sungha Jung. All the TABs are in 4/4 time signature, and they can be in various keys. We reserve 30 TABs for validation and performance evaluation, and use the rest for training.

Please note that, similar to the MIDI files available in Lakh MIDI [33], the TAB files we collect do not contain *performance* information such as expressive variations in dynamics (i.e., note velocity) and micro-timing [23, 29]. To increase velocity variation, we use Ample Sound [1] to add velocity to each note by its humanization feature. We do not deal with micro-timing in this work.


3.1 Fingerstyle

It is interesting to focus on only fingerstyle guitar in the context of this work, as we opt for validating the effectiveness of Transformers for single-track TABs first, before moving to modeling multi-track performances that involve at least a guitar (e.g., a rock song). We give a brief introduction of fingerstyle guitar below.

Fingerstyle [3] is at first a term that describes using fingertips or fingernails to pluck the strings to play the guitar. Nowadays, the term is often used to describe an arrangement method to blend multiple parts of musical elements or tracks, which are initially played by several instruments, into the composition of one guitar track. Therefore, a guitarist playing fingerstyle has to simultaneously take care of

category/type	description
NOTE-ON	45 different pitches (E2–C6)
NOTE-DURATION	multiples of the 32th note (1–64)
NOTE-VELOCITY	note velocity as 32 levels (1–32)
POSITION	temporal position within a bar; multiples of the 16th note (1–16)
BAR	marker of the transition of bars
STRING	6 strings on a tab
FRET	20 fret positions per string
TECHNIQUE	5 playing techniques: slap, press upstroke, downstroke, and hit-top
GROOVING	32 grooving patterns

Table 2. The list of events adopted for representing a tab as an event sequence. The first five are adapted from [19,20], whereas the last four are tab-specific and are new. We have in total 45+64+32+16+1+6+20+5+32=231 unique events.

Figure 2. An example of the result of "TAB-to-event" conversion needed for modeling a tab as a sequence. Here, we show the resultant event representation of a C chord.

the melody line, bass line, chord comping and the rhythmic groove. Groove, in particular, is important in fingerstyle, as it is now only possible to work on the rhythmic flow of music with a single guitar and the use of the two hands. We hence pay special attention to groove modeling in this work (see Section 4.3).

4. MODELING GUITAR TABS

In this section, we elaborate how we design an event representation for modeling guitar tabs, or more generally tabs of instruments played by string strumming.

4.1 Event Representation for MIDIs: A Quick Recap

In representing MIDIs as a sequence of "events," Huang *et al.* [20] considered, amongst others, the following event tokens. Each note is represented by a triplet of NOTE-ON, NOTE-DURATION, and NOTE-VELOCITY events, representing the MIDI note number, quantized duration as an integer multiple of a *minimum duration*, and discrete level of note dynamics, respectively. The minimum duration is set to the 32th note. The onset time of the notes, on the other hand, is marked (again after quantization) on a time grid with a specific *resolution*, which is set to the 16th note as in [19]. Specifically, to place the notes over the 16-th note time grid, they use a combination of POSITION and BAR events, indicating respectively the position of a note onset within a bar, among the 16 possible locations, and the beginning of a new bar as the music unfolds over time. This

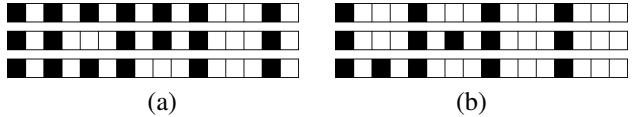
event representation has been shown effective in modeling pop piano [20]. We note that the time grid outlined with this combination of POSITION and BAR events can also contribute to modeling the rhythm of fingerstyle guitar.

4.2 Event Representation for Tabs

To represent TABs, we propose to add, on top of the aforementioned five types of events for MIDIs,[2] the following three new types of fingering-related events: STRING, FRET, TECHNIQUE, and a type of rhythm-related events: GROOVING. We introduce the first three below, and the last in the next subsection. Table 2 lists all the events considered, whereas Figure 2 gives an example of how we represent a C chord with such an event representation.

We use the first 20 frets of the 6 strings in the collected TABs, i.e., each string can play 20 notes. The pitch range of the strings overlaps, so a guitarist can play the same pitch on different strings, with moderate but non-negligible difference in timbre. The fingering of the notes also affects playability [46]. In standard tuning, the strings can play 45 different pitches, from E2 to C6.

In our implementation, we adopt the straightforward approach to account for the various possible playing positions of the notes—to add STRING and FRET tokens right after the NOTE-ON tokens in the event sequence representing a tab. We note that the FRET tokens are actually *redundant*, in that the combination of NOTE-ON and STRING alone is sufficient to determine the fret position to use. However, in pilot studies we found the inclusion of FRET makes the model converges faster at the training time.

Specifically, instead of a 3-tuple representation of a note as the case in MIDIs, we use a 5-tuple note representation that consists of successive tokens of NOTE-VELOCITY, NOTE-ON, NOTE-DURATION, STRING and FRET for TABs. As such five tokens always occur one after another in the training sequences, it is easy for a Transformer not to miss any of them when generating a new NOTE-ON event at the inference time, according to our empirical observation of the behavior of the Transformers.


However, as we do not impose constraints on the association between NOTE-ON and STRING, it remains to be studied whether a Transformer can learn to compose tabs with reasonable note-string combinations. This is the subject of the **1st RQ** outlined in Section 1.

As for the TECHNIQUEs, we consider the following five right-hand techniques: slap, press, upstroke, downstroke, and hit-top, which account for ∼1% of the events in our training set. The inclusion of other techniques, such as sliding and bending, is left as a future work.

Similar to [19, 20], we consider the 16th note as the resolution of onset times, which is okay for 4/4 time signature. Increasing the resolution further to avoid quantization errors and to enhance expressivity is also left to the future.

4.3 Groove Modeling

Groove can be in general considered as a rhythmic feeling of a changing or repeated pattern, or "humans' pleasurable

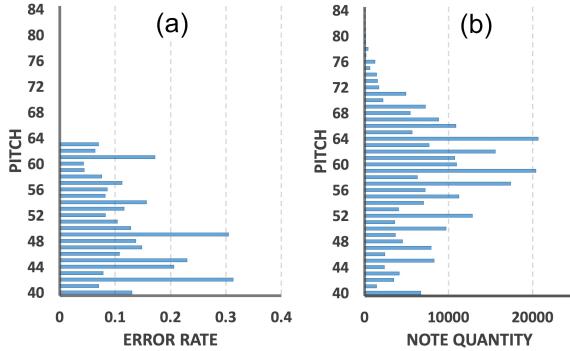
---

[2] Huang *et al.* [20] actually considered the Chord and Tempo events additionally; we found these two types of event less useful in modeling tabs, according to preliminary experiments.

(a)   (b)

Figure 3. Samples of 16-dim hard grooving patterns assigned to 2 different clusters (a), (b) by $k$means clustering.

urge to move their bodies rhythmically in response to music" [36]. Unlike the note-related or time-related events, groove is usually *implicitly* implied as a result of the arrangement of note onsets over time, instead of be explicitly specified in either a MIDI or TAB file. Hence, it might be possible for a Transformer to learn to compose music with reasonable groove, without we *explicitly* inform it what groove is. We refer to this baseline variant of our Transformer as the **no grooving** version, which considers all the events listed in Table 2 but GROOVING.

However, as a tab is now represented as a sequence of events, it is possible to add groove-related events to help the model make sense of this phenomenon. Since our event representation has the BAR events to mark the bar lines, we can ask the model to learn to generate a "bar-level" GROOVING event right after a BAR event, before proceeding to generate the actual content of the bar. Whether such a groove-aware approach benefits the quality of the generated tabs is the subject of our **2nd RQ**.


To implement such an approach, we need to come up with 1) a bar-level grooving representation of symbolic music, and 2) a method to convert the grooving representation, which might be a vector, to a discrete event token.

In this work, we represent groove by the *occurrence of note onset* over the 16-th time grid, leading to the following four grooving representations of music.

- **Hard grooving**: A 16-dim binary vector marking the presence of (at least one) onset per each 16 positions of a bar. A popular pattern in our dataset, for example, is $[1, 0, 0, 0, 1, 0, 0, 0, 1, 0, 0, 0, 1, 0, 0, 0]$, meaning onsets on beats only.

- **Soft grooving**: A soft version that considers the number of onsets (but disregarding the velocity values) for each position, normalized by the maximum in the bar, leading to a 16-dim real-valued vector.

- **Multi-resolution hard (or soft) grooving**: Variants of the last two that additionally consider corresponding down-sampled 8-dim and 4-dim vectors to emphasize the beats (e.g., counting only the onsets on beats), and then concatenate the vectors together, yielding a 28-dim vector (i.e., 16+8+4).

To convert the aforementioned grooving patterns to events, a discretization is needed. Among various possible approaches, we experiment with the simplest idea of grouping the grooving patterns seen in the training set into a number of clusters. We can then use the ID of the cluster a grooving pattern is associated with for the GROOVING event of that grooving pattern. For simplicity, we employ the classic $k$means algorithm [17] here, setting k to 32. Please see Figure 3 for an example of the clustering result.

Figure 4. Distributions of (a) the error rate for each note in the string arrangement prediction of our model, and (b) the counts of each note in the training set.

	string (high-pitched ↔ low-pitched)					
	1st	2nd	3rd	4th	5th	6th
(a) accuracy	100%	99%	97%	94%	91%	90%
(b) pitch 42	∼0%	∼0%	10%	∼0%	27%	63%
(c) pitch 57	∼0%	6%	65%	26%	∼0%	∼0%
(d) pitch 69	85%	14%	∼0%	∼0%	∼0%	∼0%

Table 3. (a) The average accuracy of our model in associating each `STRING` with a `NOTE-ON`, broken down by string; (b–d) The string-relevant output probability estimated by our model for three different pitches.

4.4 Transformer-XL-based Architecture

Following [14, 20], we use the Transformer-XL [12] for the architecture of our model. Unlike the Transformer used in [19], the Transformer-XL gains a longer receptive filed with a segment-level recurrence mechanism, thereby seeing further into the history and benefiting from the extended memory. We base our implementation on the open source code of [20], adopting many of their settings. For example, we also set the sequence length and recurrence length to 512 events, and use 12 self-attention layers and 8 attention heads. The model has in total ∼41M trainable parameters. The training process converges within 12 hours on a single NVIDIA V100 GPU, with batch size 32.

5. EVALUATION

5.1 Experiment 1: On Fingering

The 1st RQ explores how a Transformer learns the association between notes and fingering, without human-assigned prior knowledge/constraints on the association. For simplicity, we use the **no grooving** variant of our model here.

A straightforward approach to address this RQ is to let the model generates randomly a large number of event sequences (i.e., compositions) and examine how often it generates a plausible `STRING` event after a `NOTE-ON` event. Table 3(a) shows the average note-string association accuracy calculated from 50 generated 16-bar tabs, broken down into six values according to `STRING`. To our mild disappointment, the accuracy, though generally high, is not

	Hard accuracy ↑		Soft distance ↓	
	mean	max	mean	min
hard grooving	76.2%	82.4%	56.3	44.6
soft grooving	76.9%	83.0%	**56.2**	**43.7**
multi-hard	**79.0%**	**85.7%**	57.8	44.3
multi-soft	74.6%	81.1%	64.7	52.9
no grooving	70.0%	80.1%	58.6	47.7
training data	**82.1%**	**89.5%**	**43.8**	**28.6**
random	64.9%	71.3%	70.6	59.6

Table 4. Objective evaluation on groove coherence.

perfect. This indicates that some post-processing is still needed to ensure the note-string association is correct.

As Table 3(a) shows larger errors toward the 6th string, we also examine how the errors distribute over the pitches. Interestingly, Figure 4(a) shows that the model makes mistakes only in the low end; the fingering prediction is good for pitches (i.e., MIDI numbers) from 64 to 84.

It is hard to find out why exactly this is the case, but we present two more observations here. First, we plot in Figure 4(b) the popularity of these pitches in the training set. The Pearson correlation coefficient between the note quantity and the error rate is weak, at 0.299, suggesting that this may not be due to the sparseness of the low-pitched notes. Second, we show in Table 3(b)–(d) the note-string association output probability estimated by our model for three different pitches. Interestingly, it seems the model has the tendency to use neighboring strings for each pitch. For example, pitch 42 is actually a bass note playable on the 6th string, and it erroneously "leaks" mostly to the 5th string.

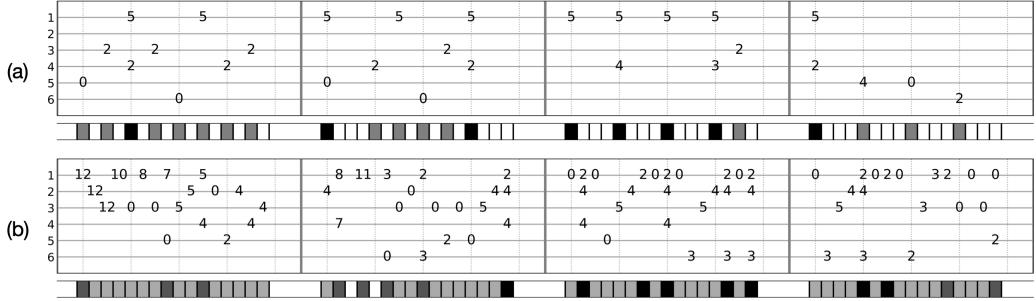
5.2 Experiment 2: On Groove


Figure 5 gives two examples of tabs generated by the hard grooving model. It seems the grooving is consistent across time in each tab. But, how good it is?

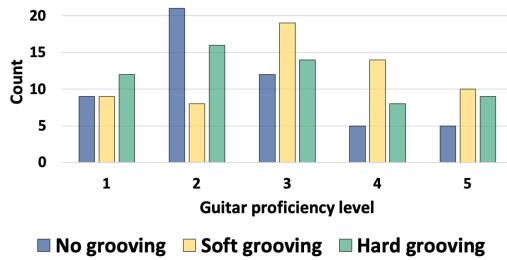
The 2nd RQ tests whether the added `GROOVING` events help a Transformer compose tabs with better rhythmic coherence. We therefore intend to compare the performance of models trained with or without `GROOVING` for generating "continuations" of a given "prompt."


We consider both objective and subjective evaluations here. For the former, we compare the models trained with `GROOVING` events obtained with each of the four vector-quantized grooving representations described in Section 4.3. We ask the models to generate 16-bar continuations following the first 4 bars of the 30 tabs in the validation set. The performance of the models is compared against that of the 'no-grooving' baseline, the 'real' continuations (of these 30 tabs), and a 'random' baseline that picks the next 16 bars from another tab at random from the validation set. The last two are meant to set the high-end and low-end performances, respectively. For fair comparison, we also project the note onsets of the validation data onto the 16th-note grid underlying our training data.

We consider the following two simple objective metrics:

- **Hard accuracy**: Given the hard grooving patterns $\mathbf{X} = (\mathbf{x}_1, \ldots, \mathbf{x}_N)$ of the prompt, and those of the

Figure 5. Segments of 2 tabs randomly generated by the hard grooving model; below each tab—the soft grooving patterns.

Figure 6. Result of the first user study asking subjects to choose the best among the three continuations generated by different models, with or without GROOVING, given a man-made prompt. The result is broken down according to the self-report guitar proficiency level of the subjects.

continuation $\mathbf{Y} = (\mathbf{y}_1, \ldots, \mathbf{y}_M)$, where both $\mathbf{x}_i$ and $\mathbf{y}_j$ are in $\{0,1\}^K$, $N = 4$, $M = 16$, $K = 16$, we compare the similarity between $\mathbf{X}$ and $\mathbf{Y}$ by

$$\text{mean}_{i=(1,\ldots,N)} \frac{1}{MK} \sum_{j=1}^{M} \sum_{k=1}^{K} \text{XNOR}(x_i^{(k)}, y_j^{(k)}), \tag{1}$$

where $\text{XNOR}(\cdot, \cdot)$ returns, element-wisely, whether the k-th element of $\mathbf{x}_i$ and $\mathbf{y}_j$ are the same. Alternatively, we replace the mean aggregator by $\max$, to say it is good enough for $\mathbf{y}_j$ to be close to any $\mathbf{x}_i$.

- **Soft distance**: We consider instead the soft grooving patterns $\tilde{\mathbf{x}}_i$ and $\tilde{\mathbf{y}}_j$, and compute the distance between them as $\text{mean}_{i=(1,\ldots,N)} \frac{1}{M} \sum_{j=1}^{M} \|\tilde{\mathbf{x}}_i - \tilde{\mathbf{y}}_j\|_2^2$. We can similarly replace mean by the $\min$ function.

Table 4 shows that, consistently across different metrics, groove-aware models outperform the no-grooving model. Moreover, the scores of the groove-aware models are closer to the high end than to the low end. It is also important to note that, there is still a moderate gap between the best model's composition and the real data, which has to be further addressed in the future work.

Figure 6 shows the result of the subjective evaluation, where we present the audio rendition (using a guitar synthesizer) of the aforementioned 16-bar continuations to human listeners, and ask them to choose the one they like the most, among those generated by the 'no-grooving,'

	Real	No grooving	Hard grooving
MOS	3.48±1.16	2.80±1.03	3.43±1.12

Table 5. Result of the second user study (in mean opinion score, from 1 to 5) comparing audio renditions of real tabs and machine-composed tabs by two variants of our model.

'soft-grooving,' and 'hard-grooving' models. We divide the response from 57 participants by their self-report proficiency level in guitar. Figure 6 shows that professionals are aware of the difference between groove-aware and no-grooving models. According to their optional verbal response, groove-aware models continue the prompts better, and generate more pleasant melody lines.

5.3 Experiment 3: On Comparison with Real Tabs

Finally, our last RQ involves another user study where we ask participants to rate, on a Likert five-point scale how they like the audio rendition of the continuations, this time including the result of real continuations. For groove-aware models, we consider hard-grooving only, for its simplicity and also for reducing the load on the subjects. Much to our surprise, the average result from 23 participants (see Table 5) suggests that hard-grooving compositions are actually on par with real compositions. We believe this result has to be taken with a grain of salt, as it concerns with only fairly short pieces (i.e., 16 bars) that do not contain performance-level variations. Yet, it provides evidence showing the promise of deep learning for tab composition.

6. CONCLUSION

In this paper, we have presented a series of evaluations supporting the effectiveness of a modern neural sequence model, called Transformer-XL, for automatic composition of fingerstyle guitar tabs. The model still has troubles in ensuring the note-string association and the rhythmic coherence of the generated tabs. How well the model generates tabs of plausible long-term structure is not yet studied. And, much of the expression in guitar music is left unaddressed. Much work are yet to be done to possibly redesign the network architecture and the tab representation. Yet, we hope this work shows promises that inspire more research on this intriguing area of research.

ABSTRACT

A DJ mix is a sequence of music tracks concatenated seamlessly, typically rendered for audiences in a live setting by a DJ on stage. As a DJ mix is produced in a studio or the live version is recorded for music streaming services, computational methods to analyze DJ mixes, for example, extracting track information or understanding DJ techniques, have drawn research interests. Many of previous works are, however, limited to identifying individual tracks in a mix or segmenting it, and the sizes of the datasets are usually small. In this paper, we provide an in-depth analysis of DJ music by aligning a mix to its original music tracks. We set up the subsequence alignment such that the audio features are less sensitive to the tempo or key change of the original track in a mix. This approach provides temporally tight mix-to-track matching from which we can obtain cue-points, transition length, mix segmentation, and musical changes in DJ performance. Using 1,557 mixes from *1001Tracklists* including 13,728 tracks and 20,765 transitions, we conduct the proposed analysis and show a wide range of statistics, which may elucidate the creative process of DJ music making.

1. INTRODUCTION

A Disc Jockey (DJ) is a musician who plays a sequence of existing music tracks or sound sources seamlessly by manipulating the audio content based on musical elements. The outcomes can be medleys (mix), mash-ups, remixes, or even new tracks, depending on how much DJs edit the substance of the original music tracks. Among them, creating a mix is the most basic role of DJs. This involves curating music tracks and their sections to play, deciding the order, and modifying them to splice one section to another as a continuous stream. In each step, DJs consider various elements of the tracks such as tempo, key, beat,

chord, rhythm, structure, energy, mood and genre. These days, DJs create the mix not only for a live audience but also for listeners in music streaming services.

Recently, imitating the tasks of DJ using computational methods has drawn research interests [1–7]. On the other hand, efforts have been made to understand the creative process of DJ music making. In the perspective of reverse engineering, tasks extracting useful information from real-world DJ mixes can be useful in such a pursuit. In the literature, at least the following tasks have been studied. (1) *Track identification* [8–10]: identifying which tracks are played in DJ music which can be either a mix or a manipulated track. (2) *Mix segmentation* [11, 12]: finding boundaries between tracks in a DJ mix. (3) *Mix-to-track alignment* [13, 14]: aligning the original track to an audio segment in a DJ mix. (4) *Cue point extraction* [14]: finding when a track starts and ends in a DJ mix. (5) *Transition unmixing* [13, 14]: explaining how DJs apply audio effects to make a seamless transition from one track to another. However, the previous studies only focused on solving the tasks usually with a small dataset and did not provide further analysis using extracted information from the tasks. For example, Sonnleitner et al. [8] used 18 mixes for track identification. Glazyrin [11] and Scarfe et al. [12] respectively collected 103 and 339 mixes with boundary timestamps for mix segmentation. The majority of previous studies concentrated on identification and segmentation and few studies on the other three tasks used artificially generated datasets [13, 14].

To address the need of a large-scale study, we collected in a total of 1,557 real-world mixes and original tracks played in the mixes from *1001Tracklists*, a community-based DJ music service. [1] The mixes include 13,728 unique tracks and 20,765 transitions. However, tracks used in DJ mixes usually include various versions so-called "extended mix", "remix", or "edit". Also, a few tracks in track-lists of the collected dataset are annotated incorrectly by users. Therefore, an alignment algorithm is required to ensure that the collected tracks are exactly the same versions as the ones used in the mixes. More importantly, the alignment will be a foundation for further computational analysis of DJ mixes. With these two motivations, we

Summary statistic	All	Matched
The number of mixes	1,564	1,557
The number of unique tracks	15,068	13,728
The number of played tracks	26,776	24,202
The number of transitions	24,344	20,765
Total length of mixes (in hours)	1,577	1,570
Total length of unique tracks (in hours)	1,038	913
Average length of mixes (in minutes)	60.5	60.5
Average length of unique tracks (in minutes)	4.1	4.0
Average number of played tracks in a mix	17.1	15.5
Average number of transitions in a mix	14.5	12.9

Table 1. Statistics of the *1001Tracklists* dataset. The original dataset size is denoted as 'All' and the size after filtering as 'Matched'.

set up the mix-to-track subsequence dynamic time warping (DTW) [15] such that the mix can be aligned with the original tracks in presence of possible tempo or key changes. The warping paths from the DTW provide temporally tight mix-to-track matching from which we can obtain cue points, transition lengths, and key/tempo changes in DJ performances in a quantitative way. To evaluate the performances of the alignment and the cue point extraction methods simultaneously, we evaluate mix segmentation performances regarding the extracted cue points as boundaries dividing two adjacent tracks in mixes, comparing them to human-annotated boundaries. Furthermore, by observing the performance changes depending on the three different types of cue points, we analyze the human annotating policy of track boundaries.

Although DJ techniques are complicated and different depending on the characteristics of tracks, there has been common knowledge for making seamless DJ mixes. However, to the best of our knowledge, the domain knowledge has never been addressed in the literature with statistical evidence obtained by computational analysis. In this study, we analyze the DJ mixes using the results from the subsequence DTW mentioned above for the following hypotheses: 1) DJs tend not to change tempo and/or key of tracks much to avoid distorting the original essence of the tracks. 2) DJs make seamless transitions from one track to another considering the musical structures of tracks. 3) DJs tend to select cue points at similar positions in a single track.

The analysis is performed based on the results obtained from the subsequence alignment and provides insights statistically for tempo adjustment, key transposition, track-to-track transition lengths, and agreements of the cue points among DJs. We hope that the proposed analysis and various statistics may elucidate the creative process of DJ music making. The source code for the mix-to-track subsequence DTW, the cue point analysis and the mix segmentation is available at the link. [2]

2. THE DATASET

Our study is based on DJ music from *1001Tracklists*. We obtained a collection of DJ mix metadata via direct personal communication with *1001Tracklists*. Each entry of

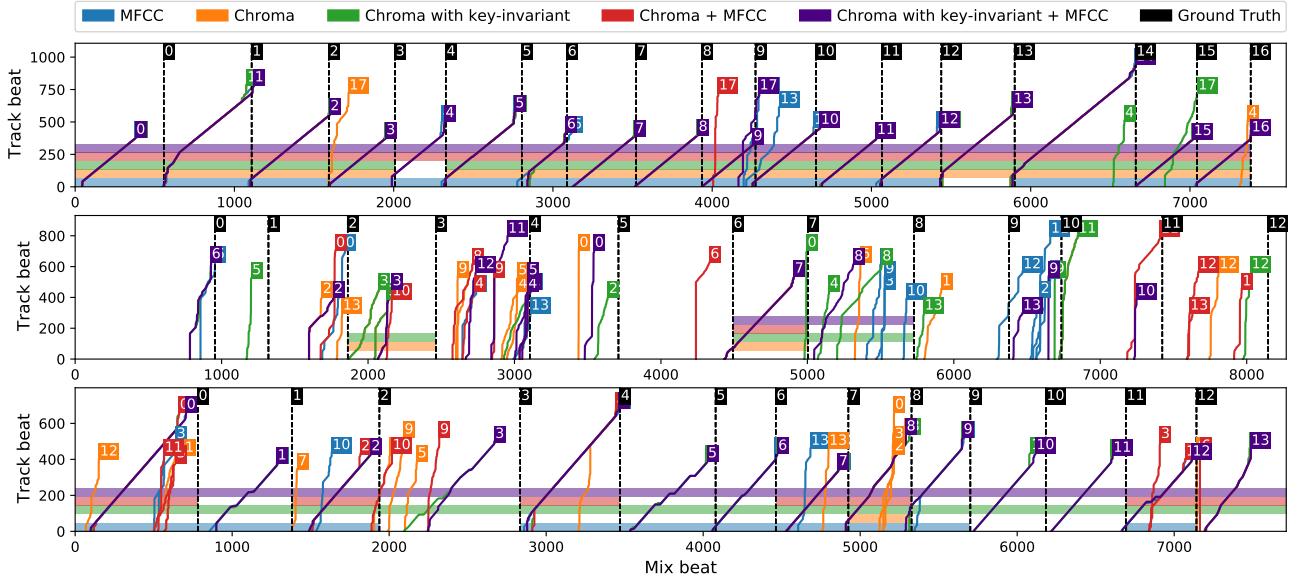
mixes contains a list of track, boundary timestamps and genre. It also contains web links to the audio files of the mixes and tracks. We downloaded them separately from the linked media service websites on our own. We found a small number of web links to tracks are not correct and so filtered them out by a mix-to-track alignment method automatically (see Section 3.3). The boundary timestamps of tracks in a mix are annotated by the users of *1001Tracklists*.

Table 1 summarizes statistics of the dataset. The original size of the dataset is denoted as 'All' and the size after filtering as 'Matched' in Table 1. Note that the number of played tracks is greater than the number of unique tracks as a track can be played in multiple mixes. The dataset includes a variety of genres but mostly focuses on House and Trance music. More detailed statistics of the dataset are available on the companion website. [3]

3. MIX-TO-TRACK SUBSEQUENCE ALIGNMENT

The objective of mix-to-track subsequence alignment is to find an optimal alignment path between a subsequence of a mix and a track used in the mix. This alignment result will be the basis of diverse DJ mix analysis concerning the cue point, track boundary, key/tempo changes and transition length. We also use it for removing non-matching tracks. This section describes the detail of computational process.

3.1 Feature Extraction

When DJs create a mix, they often adjust tempo and/or key of the tracks in the mix or add audio effects to them. Live mixes contain more changes in timbre and even other sound sources such as the voices from the DJ. In order to address the acoustic and musical variations between the original track and the matched subsequence in the mix, we use beat synchronous chroma and mel-frequency cepstral coefficients (MFCC). The beat synchronous feature representations enable tempo invariance and dramatically reduces the computational cost in the alignment. The aggregation of the features from the frame level to the beat level also smooths out local timbre variations. The chroma feature, on the other hand, facilitates key-invariance as circular shift of the 12-dimensional vector corresponds to key transposition. The MFCC feature captures general timbre characteristics. We used Librosa [4] to extract the chroma and MFCC features with the default options except that the dimentionality of MFCC was set to 12 and the type of chroma was to chroma energy normalized statistics (CENS) [16].


3.2 Key-Invariant Subsequence DTW

We compute the alignment by applying subsequence DTW to the beat synchronous features [15]. We used an implementation from Librosa, adopting the transposition-invariant approach from [17]. Specifically, we calculated 12 versions of chroma features by performing all possible

---

Figure 1. Visualizations of the result of a DTW-based mix-to-track subsequence alignment between a mix and the original tracks played in that mix. The colored solid lines show the warping paths of the alignment depending on the input feature, and whether or not applying the transposition-invariant method on the subsequence DTW. The tagged numbers on warping paths and ground truth boundaries indicate played and timestamped indices in the mix, respectively. A colored bar at the bottom of the figures is added if the alignment of the method is considered successful according to the match rate. (Top) A correctly matched example. (Middle) An unsuccessful example, due to the low sound quality of the mix. (Bottom) The alignment can be improved using the key-invariant chroma. Best viewed in color.

circular shifts on the original track side and select the one with the lowest matching cost in the subsequence DTW. This result returns not only the optimal alignment path but also the key transposition value of the original track.

Figure 1 shows three examples of the alignment results when different combinations of features (MFCC, chroma, and key-invariant chroma) are used. When the alignment path of the subsequence satisfies a match rate (described in Section 3.3), we put a color strip corresponding to each feature in the bottom of the figure. Since we use beat synchronous representations for them, the warping paths become diagonal with a slope of one if a mix and a track are successfully aligned. The top panel in the figure shows an successfully aligned example for the most of tracks and features where all warping paths have straight diagonal paths.[5] The middle panel shows a failing example because sounds from crowds are also recorded in the mix.[6] The bottom panel shows a example where chroma with circular shift distinctively works better others as the DJ frequently uses key transposition on the mix.[7]

3.3 Filtering Using Match Rates

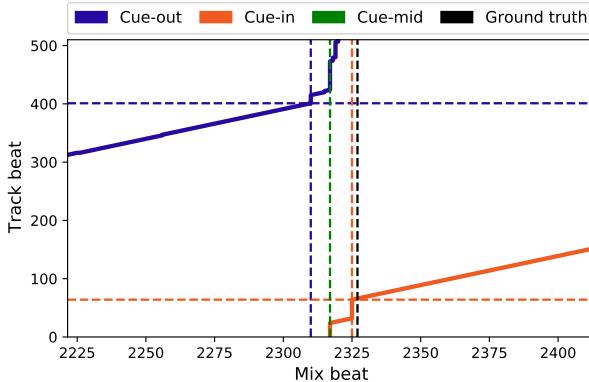
As stated above, we can measure the quality of the alignment from the warping path. Ideally, when every single move on the path is diagonal, that is, one beat at a time for both track and mix axis, we will obtain a perfect straight diagonal line. However, the acoustic and musical changes deform the path. We define the ratio of the diagonal moves

in a mix (one move per beat) as the *match rate* and use it for filtering out incorrectly annotated tracks. We experimentally chose 0.4 as a threshold. The size of the dataset after the filtering is denoted as "Matched" in Table 1. We only use the matched tracks for the analysis in this paper.

4. CUE POINT EXTRACTION

Cue points are timestamps in a track that indicate where to start and end the track in a mix. Determining the cue points of played tracks is an essential task of DJ mixing. This section describes extracting cue points using the warping paths obtained from the aforementioned mix-to-track subsequence alignment.

4.1 Term Definitions

We first define terms related to cue points. In the context of the track-to-track transition, a *cue-out* point is a timestamp that the previous track starts fading out and the next track starts fading in, and a *cue-in* point is when the previous track is fully faded out and only the next track is being played. The *transition* region is defined as the time interval from the cue-out point of the previous track to the cue-in point of the next track. Additionally, we define a *cue-mid* point as the middle of a transition, which can technically be considered as a boundary of the transition.


4.2 Methods

The mix-to-track alignment results naturally yield cue points of matched tracks. Figure 2 shows an example of extracted cue points (a zoomed-in view of the top figure in

[7] `https://1001.tl/bcx2z0t`

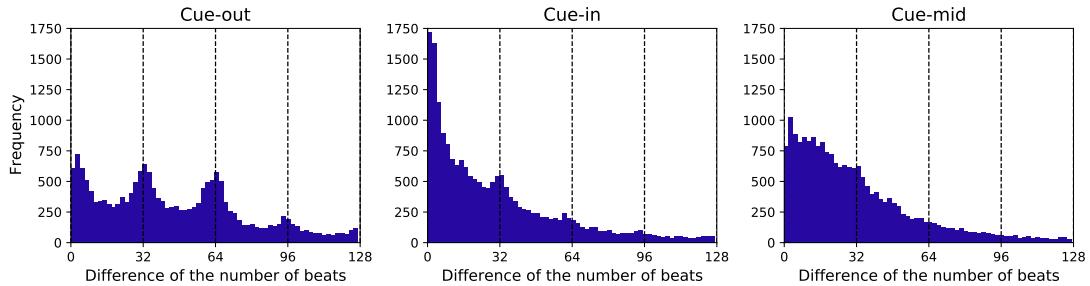
Figure 2. A zoomed-in view of a visualization of mix-to-track subsequence alignment explaining the three types of extracted cue points. The two solid lines indicate warping paths representing alignment between the mix and tracks. The vertical colored dotted lines represent the extracted cue points on the mix and the horizontal dotted lines represent the points on each track. The vertical black dotted line is a human-annotated ground truth boundary between the two tracks. The solid lines are the fourth and fifth warping paths from the top of Figure 1. Best viewed in color.

Figure 1). The two alignment paths drift from the diagonal lines in the transition region (between 2310 and 2324 in mix beat) because the two tracks cross-fades. Based on this observation, we detect the cue-out point of the previous track by finding the last beat where preceding 32 beats have diagonal moves in the alignment path. Likewise, we detect the cue-in point of the next track by finding the first beat where succeeding 32 beats have diagonal moves in the alignment path.

5. MIX SEGMENTATION

The goal of mix segmentation is to divide a continuous DJ mix into individual tracks, which can enhance the listening experience and can be a foundation of further analysis or learning of DJ mixes. Since DJs make seamless transitions, it is difficult to notice that a track is fading in or out. To quantitatively measure how difficult it is, a study analyzed how accurate humans are at creating the boundary timestamps and found that the standard deviation of the human disagreement for track boundaries in mixes is about 9 seconds, which implies it is difficult to find the optimal boundaries even for humans [12]. Furthermore, the ambiguous definition of the boundary and long lengths of transitions makes it difficult to annotate the boundary timestamps [8].

5.1 Cue Point based Estimation

Given the extracted cue point so far, we can estimate the track boundaries with three possible choices. The first is the position that the next track fully appears (cue-in point), the second is the position that previous track starts to disappear (cue-out point), and the last is the middle of the transition (cue-mid point). By comparing each of them


with human-annotated boundary timestamps, we can measure which type of cue point humans tend to consider as a boundary.

Figure 3 shows three histograms where each of them is computed from the differences between human-annotated boundary timestamps and one of the cue point types in beat unit. The overall trend shows that the distribution of cue-in point is mostly skewed towards zero. Interestingly, the distribution of cue-out point has more distinctive peaks around every 32 beat than the distribution of cue-in point. Considering the histogram of the transition length has peaks at every 32 beat as shown in Figure 6, this reflects that human annotators tend to label cue-in points as a boundary compared to cue-out (note that the transition length is computed by subtracting the cue-in point from the cue-out point). On the other hand, the distribution of cue-mid point has a gradually decreasing curve without peaks. While this distribution looks like having better estimates than the cue-out point, Table 3 shows an opposite result. That is, in terms of the number of cue points closest to the human annotations, the cue-out point is the second and the cue-mid point is the worst among the three types. These results indicate that the cue-mid point is a safe choice. That is, although the cue-mid point is least likely to be a boundary as shown in Table 3, the difference between the estimate and human annotation is relatively small because it is the middle of the transition region.

Table 2 shows the difference between human-annotated boundary timestamps and one of the cue point types in terms of median time (in seconds) on the left side. The overall trend confirms that the cue-in is the best estimate of track boundary and the cue-mid is a safer choice than the cue-out. The table also shows the result of "cue-best". This is computed with the minimum difference among the three cue point types for each of the transition region. The result shows that the median time differences are dramatically decreased to 4-5 seconds. Table 2 also shows the difference between human-annotated boundary timestamps and the cue-in point in terms of hit rates on the right side. The hit rates are computed the ratio of correct estimates given a tolerance window. If the estimate is within the tolerance window on the human-annotated boundary timestamp, it is regarded as a correct estimate. We set three tolerance windows (15, 30, and 60 seconds) considering that the average tempo of tracks in the dataset is 127 beat per minute (BPM) and then the tolerance windows approximately correspond to 32, 64, 128 beats (multiples of a phrase unit). The result shows that the best hit rate with the 30 second window (about 64 beats) is above 80%. Given the long transition time as shown in Figure 6, the cue-in point may be considered as a reasonable choice.

5.2 Effect of Audio Features

Table 2 also compares the median time difference between human-annotated boundary timestamps and one of the cue point types for different audio features used in the subsequence DTW. In general, the chroma features are a better choices than MFCC (p-value of t-test < 0.001 for chroma

Figure 3. Histograms of distances to ground truth boundaries in the number of beats depending on the type of the cue point. The dotted lines are plotted at every 32 beats which is usually considered as a phrase in the context of dance music.

Feature	Median time difference (in seconds)				Cue-in hit rate		
	Cue-out	Cue-in	Cue-mid	Cue-best†	15 sec	30 sec	60 sec
MFCC	27.92	14.27	13.55	5.340	0.5187	0.7591	0.9023
Chroma	23.85	11.80	12.33	**4.230**	0.5837	0.7973	0.9286
Chroma with key-invariant	23.87	11.77	12.37	4.240	0.5843	0.7968	0.9282
Chroma + MFCC	23.41	11.48	**12.16**	4.380	0.5866	0.8035	0.9284
Chroma with key-invariant + MFCC	**23.38**	**11.40**	**12.16**	4.380	**0.5881**	**0.8040**	**0.9288**

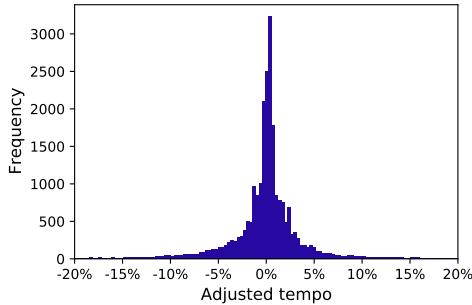
Table 2. Mix segmentation performances depending on the type of cue point and the input feature used to obtain the warping paths. Median time differences between cue points and ground truths are shown on the left side and hit rates of cue-in points with thresholds in seconds are shown on the right side. "Key-invariant" indicates applying the key transposition-invariant method for the DTW. The best score of each criteria is shown in **bold**. $\dagger$ indicates the scores are computed using the best score among the three cue types.

Cue-out	Cue-in	Cue-mid
6,151 (30%)	10,844 (52%)	3,770 (18%)

Table 3. The number of ground truth boundary timestamps closest to the type of cue point.

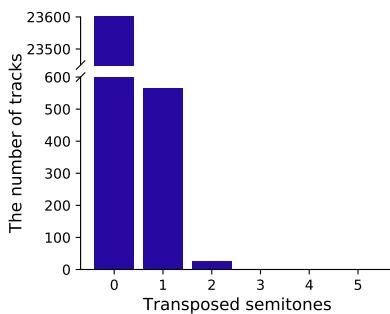
with or without key-invariant). When both of chroma and MFCC are combined, the median time difference slightly reduces but it is statistically insignificant (p-value of t-test > 0.1). However, we observed that the subsequence DTW does not work well for some genres such as Techno which only contain drum and ambient sounds. This might can be improved by using MFCCs with a large number of bins or using mel-spectrograms. The use of key-invariant chroma generally does not make much difference because key transposition does not performed frequently as discussed in Section 6.2.

6. MUSICOLOGICAL ANALYSIS OF DJ MIXES

We hypothesize that DJs share common practices in the creative process in terms of tempo change, track-to-track transition, and cue point selection. In this section, we validate them using the results from the mix-to-track subsequence alignment and the cue point extraction.


6.1 Tempo Adjustment

We compare the estimated tempo of the original track to the tempo of each audio segment where the track is played in a mix. Figure 4 shows a histogram of percentage dif-

ferences of tempo between the original track and the audio segment in the mix. For example, a difference of 5% indicates the tempo of the original track is increased by 5% while played in the mix. As shown in the histogram, the adjusted tempo has an double exponential distribution, which means the adjusted tempo values are skewed towards zero. In detail, 86.1% of the tempo are adjusted less than 5%, 94.5% are less than 10%, and 98.6% are less than 20%. If one implements an track identification system for DJ mix that is robust to tempo adjustment, this distribution could be a reference.


6.2 Key Transposition

A function so-called "master tempo" or "key lock" that preserves pitch despite tempo adjustments is activated by default in modern DJ systems such as stand-alone DJ systems, DJ softwares, and even turntables for vinyl records. Therefore, key transposition is usually performed when a DJ intentionally wants to change the key of a track. As mentioned in Section 3.2, the transposition-invariant DTW can provide the number of transposed semitones as a by-product. We computed the statistics of key transposition using them (using DTW taking both MFCCs and key-invariant chroma). Figure 5 shows a histogram of key transposition between the original track and the audio segment in the mix. Only 2.5% among the total 24,202 tracks are transposed and, among those transposed tracks, 94.3% of them are only one semitone transposed. This result indicates that DJs generally do not perform key transposition much and leave the "master tempo" function turned on in most cases.

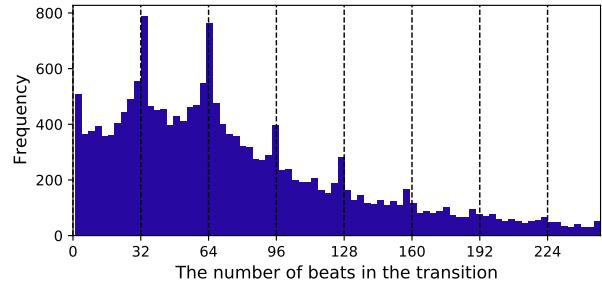
Figure 4. A histogram of adjusted tempo of tracks in mixes.


Figure 5. The number of tracks depending on the number of semitones in mixes.

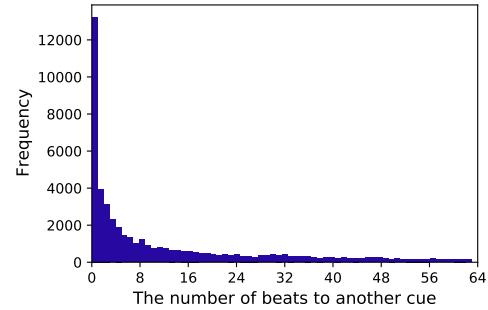
Figure 6. A histogram of the transition lengths in number of beats. The dotted lines are plotted at every 32 beats.

Figure 7. A histogram of distances between cue points of a single track in the number of beats.

6.3 Transition Length


Once we extract cue-in and cue-out points in the transition region, we can calculate the transition length. This can provide some basic hints on how DJ makes the track-to-track transition in a mix. Figure 6 shows a histogram of transition lengths in the number of beats. We annotated the dotted lines every 32 beat which is often considered as a phrase in the context of dance music. The histogram has peaks at every phrase. This indicates that DJs consider the repetitive structures in the dominant genres of music when they make transitions or set cue points.

6.4 Cue Point Agreement among DJs

Deciding cue points of played tracks is a creative choice in DJ mixing. Observing the agreement of cue points on a single track among DJs may elucidate the possibility of finding some common rules. To the end, we collected all extracted cue points for each track and computed the statistics of deviations in cue-in points and cue-out points among DJs. Specifically, we computed all possible pairs and their distances separately for cue-in points and cue-out points. Since the two distributions were almost equal, we combined them into a single distribution in Figure 7. From the results, 23.6% of the total cue point pairs have zero deviation. 40.4% of them were within one measure (4 beats), 73.6% were within 8 measures and 86.2% were within 16 measures. This indicates that there are some rules that DJs share in deciding the cue points. It would be interesting to perform detailed pattern analysis to estimate the cue points using this data in future work.

7. CONCLUSIONS

We presented various statistics and analysis of 1,557 real-world DJ mixes from *1001Tracklists*. Based on the mix-to-track subsequence DTW, we conducted cue point analysis of individual tracks in the mixes and showed the possibility of common rules in the music making that DJs share. We also investigated mix segmentation by comparing the three types of cue point to human-annotated boundary timestamps and showed that humans tend to recognize cue-in points of the next tracks as boundaries. Finally, we showed the statistics of tempo and key changes of the original tracks in DJ performances. We believe this large-scale statistical analysis of DJ mixes can be beneficial for computer-based research on DJ music. The cue point analysis can be the ground for the precise definition of cue points and the tempo and key analysis can provide a guideline of the musical changes during the DJ mixing.

As a future work, we plan to estimate cue points within a track as a step towards automatically generating a mix [3, 4]. The cue point estimation has many application such as DJ software and playlist generation on music streaming services. This will require structure analysis or segmentation of a single music track, which is an important topic in MIR. Furthermore, we plan to analyze the transition region in a mix to investigate DJ mixing techniques. For example, it is possible to estimate the gain changes in the cross-faded region by comparing the two adjacent original tracks and the mix [13, 14]. The methods can be extended to the spectrum domain. Such detailed analysis of mixing techniques will allow us to understand how DJs seamlessly concatenate music tracks and provide a guide to develop automatic DJ systems.

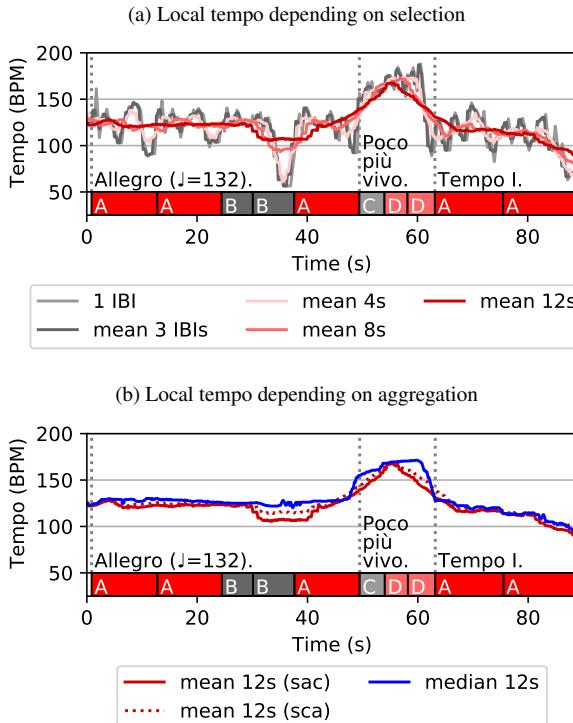
{hendrik.schreiber,frank.zalkow,meinard.mueller}@audiolabs-erlangen.de

ABSTRACT

Even though local tempo estimation promises musicological insights into expressive musical performances, it has never received as much attention in the music information retrieval (MIR) research community as either beat tracking or global tempo estimation. One reason for this may be the lack of a generally accepted definition. In this paper, we discuss how to model and measure local tempo in a musically meaningful way using a cross-version dataset of Frédéric Chopin's Mazurkas as a use case. In particular, we explore how tempo stability can be measured and taken into account during evaluation. Comparing existing and newly trained systems, we find that CNN-based approaches can accurately measure local tempo even for expressive classical music, if trained on the target genre. Furthermore, we show that different training–test splits have a considerable impact on accuracy for difficult segments.

1. INTRODUCTION

While *global* tempo is well defined for music with little or no tempo variability [1], this is less so the case for *local* tempo, especially for expressive classical music. Composer markings like *rubato* (expressive, local tempo change) or *ritardando* (slow down) indicate continuous or even abrupt tempo changes, leading to one or more segments with stable tempi and segments of tempo instability in between. Figure 1, for example, shows tempo markings for Frédéric Chopin's Mazurka Op. 68, 3 (details are discussed in Section 2). Naïvely, one may model local tempo for such a piece as one of two extremes: at the *micro level*, as an instantaneous value, e.g., as the Inter Beat Interval (IBI) between two consecutive beats, or at the *macro level*, by averaging the number of beats over a longer period of time. For expressive music, both approaches have disadvantages. IBIs exhibit a large variance, and averaging beat counts may underestimate the tempo, because expression leads more often to longer than shorter IBIs [2]. Repp therefore attempts to find a definition for the *basic tempo* [3], i.e., the implied tempo the instantaneous tempo


Work	Measures	Beats	Recordings
Op. 17, 4	132	396	62
Op. 24, 2	120	360	64
Op. 30, 2	65	193	34
Op. 63, 3	77	229	88
Op. 68, 3	61	181	50

Table 1: Dataset overview [13]: Number of measures, beats, recordings for five Chopin Mazurkas.

varies around. In [2], he suggests to derive the basic tempo from the first quartile of eighth-note Inter Onset Intervals (IOIs). Similarly, Dixon [4] proposes IOI clustering, using centroids as tempo hypotheses. Grosche and Müller [5] propose yet another approach by defining local tempo as the mean of three consecutive IBIs, which is identical to using Inter Measure Intervals (IMIs) for pieces in ¾ time. The same method is also used by Chew and Callender [6]. In summary, local tempo is usually modeled by aggregating local pulse information, but there appears to be no clear consensus on how. Even though local tempo estimates are popular intermediate features for beat trackers (e.g., [7,8]), few works explicitly estimate and evaluate local tempo estimates. Peeters [9] simply measures whether 75% of the estimated local tempi match the annotated global tempo. In subsequent work [10], he compares the median of local tempi with a global ground truth. A similar approach is taken in [11]—after beat tracking, the median IBI is used as global tempo and then evaluated. Similar to global tempo evaluation, Grosche and Müller [5] compute the accuracy of their IMIs allowing a 4% tolerance and certain integer factors. Schreiber and Müller [12] only provide visualizations for local tempo estimates. To our knowledge, there is no commonly accepted evaluation procedure. Even less researched than local tempo is tempo *stability*, usually only referred to as a precondition for global tempo estimation [1]. Grosche et al. [13] mention that beat trackers tend to have problems with the first and last few beats of Mazurkas due to boundary problems, and observe increased error-levels caused by sudden tempo changes, but as far as we know no measure for local tempo stability has been proposed.

Modeling local tempo, determining its stability, and estimating it automatically from audio are problems at the intersection of music information retrieval (MIR) and computational musicology. We believe that all three problems have to be solved together in order to provide use-

(a) Local tempo depending on selection

(b) Local tempo depending on aggregation

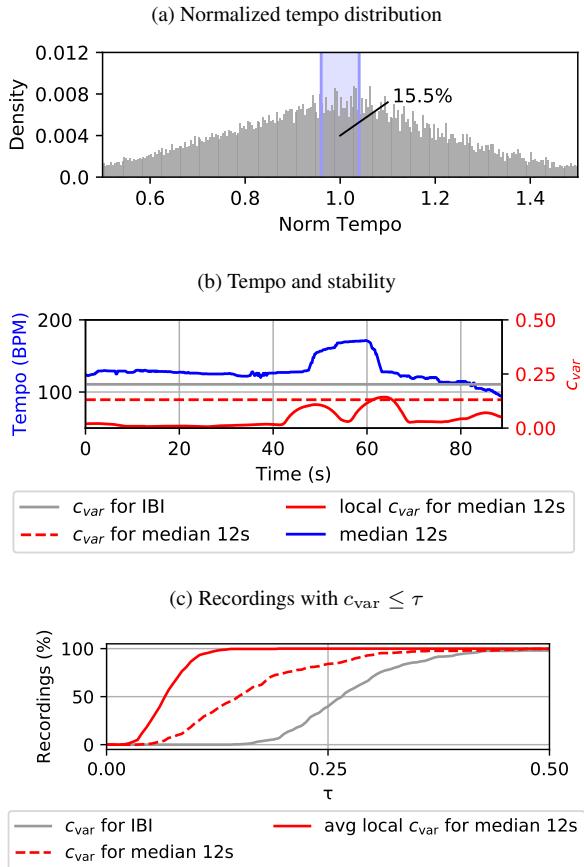
Figure 1: Local reference tempo depending on **(a)** selection and **(b)** aggregation functions for Op. 68, 3 (Cohen, 1997) with section boundaries and score tempo markings.

ful tools for computational music performance analysis (MPA) [14]. Such tools can, for example, be used to determine how well a given performance matches the score—similar to how it has been done for dynamics [15]. Studies like [16], comparing relative local tempo variations within performance collections, could be enhanced by using absolute tempo information.

Working towards this goal, we investigate how to model local tempo (Section 2) and tempo stability (Section 3) for expressive music using Mazurkas by Chopin. As our main contribution, we estimate local tempi using neural network-based approaches, adapt these approaches to our use case, and explore their behavior and potential (Section 4). In our evaluation, we focus on identifying error classes and sources, and in particular the effect of stability. In Section 5, we discuss our findings and draw conclusions.

2. LOCAL TEMPO

Cancino-Chacón et al. [17] see the *global tempo* of a performance as the approximate rate at which musical events happen throughout that performance. In contrast, *local tempo* refers to the rate of events within a smaller time window and can therefore be regarded as local deviation from the global tempo. In accordance with this definition, we are interested in a musically meaningful, single-value description of a segment of limited length. We can define this length musically, e.g., as three consecutive IBIs [5, 6], or physically, e.g., as 6 s or 8 s segments [9, 10]. In either case, we first *select* beat events, because they fall into a time

span, and then *aggregate* them. For example, we may use the mean or the median of all IBIs falling into a 4 s interval. One purpose of this aggregation is to be able to largely ignore *expressive timing*, which can be defined as deviations of individual beat events from the local tempo [17], e.g., rolled or arpeggiated chords [18]. Note that, in this work, we are not attempting to find the *most* suitable selection and aggregation functions (see [3]), but merely discuss options and aim to establish a framework that can be used for such an endeavor. To illustrate different choices, we use Chopin's Op. 68, 3 (piano: Cohen, 1997) as an example. It is one of over 2,700 recordings of 49 Mazurkas by Chopin collected by the Mazurka Project.[1] Of all collected recordings, 298 recordings of five Mazurkas have been manually beat-annotated [19]. We refer to this subset as the *Mazurka-5* dataset. It contains between 34 and 88 different versions of each of the five Mazurkas (Table 1).


Our example, Op. 68, 3 (Cohen, 1997), consists of four different musical sections A to D (Figure 1). While the score does not contain section markers,[2] it explicitly specifies two tempo changes: at the start of section C from *Allegro, ma non troppo (♩=132)* (fast, but not too fast), to *Poco più vivo* (a little more lively), and back to *Tempo I* after the second D-section. Figure 1a depicts the effects of different selection functions using the mean for aggregation. We see that defining local tempo as individual IBIs leads to very high variance. Using three consecutive IBIs smoothes the tempo curve slightly. The shown tempo curves based on 4 s, 8 s, and 12 s segments progressively lead to less variance. While the 4 s tempo curve still follows the phrasing closely (distinct minima at the end of each musical section), this is less the case for the curves based on longer segments. This is especially obvious at the end of the 2nd B section at 38 s.

Figure 1b shows the differences between using mean and median as aggregation function. The tempo curves for mean show local over-smoothing in transitional sections, leading to a triangular shape in the more lively CDD-section from $50 - 60$ s. Because of the edge-preserving property of median-filtering, the median curve captures sudden tempo changes better. The CDD-section resembles a rectangle, i.e., a high tempo plateau. At the same time, the local minimum at the end of the 2nd B disappears. Thus, the median curve corresponds to the composer's markings.

So far we first selected IBIs, aggregated them, and then converted the result to BPM (selection → aggregation → conversion: sac). As an alternative, we could have first converted IBIs to BPM and then aggregated them (selection → conversion → aggregation: sca). When using mean, the result is not the same. For sections with changing tempo (Figure 1b, $30 - 70$ s), local tempo values are lower when we first average and then convert (sac, solid red line) as opposed to first convert and then average (sca, dotted red line). Note that the median is unaffected by this issue.

3. TEMPO STABILITY

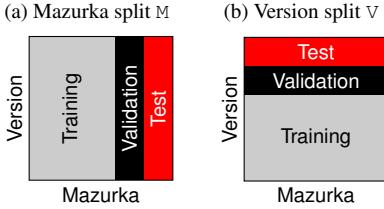
For the evaluation of global tempo estimation one typically requires recordings with approximately constant tempi [1], i.e., a certain degree of tempo stability. Since local tempo estimation is in fact global tempo estimation for very short segments, we seek to quantify local tempo stability in order to conduct an informed evaluation of our experiments in Section 4. As a first approach to describe tempo stability quantitatively on the intra-track level, we convert all *Mazurka-5* IBIs to tempo values and normalize them by dividing by their respective track's average. Figure 2a depicts the resulting normalized histogram.[3] Only 15.5% of the *Mazurka-5*'s normalized tempi are in the interval between 0.96 and 1.04—the often used $\pm 4\%$ tolerance interval for stable tempi [1]. For comparison, 90.9% of the *Ballroom* [1,20] dataset's normalized tempi are in the same interval. Obviously, the two datasets are very different w.r.t. intra-track tempo stability.

While the $\pm 4\%$ interval is illustrative when categoriz-

ing stable vs. unstable, it is a rather arbitrary threshold. Arguably, the standard deviation of a track's normalized tempi is better suited to describe intra-track tempo variability. It is identical to the coefficient of variation,[4] which is defined as the ratio between the standard deviation σ and the mean μ:

$$c_{\mathrm{var}} = \frac{\sigma}{\mu}. \tag{1}$$

We show this IBI-based c_{var}-value for our example Op. $68, 3$ (Cohen, 1997) as a horizontal gray line in Figure 2b. As discussed in Section 2, instantaneous tempo values like IBIs tend to overestimate the variance of a musically meaningful local tempo for expressive music. From a musical point of view, it is therefore more appropriate to analyze tempo stability of Mazurkas not based on individual IBIs, but on the basic tempo, which—*for the purpose of this discussion*—we approximate with the median tempo over $12\,\mathrm{s}$ segments (Figure 2b, blue line). Sampling the local median tempo allows us to calculate an arguably more appropriate c_{var} (Figure 2b, dashed red line), which lies well below the gray line, indicating higher stability. This however, still ignores the fact that Mazurkas may contain multiple sections with stable but different tempi. We can take this into account by calculating local coefficients of variation for short segments of the median-based tempo curve. The solid red curve in Figure 2b shows the results for overlapping $12\,\mathrm{s}$-segments. For most of the recording it is very low. Only in the transitional regions, at the beginning and end of the CDD-section, we see higher values. Note that by averaging the local c_{var} we can obtain a measure for intra-*segment* stability, while the two track-level c_{var} measures represent intra-*track* stability. Figure 2c depicts how many recordings of our dataset have a c_{var} below a threshold τ for all three ways of calculating it. The comparison shows that for *Mazurka-5* intra-segment variability is far smaller than intra-track variability.

4. EXPERIMENTS


We now investigate how different local tempo estimation systems perform when tested with *Mazurka-5*. We consider the following systems: The RNN-based beat tracking system Böck[5] [21] (estimated beats are aggregated identically to the ground truth), the CNN-based tempo estimation system DeepTemp[6] [22], and the system DT-Maz, which is set up identically to DeepTemp, but has been trained on *Mazurka-5* recordings instead of Pop/Rock, EDM, and Ballroom music. Based on our observations in Section 2 and informal experiments with several segment lengths, we model the local tempo with median-aggregated IBIs from $11.9\,\mathrm{s}$ segments.[7] As mentioned in Section 2, we do not claim that this is the best possible selection or aggregation, but a reasonable configuration.

---

[3] The comb pattern is a consequence of the $10\,\mathrm{ms}$ resolution of the original annotations.

[4] Also known as CV or relative standard deviation (RSD).

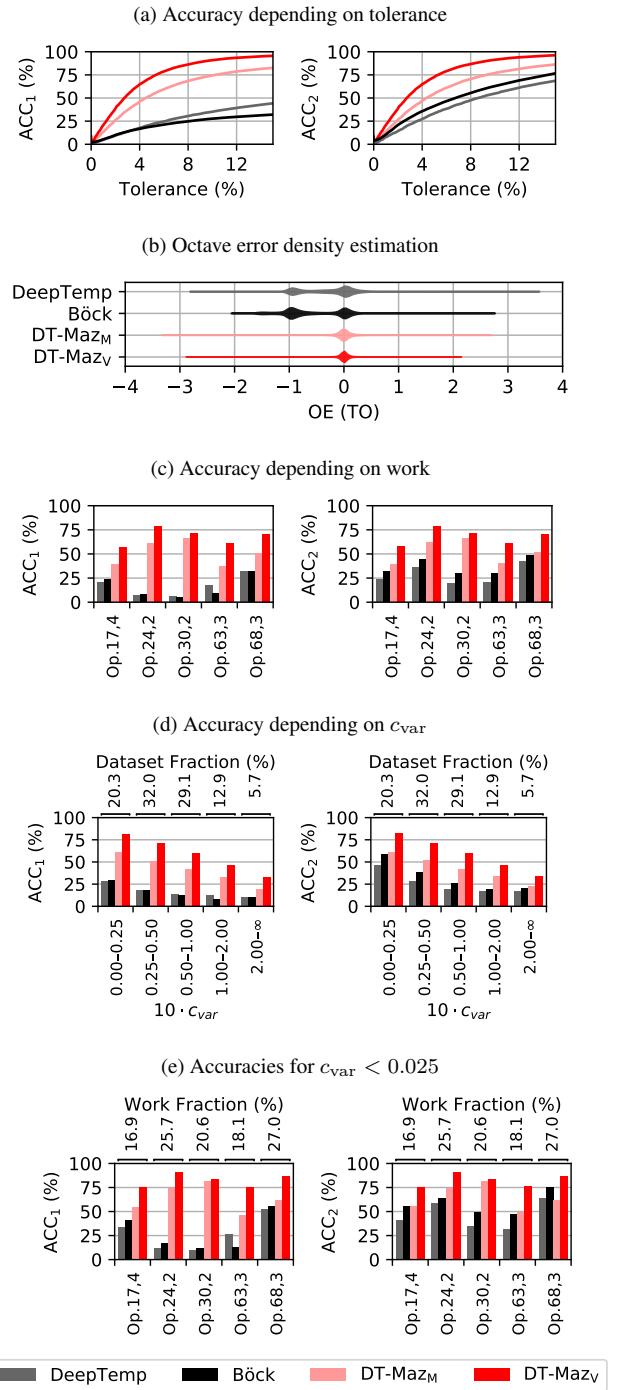
[6] Scaled with model sizing parameter $k = 16$, see [22] for details.

[7] We chose $11.9\,\mathrm{s}$ instead of the previously used $12\,\mathrm{s}$ for practical reasons. The system DeepTemp is already trained on $11.9\,\mathrm{s}$.

Figure 3: Dataset splitting into training, validation, and test sets.

4.1 Setup


We trained DT-Maz from scratch [8] on *Mazurka-5* recordings using 5-fold cross validation with two different kinds of splits, M for Mazurka and V for version (or performance). For M, each split contains all versions of one Mazurka (Figure 3a). For V, each split consists of a disjoint 5th of all versions of each of the five Mazurkas (Figure 3b). During training, three splits were used as training data and one for validation. The remaining 5th split was used for testing. Each split was used exactly once for validation or testing. We refer to the models trained on M-splits as DT-Maz$_M$ and to the V-split models as DT-Maz$_V$. The employed training procedure was very similar to [12]. Audio is first converted to mel-magnitude-spectrograms. Then samples with the dimensions $F \times T$ are used as network input. $F = 40$ being the number of frequency bins covering the frequency range $20 - 5,000$ Hz, and $T = 256$ being the number of time frames with a length of 46 ms per frame, corresponding to 11.9 s. We further use scale & crop data augmentation [12] with time scale factors drawn from $\mathcal{N}(1, 0.1)$, but limited to $[0.7, 1.3]$ to avoid extreme distortions. After augmentation, samples are standardized to zero mean and unit variance. Like [12], we use categorical crossentropy as loss, because we cast tempo estimation as a classification problem, predicting tempo as one of 256 linearly spaced classes ranging from 30 to 255 BPM. [9] Adam [23] is used as optimizer with a batch size of 32 and an initial learning rate of 0.001. The rate is halved once the validation loss stops improving and training is continued with the best performing model up to that point (stepwise annealing). We repeat this at most 10 times. If reduction does not lead to a lower validation loss three times in a row, training is stopped. To avoid overfitting to longer recordings, we ensure that samples from all training recordings are presented with the same frequency.

4.2 Evaluation

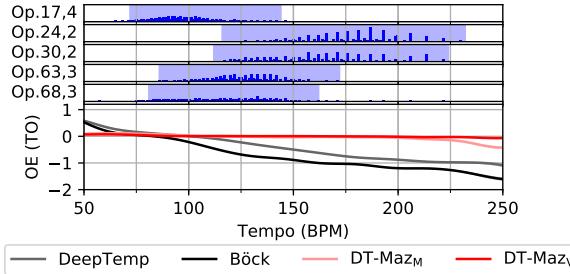
To evaluate, we estimate the tempo for a sliding segment with length 11.9 s (256 frames) and a hop size of 186 ms (4 frames) over all recordings. As metric we use ACC$_1$ (tempo accuracy) and ACC$_2$ (accuracy allowing so-called *octave errors*, i.e., estimates that are wrong by the factor 2, ½, 3 or ⅓) from the global tempo estimation


Figure 4: **(a)** Local ACC$_1$ and ACC$_2$ depending on accuracy tolerance. **(b)** Density estimation for OE. **(c)** Local ACC$_1$ and ACC$_2$ for the five Mazurkas. **(d)** Local ACC$_1$ and ACC$_2$ considering c_{var} ranges. **(e)** Accuracies for segments with $c_{var} < 0.025$.

task [1], which are meant for music with low intra-track tempo variability. This is reasonable, because we apply the metric locally for each segment, so that the tolerance does not have to correspond to intra-track, but to intra-segment variability, and as we have shown in Section 3, intra-segment variability is relatively low. Nevertheless, we consider the typical 4% tolerance an arbitrary threshold and therefore plot accuracy values for the tolerance interval

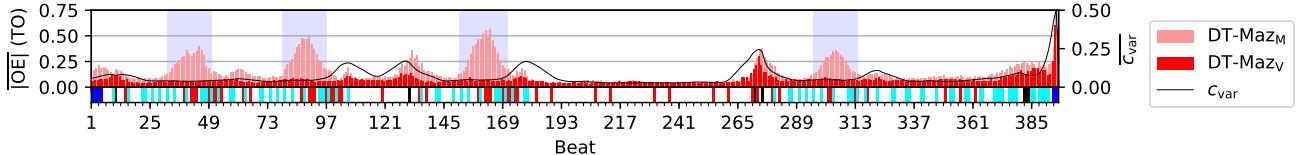
Figure 5: **(top)** Sweet octaves in light-blue. Local tempo histograms in dark-blue. **(bottom)** Estimates of generalized additive models fit to OE/tempo-pairs

$0-15\%$ in Figure 4a. For both variants of `DT-Maz`, ACC_1 values are higher than for the other systems, regardless of tolerance. Not surprisingly, ACC_1 values are also generally higher for higher tolerances.[10] The best performing system for the tolerances 4%, 8%, and 12% is `DT-Maz`$_V$ with remarkable 64.6%, 86.4%, and 93.5%. The worst performing system is `Böck`, with 16.8%, 24.8%, and 29.7%. For ACC_2 the best performing system is also `DT-Maz`$_V$ with 64.8%, 86.8%, and 94.0%, and the worst performing system is `DeepTemp` with 27.3%, 47.5%, and 61.2%. In the following paragraphs we discuss the most prominent errors, namely octave errors, tempo stability related errors, and problems with specific musical properties.

Tempo Octave. Using violin plots, Figure 4b depicts kernel density estimates (KDE) of the octave error OE defined as

$$\text{OE}(y, \hat{y}) = \log_2 \frac{\hat{y}}{y}, \qquad (2)$$

with $y, \hat{y} \in \mathbb{R}_{>0}$ as the ground truth and estimate. Identifiable by the very dense section around -1 Tempo Octaves (TO), `DeepTemp` and `Böck` suffer most from underestimating the actual tempo. As Figure 4c shows, octave errors are not evenly distributed among the five Mazurkas. Op. 24, 2 and Op. 30, 2 are much more affected than the other three. This can be partially explained by the fact that on average versions for Op. 24, 2 and Op. 30, 2 are much faster. Their *sweet octaves* [24], i.e., the tempo octave most tempo values are in, are $[116, 232)$ and $[112, 224)$ BPM, while the sweet octaves for Op. 17, 4, Op. 63, 3, and Op. 68, 3 are $[72, 144)$, $[86, 172)$, and $[81, 162)$ BPM (Figure 5, top). A closer investigation shows that for the tested Mazurkas, both `DeepTemp` and `Böck` lean towards negative octave errors for higher tempi, revealing an *octave bias* [24]. This is visualized in Figure 5, bottom. It shows the estimates of generalized additive models (GAM) that are fit to measured OE per reference tempo. It illustrates what kind of estimation error we can expect depending on a given true tempo. For tempi greater than 100 BPM, `Böck` and `DeepTemp` tend to suffer from negative octave errors.

Stability. Figure 4d shows that accuracy is higher when considering only segments with low c_{var}-values—our proxy for tempo variability. When only considering


relatively stable segments with $c_{\text{var}} < 0.025$ (Figure 4e), the accuracy scores for all five Mazurkas increase substantially. The comparison of `DT-Maz`$_M$ and `DT-Maz`$_V$ shows that `DT-Maz`$_M$ performs much worse for some Mazurkas (Op. 17, 4, Op. 63, 3, and Op. 68, 3) than `DT-Maz`$_V$. Apparently, differences in stability cannot fully explain differences in accuracy for the five works.

Musical Properties. We have seen in Figure 4e that even for stable segments, `DT-Maz`$_V$ performs better than `DT-Maz`$_M$. To find out why, we exploit beat annotations for each recording of the five Mazurkas. They allow us to compute stability and the absolute octave error $|\text{OE}|$ for $11.9\,\text{s}$ segments with a beat at their center, i.e., stability and error on a musical time axis. Using musical time, we can summarize errors and stability measures *cross-version* by averaging per beat over all recordings of a given Mazurka. Figure 6 shows the results for Op. 17, 4 and as expected, the $\overline{c_{\text{var}}}$-curve roughly correlates with errors by both `DT-Maz`$_M$ and `DT-Maz`$_V$. For `DT-Maz`$_M$ we see four additional peaks around beats 42, 89, 162, and 305 (highlighted in light-blue). These peaks loosely correlate with the occurrence of dense mixtures of ornamented beats (red) and weak bass beats (cyan), i.e., piece-dependent musical properties (classification from [13]), which are apparently the main reason for the difference in accuracy. Trained on the V-split, `DT-Maz`$_V$ was able to learn piece-specific musical properties and generalize them across versions. This implies that expecting `DT-Maz`$_M$'s accuracy levels is more realistic when using either model on unseen Mazurkas.

5. DISCUSSION AND CONCLUSIONS

With five of Chopin's Mazurkas as use case, we have shown that local tempo for expressive music can be modeled using `median` aggregated IBIs, and tempo stability can be measured using the coefficient of variation (c_{var}) of local tempo values. Using these tools, we have found that the five Chopin Mazurkas exhibit high intra-track tempo variability, but low intra-segment variability, i.e., the local tempo is relatively stable and thus musically meaningful. This has allowed us to conduct a local tempo estimation experiment. As was to be expected, a standard beat-tracker like `Böck` and a tempo estimation CNN like `DeepTemp`—trained on Pop, EDM, and Ballroom music—perform relatively poorly for Mazurkas. Even when ignoring tempo octave errors, the results are by far inferior to those achieved by the same kind of CNN as `DeepTemp`, but trained on recordings from the target genre. It is reasonable to assume that training the `Böck` system on Mazurkas would also improve performance substantially—at the price of a strong genre bias. More interestingly, we have been able to confirm a relationship between estimation accuracy and tempo stability measured in c_{var}. Arguably, segments with a very high c_{var} may not have a meaningful local tempo and should therefore be excluded from local tempo evaluation. Another valuable insight results from the comparison of local accuracy results for `DT-Maz`-models trained on either the piece-wise M- or the performance-wise V-split. It

---

[10] To keep the evaluation concise, the reported local accuracy in all following accuracy figures use 4% tolerance.

Figure 6: Averaged c_{var} and $|OE|$ for Op. 17, 4 around beats with classifications from [13]: non-event beats (black ■), boundary beats (blue ■), ornamented beats (red ■), and weak bass beats (cyan ■). High-error sections, unexplained by tempo instability, are highlighted in light-blue.

allows identification of piece-specific, musically difficult passages. When training and testing on the `V`-split, the network apparently has a chance to learn these piece-specific features not covered by data augmentation. One might also argue, `DT-Maz`$_V$ overfits to the pieces ("cover song effect" [25]). While usually seen as a negative effect, we exploit this to learn about our dataset by contrasting results with `DT-Maz`$_M$.

As with all deep learning systems, performance depends largely on the training data. For a production system, one is therefore well advised to use a larger and more diverse training set than we did in this case study.

6. FUTURE WORK

We consciously refrained from attempting to find ideal segment lengths and aggregation functions. We would therefore welcome studies on larger corpora of expressive music that search for optimal selection and aggregation functions as well as c_{var} ranges useful for meaningful evaluations.

ABSTRACT

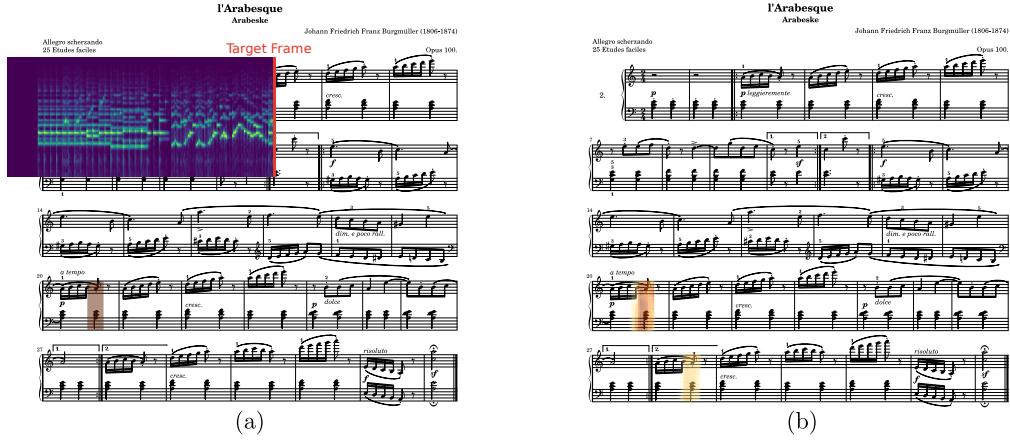
This paper addresses the task of score following in sheet music given as unprocessed images. While existing work either relies on OMR software to obtain a computer-readable score representation, or crucially relies on prepared sheet image excerpts, we propose the first system that directly performs score following in full-page, completely unprocessed sheet images. Based on incoming audio and a given image of the score, our system directly predicts the most likely position within the page that matches the audio, outperforming current state-of-the-art image-based score followers in terms of alignment precision. We also compare our method to an OMR-based approach and empirically show that it can be a viable alternative to such a system.

1. INTRODUCTION

Score following is a fundamental task in MIR and the basis for applications such as automatic accompaniment [1, 2], automatic page turning [3] or the synchronization of live performances to visualizations [4, 5]. These applications require a real-time capable system that aligns a musical performance to a symbolic score representation in an online fashion. To solve this, existing systems either require a computer-readable score representation (e. g. extracted using Optical Music Recognition (OMR) [6]) or rely on fixed-size (small) snippets of sheet images.

Models from the latter category are by design only capable of handling fixed-sized excerpts of the sheet image due to a limited action space to predict the next position in the score. This is a severe constraint, as the sheet image snippet has to (at least partly) correspond to the incoming audio excerpt. If it does not match the audio anymore (due to some tracking error), no proper prediction can be formed. To overcome this limitation, we attempt score following directly in the full sheet image, enabling the system to observe the whole page at any given time. This makes the problem significantly more challenging, e. g., due to repetitive musical score structures, compared

to locally constrained systems that only look at snippets.

To the best of our knowledge, we present the first system that requires neither OMR nor any other form of score pre-processing and directly follows musical performances in full sheet images in an end-to-end fashion. [1]


Specifically, we formulate score following as a *referring image segmentation task* and introduce an appropriate model architecture in Section 3, including a conditioning mechanism in the form of a Feature-wise Linear Modulation (FiLM) layer [7] as a central building block. In Section 4, we demonstrate the system on polyphonic piano music, taken from the MSMD dataset [8]. To analyze its generalization capabilities, we also test it on real musical performances taken from the MSMD test split, in Section 5. The results will show that our model outperforms current state-of-the-art image based trackers in terms of alignment precision, but also that it currently lacks robustness across different audio conditions.

2. RELATED WORK

Score following approaches can be broadly categorized into those that rely on the presence of a computer-readable score representation, such as MusicXML or MIDI, and those that try to do without such a symbolic representation. In the former category, techniques like Dynamic Time Warping (DTW) [4, 9, 10] and Hidden Markov Models (HMMs) [11–13] are applied to achieve robust and reliable tracking results. The main issue with these approaches is the need for computer-readable score representations, which must either be created manually in a tedious and time consuming process, or automatically extracted using OMR. In the OMR case, the faithfulness of the symbolic score to what is depicted on the sheet image strongly depends on the quality of the OMR system, which may introduce errors that impede the actual score following task. Empirical evidence for this claim was published in [14], where a DTW-based score following system that relied on MIDI scores extracted via an OMR system had difficulties tracking synthetically created test data.

Several recent publications deal with the latter category, and investigate score following in the context of non-computer-readable score representations, represented as raw sheet images. In [15], the authors propose a multi-

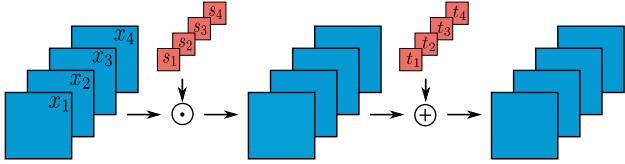
Figure 1. Score Following Task as modelled in this work: Given a score (sheet image) and an incoming musical performance (audio), the goal is to predict the current location in the score in real time. The audio is fed to the tracker frame by frame and the system processes the last 40 frames to predict the position for the latest frame (the *Target Frame* marked red in (a)). The ground truth (bounding box around current score position; see (a)) is given as a binary segmentation mask. The system predicts a probability for each pixel to correspond to the current audio; thus it highlights those regions that are most likely to match the correct location. Ideally, this should be only a single region. However, in (b) we see that such a prediction is not perfect: while the highest probability is assigned to the correct position in staff four, there is also a small likelihood in the last staff, as the notes are the same for both locations. To predict the location correctly, the system needs to consider the whole audio up to the current point in time, which motivates our design choices introduced in Section 3.

modal deep neural network to predict the position within a sheet snippet based on a short audio excerpt. In [16] and [14], score following is formulated as a reinforcement learning (RL) problem, where the RL agent's task is to adapt its reading speed in an unrolled sheet image, conditioned on an audio excerpt. One of the limitations of all these methods is that they require the score to be represented in an unrolled form, i. e., staves need to be detected in the sheet image, cut out and presented to the score following system in sequence.

To overcome this, [17] introduced a system that directly infers positions within full sheet images for monophonic piano music. However, the temporal aspect of score following was neglected altogether — based on an audio excerpt all possible matching positions in the full sheet image are highlighted, including those that were already played — making it interesting preliminary work, but not a reasonable score following system. In the following we build upon their foundation and incorporate long term audio context, proposing the first fully capable score following system that works on entire sheet images, without needing any pre-processing steps.


3. SCORE FOLLOWING AS A REFERRING IMAGE SEGMENTATION TASK

Similarly to [17], we model score following as an image segmentation task — more specifically, as a *referring* image segmentation task. In computer vision, the goal of referring image segmentation is to identify a certain region or object within an image based on some language expression [18, 19]. It shows similar characteristics as the multimodal approach to score following — we want to locate the position in the sheet image that the incoming audio refers to, meaning we treat the audio as the language expression, and the score image as the entity to reason about. More

precisely, our modeling setup is as follows: based on the incoming musical performance up to the current point in time, the task of the model is to predict a segmentation mask for the given score that corresponds to this currently played music, as shown in Figure 1. The ground truth for this task is chosen to be a region around the current position in the score with a fixed width and a height depending on the height of the staff. While the size of this mask can be arbitrarily chosen, we define it such that it provides a meaningful learning target first and foremost.

A challenging question arising with such a setup is how to combine the different input modalities, audio and score. While [14–16] learn a latent representation for both input modalities which are subsequently concatenated and further processed, we follow the direction of [17] instead, and employ a *conditioning mechanism* that directly modulates the activity of feature detectors that process the score image. The former setup would be problematic due to the increasing number of parameters. Furthermore, this design is able to retain the fully-convolutional property of our model, i. e., if desired one could process sheet images of arbitrary resolution. [2] In contrast to [17], we apply the conditioning mechanism on top of a recurrent layer to provide a longer temporal context. This permits the audio input up until the current point in time to guide the segmentation towards the corresponding position in the score image. We argue that it is necessary for this task to have such a long temporal audio context in order to form more reliable predictions. For example, it is common to have repeating note patterns in the score spanning over a longer period of time in the audio. Existing trackers that use only a fixed-size audio input are not able to distinguish between such patterns, if they exceed the given audio context.

---

[2] Note that while we do not investigate this further and work with fixed-sized sheets, this could be useful in a real world application.

Figure 2. Sketch of the FiLM layer [7]. The layer scales and translates the feature maps $\mathbf{x}$ using learned functions $\mathbf{s}(\mathbf{z})$ and $\mathbf{t}(\mathbf{z})$, respectively. $\mathbf{z}$ is an additional, external input carrying the conditioning information.

Audio (Spectrogram) 78×40
2 x (Conv(3, 1, 1)-24 - LN - ELU) - MP(2)
2 x (Conv(3, 1, 1)-48 - LN - ELU) - MP(2)
2 x (Conv(3, 1, 1)-96 - LN - ELU) - MP(2)
2 x (Conv(3, 1, 1)-96 - LN - ELU) - MP(2)
Conv(1, 0, 1)-96 - LN - ELU
Dense(32) - LN - ELU

Table 1. The context-based encoder used for the experiments. Conv(f, p, s)-k denotes a convolutional layer with k $f \times f$ kernels, padding of p and stride s. We use layer normalization (LN) [20], ELU activation [21] and max pooling (MP) with a pool size of 2×2. The output of the last layer is fed into a LSTM as shown in Figure 3. The network resembles the one used in [8].

3.1 Feature-wise Linear Modulation

The Feature-wise Linear Modulation (FiLM) layer is a simple linear affine transformation of feature maps, conditioned on an external input [7]. The purpose of using this layer is to directly interfere with the learned representation of the sheet image by modulating its feature maps, assisting the convolutional neural network to focus only on those parts that are required for a correct segmentation. In our case, the external input $\mathbf{z}$ is the hidden state of a recurrent layer that takes as input an encoded representation of an audio excerpt. This encoded representation is created by a neural network, e. g., as depicted in Table 1. The FiLM layer itself is defined as

$$f_{\text{FiLM}}(\mathbf{x}) = \mathbf{s}(\mathbf{z}) \cdot \mathbf{x} + \mathbf{t}(\mathbf{z}), \qquad (1)$$

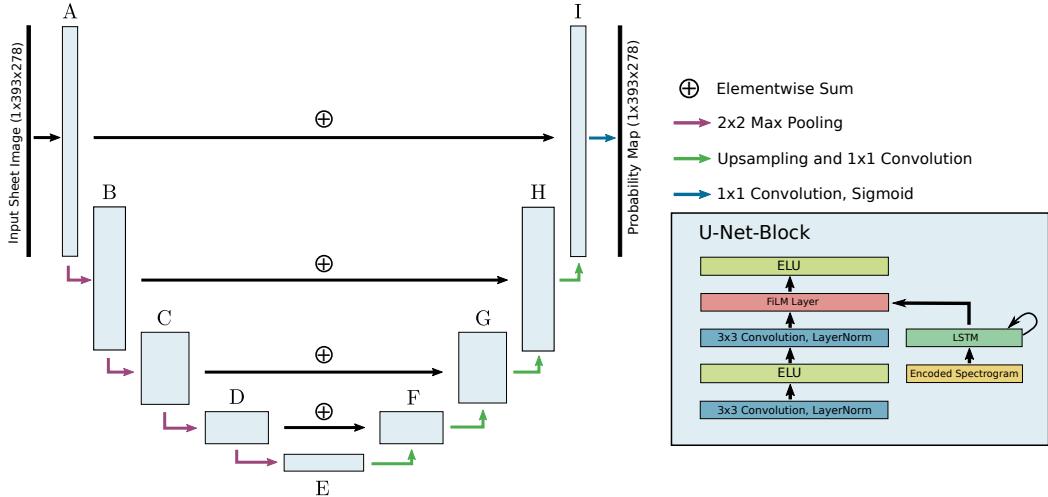
where $\mathbf{s}(\cdot)$ (for scaling) and $\mathbf{t}(\cdot)$ (for translation) are arbitrary vector-valued functions implemented as neural networks. Their values depend on the conditioning vector $\mathbf{z}$, and together they define an affine transform of the tensor $\mathbf{x}$ which refers to the collection of feature maps of a particular convolutional layer, after normalization. The affine transformation is performed per feature map, meaning that each feature map k is scaled and translated by $s_k(\cdot)$ and $t_k(\cdot)$, respectively, with k identifying the k-th output of the two functions. The number of output values for $\mathbf{s}(\cdot)$ and $\mathbf{t}(\cdot)$ is the same as the number of feature maps contained in $\mathbf{x}$, denoted by K (cf. Figure 2).

3.2 Model Architecture

Our model is based on a U-Net architecture similar to the one used in [22] for detecting musical symbols in sheet images. U-Nets were originally introduced for medical image segmentation, to segment an image into different parts, by classifying each pixel into either foreground or

background [23]. This fits naturally to our interpretation of the score following task, as a process of segmenting the sheet image into a region that corresponds to the current position in the audio input and labelling everything else as background. The overall architecture, shown in Figure 3, resembles the one proposed in [17], with several important differences. Based on the empirical findings reported in [17], we decide to incorporate conditioning information from the audio input in blocks B-H, leaving only blocks A and I without conditioning. However, we substitute the transposed convolutions in the decoder part of the network with bilinear upsampling operations with a factor of two, followed by a 1×1 convolution, both aimed at reducing checkerboard artifacts in the segmentation [24]. Due to the small batch size used during training (cf. Section 4.3) as well as the presence of the recurrent layer, we replace batch normalization with layer normalization [20].

For deriving the conditioning information from the audio input, we test two different spectrogram encoders. One takes a spectrogram snippet with a length of 40 frames, corresponding to two seconds of audio; the spectrogram is processed by the network shown in Table 1, which is roughly similar to the one used in [8]. The other version takes as input a *single spectrogram frame*, using a dense layer with 32 units, layer normalization and ELU activation function. The output of the encoders is fed to an LSTM [25] layer with 128 units and its hidden state is then used as the external input $\mathbf{z}$ in the FiLM layers.

4. EXPERIMENTS


To study the properties of our proposed approach, we conduct experiments on polyphonic piano music provided by the MSMD [8] dataset. While this section is mainly concerned with comparing data augmentation and different architectures, later on in Section 5 we will investigate the generalization capabilities of the system in terms of 16 real piano recordings from the MSMD test split. We will also contextualize the proposed system with related work described in [14], which we use as baselines for comparison.

4.1 Data

We use the *Multi-modal Sheet Music Dataset (MSMD)* [8], a standard dataset for such evaluations, comprising polyphonic piano music from various composers including Bach, Mozart, and Beethoven. The sheet music is typeset with Lilypond [3] and the audio tracks are synthesized from MIDI using Fluidsynth [4] together with a piano sound font. The original MSMD splits used by [14] encompass 354 train, 19 validation and 94 test pieces. The precise alignments between audio and sheet music in this dataset are created automatically. Despite that, it turned out that some of the pieces still contain alignment errors. We manually identified and fixed most of these errors, including wrongly aligned notes and missing or wrongly detected staves. One piece from the train set was removed, because we were not

---

Figure 3. Audio-Conditioned U-Net architecture. Each block (A-I) consists of two convolutional layers with ELU activation and layer normalization. The FiLM layer is placed before the last activation function. The spectrogram encoding given by the output of the network shown in Table 1 is passed through a recurrent layer. The hidden state of this recurrent layer is then used for conditioning in the FiLM layer. Each symmetric block has the same number of filters starting with 8 in block A and increasing with depth to 128 in block E.

able to fix it. Thus, the cleaned dataset consists of 353 train, 19 validation, and 94 test pieces, which will be made publicly available. If a piece consists of several pages, each page is treated as a single piece and the original MIDI information is partitioned accordingly.[5] Altogether, we have 945 train, 28 validation and 125 test pages. The rendered score images have a resolution of 1181×835 pixels, are downscaled by a factor of three to 393×278 pixels, and are used as the input to the U-Net. Preliminary tests showed that the downscaling does not significantly impact the performance, and benefits the speed of the training process. For the ground truth annotations, we rely on the automatic notehead alignment described in [8]. The notehead alignments yield (x, y) coordinate pairs in the sheet image, which are further adjusted for our purposes such that the y coordinates correspond to the middle of the staff the respective note belongs to. Given these coordinates, we create a binary mask with a width of 10 pixels and an adaptive height depending on the height of the staff (see Figure 1). The task of the U-Net is now to infer a segmentation mask given the image of the score together with the conditioning information derived from the audio input. Note that in theory it should be possible to directly predict x and y coordinates instead of a segmentation mask, however as shown in [26] this is a much harder task, and we were not able to achieve acceptable performance so far, even using their proposed *CoordConv* layer.

The audio is sampled with 22.05 kHz and processed at a frame rate of 20 frames per second. The DFT is computed for each frame with a window size of 2048 samples and then transformed with a semi-logarithmic filterbank that processes frequencies between 60 Hz and 6 kHz, yielding 78 log-frequency bins. Lastly, the spectrogram bins are standardized to zero mean and unit variance. The audio conditioning network is presented either with 40 consec-

utive frames (two seconds of audio) or a single frame at a time. We use the `madmom` python library for all signal processing related computations [27].

4.2 Baselines and Evaluation Measures

In the following, we will present a series of experiments, comparing the new proposed full-page tracking system to several baselines (in order to better understand the importance of some of our design choices) as well as to related state-of-the-art approaches from the literature.

First, we evaluate two different spectrogram encoders, as introduced in Section 3.2, vis-à-vis a baseline version of our system that does not have the capability to summarize all the audio up to the current point in time, i.e., that does not have memory in the form of an RNN. We do this in order to obtain empirical evidence for our argument that having access to long term temporal information is highly beneficial for obtaining good approximate solutions to the score following task. The two different encoders are denoted as context-based (CB) and frame-based (FB), using 40 spectrogram frames and a single frame, respectively. The baseline without temporal context uses the CB encoder and replaces the RNN layer with a fully connected layer of the same size. In the following this baseline will be denoted as NTC (no temporal context).

The *evaluation measures* used for this comparison are of a geometric kind (bounding box pixel error and distance on printed score page), in order to focus on the new challenge of full-page orientation: we measure the pixel-wise evaluation metrics *Precision*, *Recall* and F_1-score that were also used in [17], and the mean and median alignment error between ground truth and prediction in centimeters, both with the network output thresholded at 0.5. To calculate the alignment error between the ground truth and the predicted probability mask (recall Figure 1), we calculate the center of mass over all pixels for both masks and compute the euclidean distance between the two centers to

---

[5] This is mainly done to facilitate the training procedure. In an application, this could be solved by some simple 'hack' that turns pages when the score follower reaches the end of a page.

obtain the alignment error in pixels. Given a resolution of 72 dpi, the error is converted to centimeter using a factor of 0.0352 cm/pixel, under the assumption that the score image is printed on a sheet of DIN A4 paper.

In the second experiment we compare our system to alternative state-of-the-art approaches from the literature: the first approach is based on an OMR system that extracts symbolic MIDI information from the sheet image. The symbolic MIDI information is then synthesized to audio. The system subsequently computes chroma features with a feature rate of 20 Hz from both the synthesized and the performance audio, and applies audio-to-audio alignment using a form of online DTW [28]. This is the method described in [14] and will be abbreviated as OMR in the upcoming result table. The second and third approach, described in Section 2, are a multi-modal localization network (MM-Loc) [15] and a Reinforcement Learning (RL) agent [14, 16], both working with sheet image snippets.

The *evaluation measure* for this will be of a more music-related kind (temporal tracking error in the performance), reflecting the intended purpose of the systems (score following), and permitting a direct comparison with alternative methods. Similarly to [9, 10], we compute, for each note onset, the absolute time difference between prediction and ground truth. We set 5 threshold values, ranging from 0.05 to 5 seconds, and report the cumulative percentage of notes tracked with an error up to the given threshold. Given the ground truth alignment from note onsets to the corresponding notehead coordinates in the sheet image, we can interpolate from the predicted positions in the sheet image back to the time domain. This is straightforward for MM-Loc and the RL agent, because they both already use an unrolled score derived from the groundtruth, whereas the proposed method requires further processing. We first need to compute the center of mass of the segmented region to obtain x, y coordinates. We map the y coordinate to the closest staff, and apply a similar interpolation as before in an unrolled score to get the time difference between the predicted and actual position in the score.

For evaluating the OMR baseline we face a problem that has already been noted in [14] — we do not have the required groundtruth alignment between the OMR-extracted score and the performance. Given that only onset positions are evaluated, we are justified to assume a perfect alignment between score and audio, if for each unit of time in the audio a constant distance in the score sheet is travelled. If the OMR system makes no errors, the alignment between OMR score and performance is a diagonal in the DTW global cost matrix, correcting the overall tempo difference by a linear factor. As in [14], we evaluate the OMR-based system by measuring the offset of the actual tracking position relative to the perfect alignment.

4.3 Experimental Setup

All models are trained using the same procedure. We optimize the *Dice* coefficient loss [29], which is more suitable than e.g., *binary cross-entropy*, as we are facing an imbalanced segmentation problem with far more unimpor-

tant background pixels than regions of interest. To optimize this target we use Adam [30] with default parameters, an initial learning rate of $1e^{-4}$ and L^2 weight decay with a factor of $1e^{-5}$. If the conditioning architecture involves an LSTM, we use a batch-size of 4 and a sequence length of 16. For the audio conditioning model without a temporal context we use a batch size of 64. The weights of the network are initialized orthogonally [31] and the biases are set to zero. If the loss on the validation set does not decrease for 5 epochs, we halve the learn rate and stop training altogether when the validation loss does not decrease over a period of 10 epochs or the maximum number of 100 epochs is reached. The model parameters with the lowest validation loss are used for the final evaluation on the test set. Similar to [17], we perform data augmentation in the image domain by shifting the score images along the x and y axis. To investigate whether tempo augmentation improves model performance, we train all models without tempo augmentation as well as with 7 different tempo change factors ranging from 0.5 up to 1.5.

4.4 Results

In Table 2, we compare different conditioning architectures, no long term temporal context (NTC), a context of 40 frames (CB) and a single frame (FB) in combination with an LSTM, respectively. We observe that the NTC model has the lowest performance, both in terms of the pixel-wise measures, as well as in terms of its alignment error. A possible reason for this could be ambiguities in the sheet image, since audio excerpts could match several positions in the score. The results for CB and FB support our initial claim that a long term temporal context is required for this task. While both models achieve a good performance, CB outperforms FB in all measures. On average, the alignment error is around 1.25 cm and the median is at 0.51 cm, meaning that half of the time our model is less than 0.51 cm away from the true position. Furthermore, we observe that tempo augmentation improves the results for all models.

In Table 3, we compare our best model from Table 2 to several baselines from the literature in terms of the cumulative percentage of onsets that are tracked with an error below a given threshold. We observe that the context-based proposed model (CB) outperforms all baselines except for the highest threshold. This suggests that our method is very precise on one hand, but on the other hand is not able to track all onsets with a timing error below five seconds.

5. REAL PERFORMANCES

To test the generalization capabilities of the system under real recording conditions, we evaluate our best model on the 16 piano recordings (corresponding to 25 score pages) from the MSMD test split introduced in [14], for which we also manually corrected some of the alignments. We compare again to the baselines introduced in Section 4.2, which are likewise evaluated using the corrected alignments. In line with [14], we compare four different settings with in-

MSMD (125 test pages)						
	TA	**P**	**R**	**F$_1$**	$\overline{d}_{cm}$	$\widetilde{d}_{cm}$
NTC	✗	0.696	0.665	0.678	3.70	2.37
	✓	0.770	0.740	0.754	2.78	1.61

≤ 5.00	**97.4%**	92.0%	97.2%	93.7%

Table 3. Our best model (CB) vs. existing baselines, in terms of onsets tracked with an error below a given threshold. For the RL agent we report the average over 10 runs due to its stochastic policy. In contrast to [14], OMR, MM-Loc and RL do not stop tracking if they fall out of a given tracking window.

creasing difficulty. The first is the same synthetic setting as in Section 4. The second setting uses the performance MIDI synthesized with the same piano synthesizer used during training. The third uses the audio of the "direct out" audio output of the "Yamaha AvantGrand N2" hybrid piano used for recording, and the last one uses the audio recorded via a room microphone.

Table 4 summarizes the results. Overall, we observe that the proposed system (CB) achieves more precise results in terms of time difference (i.e., higher percentages for the tighter error thresholds) in three out of four settings. For the last setting we observe a worse performance, which indicates that our model has possibly overfit to the synthesized audio and is not yet robust enough. OMR yields very robust results in all scenarios, which is possibly due to the used chroma features. While the results are not as precise, it outperforms the other methods for higher threshold values.

A possible explanation for this is that our model has more freedom in being able to perform big jumps on the sheet image paper, thus increasing the error possibility. Models relying on sheet snippets are not designed to perform such jumps and thus can also not make very extreme errors. Furthermore, our model is more sensitive to the audio representation fed into the conditioning mechanism, as it influences the convolutional filters in multiple layers that process the sheet image. Overall, we assume that this is an issue of the synthetic dataset which can be tackled by training on more diverse performances and a more robust audio model for the conditioning mechanism.

Table 4. Comparing best performing model to several baselines on a set of 16 real piano recordings (25 pages) from the MSMD test split. Model evaluation is as described in Table 3, with the difference that for the RL agent we report the average over 50 runs due to its stochastic policy and the smaller sample size.

6. DISCUSSION AND CONCLUSION

We have proposed the first end-to-end trained score following system that directly works on full sheet images. The system is real-time capable due to a constant runtime per step, it compares favorably with existing baselines on synthetic polyphonic piano music, and sets the new state of the art for sheet-image-based score following in terms of temporal alignment error. However, there are still generalization problems for real piano recordings. While the model shows a much more precise alignment in most scenarios, we see a performance deterioration over different recording conditions. This will need to be solved in the future, either with a more robust audio model, or a data augmentation strategy that incorporates reverberation effects. Future work will also require testing on scanned or photographed sheet images, to gauge generalization capabilities of the system in the visual domain as well. As there is currently no dataset consisting of scanned sheet images with precise notehead to audio alignments, it will be necessary to curate a test set. The next step towards a system with greater capabilities, is to either explicitly or implicitly incorporate a mechanism to handle repetitions in the score as well as in the performance. We assume that the proposed method will be able to acquire this capability quite naturally from properly prepared training data, although we suspect its performance will heavily depend on its implicit encoding of the audio history so far, i.e., how large an auditory context the recurrent network is able to store.

ABSTRACT

Recent work has proposed the use of tensor decomposition to model repetitions and to separate tracks in loop-based electronic music. The present work investigates further on the ability of Nonnegative Tucker Decompositon (NTD) to uncover musical patterns and structure in pop songs in their audio form. Exploiting the fact that NTD tends to express the content of bars as linear combinations of a few patterns, we illustrate the ability of the decomposition to capture and single out repeated motifs in the corresponding compressed space, which can be interpreted from a musical viewpoint. The resulting features also turn out to be efficient for structural segmentation, leading to experimental results on the RWC Pop data set which are potentially challenging state-of-the-art approaches that rely on extensive example-based learning schemes.

1. INTRODUCTION

A common problem in Music Information Retrieval domain (MIR) is the design of musical content representations and features able to capture meaningful information in relation to a particular aspect of music. While short-term features are dominant in the literature, higher-scale features aiming to describe medium-term patterns and long-term structural properties tend to be much less addressed.

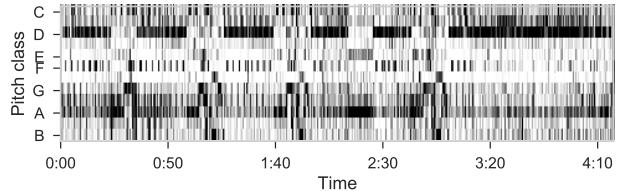
Recent work by Smith and Goto [1] has proposed the use of tensor decomposition to model repetitions in loop-based electronic music, with the purpose of separating tracks in audio content. In this paper, we explore the ability of the method to provide a sparse description of music by capturing and characterizing patterns at the bar-scale level in western pop songs in their audio form. As a testbed, we evaluate the effectiveness of the new features for structural segmentation, *i.e.* the task of retrieving the boundaries of the various musical sections (such as verses, choruses, intros, bridges...) which form a music piece.

We first recall (in section 2) the mathematical theory of the tensorial model called Nonnegative Tucker Decom-

position (NTD), and we provide detailed illustrations and interpretation of the NTD components on the audio recording of a well-known pop song. We then (in section 3) elaborate on a number of practical considerations related to NTD, which are needed to be taken into account when applying the model to real music data. In the last part of the article (sections 4 and 5), we report on experiments and results obtained with the NTD-derived features for structural segmentation of the RWC Pop Music data set [2].

2. NONNEGATIVE TUCKER DECOMPOSITION

2.1 Time-Frequency-Bar Tensor

Music in its audio form is often represented in the time-frequency domain as a spectrogram, *i.e.* a 2-dimensional matrix (further denoted as X). Along the x-axis, the temporal dimension unfolds, discretized as signal frames, while the y-axis is a frequency-related dimension (such as modules of the Fourier coefficients, pitches, constant-Q transforms, wavelet coefficients...).


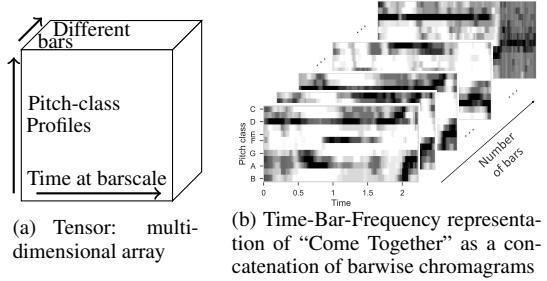


Figure 1: Chromagram of "Come Together", by The Beatles.

In this work, we describe music as chromagrams. Conventionally, the 12 rows represent the energy distribution across the song for each semi-tone of the classical western music scale, where a note and all its octave counterparts are represented in the same row. An example chromagram is shown in Figure 1.

In the tensorial approach, the temporal dimension is broken up into two distinct dimensions: a low-scale dimension representing time in terms of frame index normalized at the bar scale, and a high-scale time dimension representing the bar index within the entire piece. This new viewpoint makes it possible to represent a song as a third-order tensor $\mathcal{X}$ of size $F \times T \times B$, F being the size of the frequency dimension (12 in the case of chromas), T the number of frames used to describe bars (local time scale) and B the number of bars in the song (global time scale). We call $\mathcal{X}$ the Time-Frequency-Bar representation of the song which, from a data structure viewpoint, is the recasting of X as a 3D array. Tensor $\mathcal{X}$ can be seen as the concatenation

(a) Tensor: multi-dimensional array

(b) Time-Bar-Frequency representation of "Come Together" as a concatenation of barwise chromagrams

Figure 2: Principle and illustration of a Time-Bar-Frequency representation as a third-order tensor.

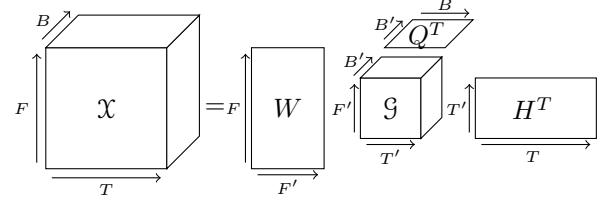
of local time-frequency representations, each of them characterizing the content of a bar, as illustrated on Figure 2. Note that, as bars can be of different lengths in absolute time, the frame hop depends on each bar, and is defined so that all bars contain the same number of frames.

2.2 Mathematical Model and Formalism

Let us denote as $\mathcal{X}$ the Time-Frequency-Bar representation of a song, with dimensions $F \times T \times B$. Assuming chroma coefficients are all nonnegative, $\mathcal{X}$ is also a nonnegative tensor. Computing a Nonnegative Tucker Decomposition (NTD) of $\mathcal{X}$ consists in finding 3 nonnegative factor matrices W, H and Q (corresponding to the three "modes" of the Time-Frequency-Bar tensor) and a nonnegative core tensor $\mathcal{G}$ which relates the three modes as of how to combine them to reconstruct (an approximation of) $\mathcal{X}$.

The dimensions $F' \times T' \times B'$ of the core tensor $\mathcal{G}$ are usually set to be lower than those of $\mathcal{X}$ (*i.e.* $F', T', B' \leq F, T, B$ respectively). As a consequence, matrices W, H and Q are respectively of dimensions $F \times F'$, $T \times T'$ and $B \times B'$ and they can be understood as transformed and compressed representations of the raw information conveyed across the three dimensions of the full tensor.

In conventional tensor-product notation [3], the approximation of $\mathcal{X}$ can be written in compact form as:

$$\mathcal{X} \approx \mathcal{G} \times_1 W \times_2 H \times_3 Q . \qquad (1)$$


which rewrites, using element-wise notation, as:

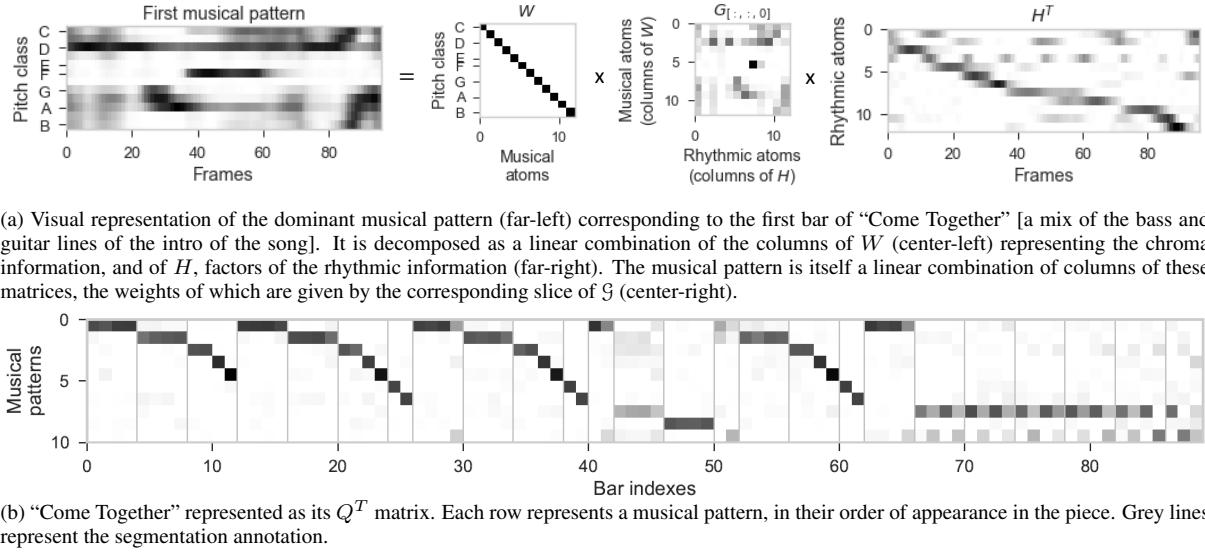
$$\mathcal{X}(f,t,b) \approx \sum_{f',t',b'=1}^{F',T',B'} \mathcal{G}(f',t',b')W(f,f')H(t,t')Q(b,b') \qquad (2)$$

In particular, any given bar of index b is represented as:

$$\mathcal{X}(:,:,b) \approx W \left(\sum_{b'=1}^{B'} Q(b,b')\mathcal{G}(:,:,b') \right) H^T \qquad (3)$$

Figure 3 depicts a schematic 3-D representation of a NTD. NTD core dimensions F', T' and B' are assumed to be known (or set empirically) prior to the decomposition. As they are lower than the dimensions of their respective mode of the tensor, NTD achieves information compression via nonlinear dimensionality reduction. Indeed, for an original tensor of size $F \times T \times B$ (*i.e.* comprising $F.T.B$ numerical values), the NTD decomposition

Figure 3: Nonnegative Tucker Decomposition of tensor $\mathcal{X}$ in factor matrices W, H, Q, and core tensor $\mathcal{G}$, with their dimensions.

will total $F.F' + T.T' + B.B' + F'.T'.B'$ values. For example, in the decomposition presented further in Figure 4, the original tensor contains 102528 real positive values ($F, T, B = 12, 96, 89$), while only 3626 for the NTD ($F', T', B' = 12, 12, 10$).


2.3 Interpretation of the NTD

Loosely speaking, music can be viewed as composed of musical events (notes, percussive sounds, ...) occurring non-randomly in bars. Under that assumption, bars can be modeled as the combination of a limited set of time-frequency templates along time within a bar, according to some rhythmic values, such as "half notes" or "beamed eight notes" for example. This is the purpose of a conventional musical score, where the major part of symbolic information represents pitch and rhythm. Following that idea, it is a very popular goal in MIR to design methods for turning back musical content (in audio form) into a sparse combination of musical events and temporal activations, as is the case, for instance, with Nonnegative Matrix Factorization (NMF) for music transcription [4]. Moreover, music often contains repetitions: different bars can entirely or partly share similar content. For instance, beside almost identical repetitions, some instrumental lines can reoccur in different contexts: an identical bass line in a verse and in a guitar solo, for example.

Combining these observations, we assume that each bar can be represented as the nonnegative combination of a few "musical patterns" (as NMF would do), where a "musical pattern" is itself a sparse combination of musical events and rhythmic activations at the bar scale (for example a melodic line, or a drum fill). Repetitions imply that some of these musical patterns should appear in several bars across a piece. NTD offers an ideal framework to model these properties for music decomposition, musical patterns being efficiently and sparsely shared across bars.

In the NTD, the W matrix represents the musical events, such as the most recurrent notes or chords. H represents rhythmic activations at the bar scale, for example 4 quarter notes on the beats. Then, each 2D "slice" of the core $\mathcal{G}$ linking these two matrices defines a musical pattern, as a linear combination of some of their columns (musical and rhythmic atoms): for example bass drum hits on the on-beats and snare hits on the off-beats. Finally, Q indicates, for each bar, the combination of musical patterns forming it (generally a few) and their respective intensity.

Figure 4 provides a detailed example of the various NTD components stemming from "Come Together" by the Beatles. While the upper part of the figure illustrates the

(a) Visual representation of the dominant musical pattern (far-left) corresponding to the first bar of "Come Together" [a mix of the bass and guitar lines of the intro of the song]. It is decomposed as a linear combination of the columns of W (center-left) representing the chroma information, and of H, factors of the rhythmic information (far-right). The musical pattern is itself a linear combination of columns of these matrices, the weights of which are given by the corresponding slice of $\mathcal{G}$ (center-right).

(b) "Come Together" represented as its Q^T matrix. Each row represents a musical pattern, in their order of appearance in the piece. Grey lines represent the segmentation annotation.

Figure 4: Visualizations of the NTD of Come Together by The Beatles, with ranks $T' = 12$ and $B' = 10$.

dominant musical pattern for the first bar together with its decomposition in NTD, the lower part depicts the description of the entire piece via the Q^T matrix of the NTD. This example has been obtained from the chromagram represented in Figure 1. Because the song is expressed on the 12-chroma scale, we expect little compressibility with respect to this dimension. We hence simplify the model by fixing W to the 12-size identity matrix. This means that each semi-tone is represented by one and only one column of W. For higher dimensions or different representations, columns of W could represent a wider range of harmonic or percussive sounds, chords, or any other frequency pattern. Conversely, ranks T' and B' (respectively the second dimension for H and Q) are adjustable parameters of the model. In the decomposition presented in Figure 4, they have been set to $T' = 12$ and $B' = 10$. All columns of H and all slices of the core linking the factor matrices W and H, which define the musical patterns, are l_2 normalized (*i.e.* divided by their standard deviation).

3. PRACTICAL INSIGHTS ON THE NTD

In this section, we discuss a number of considerations which are bound to have an impact on the actual result of the NTD-based representations and must therefore be taken into account in practical situations.

3.1 NTD Algorithm

NTD can typically be computed by minimizing the following non-convex objective function with respect to the non-negative matrices W, H, Q and the core tensor $\mathcal{G}$:

$$\|\mathcal{X} - \mathcal{G} \times_1 W \times_2 H \times_3 Q\|_F^2 \qquad (4)$$

While a direct global minimization of Eqn (4) is not tractable in general, a standard approach in the literature is to resort to alternating optimization. Following [5], we solve Eqn (4) for W, H, Q and $\mathcal{G}$ alternatively. It can be shown that each of these steps means solving a matrix non-

negative least-square problem of the form:

$$\min_{Z \geq 0} \|Y - AZ\|_F^2 \qquad (5)$$

for some matrices Y, A, Z. This problem is convex, and it is possible to solve it exactly, or up to an arbitrary precision. An efficient algorithm for solving matrix nonnegative least squares with high precision is the Hierarchical Alternating Least Squares, and we used an accelerated variant of it to speed-up computation [6]. The problem of updating $\mathcal{G}$ is also a nonnegative least squares problem, but not a matrix one. Therefore, to update the core tensor $\mathcal{G}$, we used a proximal gradient with optimal step [7, Ch. 10].

It can be shown that the proposed alternating algorithm is guaranteed to converge to a stationary point of the objective function (4), since it boils down to an alternating proximal gradient algorithm with optimal step [8]. In practice, we used a stopping criterion based either on a fixed maximal number of iterations or on a fixed minimal tolerance of improvement between two successive updates. The entire code, along with experimental notebooks, are published and open-source [1] . Under this implementation, computing the NTD for "Come Together" (4'16" song) with our algorithm takes approximately 15 seconds on a laptop with an Intel® Core(TM) i7 processor and 16GB of RAM.

3.2 Robustness of the NTD

At least two issues with the NTD make the output of any algorithm highly dependent on the initialization. First, there might be several solutions $W, H, Q, \mathcal{G}$ that provide the same (or a very similar) estimate $\hat{\mathcal{X}} \approx \mathcal{X}$. This problem, known as identifiability deficiency, has been little studied for NTD, and established identifiability conditions are very restrictive [9]. Moreover, these conditions are hard to check in practice. Therefore it is unreasonable to assess the identifiability of the NTD in our application. As a consequence, this means that there might be infinitely many

---

[1] https://gitlab.inria.fr/amarmore/musicntd/-/tree/0.1.0

solutions to minimizing Eqn (4) that are, from an optimization point of view, equally satisfying. Second, even in the case where the NTD is identifiable, the cost function of (4) is highly non-convex, and local algorithms can only hope to recover a local minimum at best.

These two issues combined give rise to a high dependency of the solution on the initial condition: from two different initializations, two different results – most probably non-identifiable local minima – are likely to be obtained. We have observed such situations in our investigations, with various initializations indeed resulting in different outputs. However, in most cases the decomposition would provide results that were reasonably interpretable from a musical perspective. In particular, when we initialized the algorithm with the absolute values of the Higher Order SVD [10] computed with the Tensorly toolbox [11], the procedure consistently provided satisfying results for segmentation, as detailed further in our experiments.

3.3 Rank Selection

The ranks F', T' and B' of the decomposition are crucial parameters of the NTD model. Indeed, low ranks tend to over-compress information in the data, failing to uncover relevant structural information in the song, while high ranks may give too much importance to details in the data, resulting in the inability of the model to group similar patterns in a same class of representations.

As developed further in section 5.4, our experiments indicate that the optimal ranks are probably specific for each song, which can be easily understood as a consequence of the diversity of intrinsic variability across music pieces. Providing an efficient method for selecting the ranks is a challenging topic, left to future work.

4. NTD-BASED SEGMENTATION

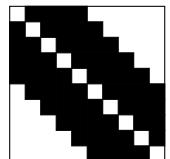
To study further the relevance of the NTD representation, we evaluated it in the context of structural segmentation. To our knowledge, this is the first attempt to exploit tensorial representations for this purpose.

4.1 Autosimilarity for Describing Structure

The autosimilarity matrix $X^T X$ of a music piece (X being its time-frequency representation) is commonly used in structural segmentation. Indeed, similar portions of the piece are likely to have high correlation values. A high density of high values around the diagonal is expected in passages with strong internal similarities, whereas low local correlations would indicate a change in homogeneity. In the ideal case, structural segments appear as consistent blocks with a high level of internal correlation while segment boundaries are points connecting such blocks, surrounded by zones of low cross-correlation.

Nonetheless, music signals usually generate dense autosimilarity matrices, as dissimilar segments in the musicological/perceptive sense (for example a guitar line on the chorus opposed to one in the verse) may still be close

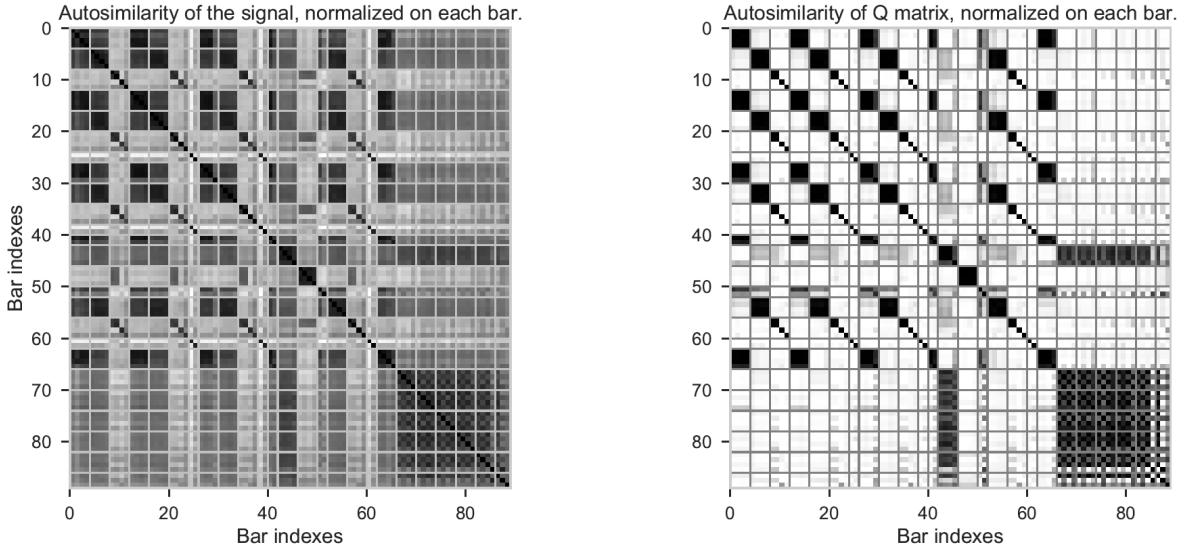
in terms of signal properties. While similar parts generate high correlation blocks, it can be harder to characterize segments boundaries when the same instruments are played in all segments (even when playing different lines).

In the present work, we replace $X^T X$ by an autosimilarity matrix $\tilde{Q}\tilde{Q}^T$ computed from the row-wise normalized Q matrix (denoted $\tilde{Q}$), and study its capacity to provide an efficient representation for structural segmentation.


Our assumption is that bar descriptions provided by $\tilde{Q}$ provide a better contrast between similar and dissimilar musical constituents. For instance, we expect two different lines of the same instrument to generate different musical patterns, resulting in lower similarity, whereas compressive effects of NTD will increase correlation of similar events in the transformed space. In that sense, NTD can be seen as a way to uncover piece-dependent features for describing bars, which can then be used to group the bars according to their relative similarity.

Figure 5 depicts the "barwise" autosimilarity matrix of the chromagram X of "Come Together": the content of each bar of the signal has been vectorized, and similarity is computed between these barscale vectors. This matrix is compared to the autosimilarity of the $\tilde{Q}$ matrix, presented on Figure 4b. This figure visually supports the hypothesis that autosimilarity matrices are sparser when computed from the matrix Q rather than from the chromas X. Still, highly similar blocks seem to be preserved.

4.2 A Segmentation Algorithm Using Autosimilarity

To assess this hypothesis, we implemented a segmentation algorithm based on the principle of a sliding convolution kernel along the diagonal of the autosimilarity matrix.


This kernel is a square binary matrix, whose entries are non-zero only on the lower and upper 4 subdiagonals around the main diagonal (Figure 6). In other terms, denoting k_{ij} the kernel elements, $k_{ij} = 1$ if $1 \leq |i - j| \leq 4$. Otherwise, $k_{ij} = 0$.

Figure 6: Kernel of size 10

For every possible segment (b_1, b_2), a kernel of size $n = b_2 - b_1 + 1$ is convolved with the corresponding autosimilarity sub-matrix (restricted to the bars between b_1 and b_2) which is then normalized by the size of the segment. This leads to a raw convolution score: $c_{b_1,b_2} = \frac{1}{n} \sum_{i,j=0}^{n-1} k_{ij} a_{i+b_1, j+b_1}$. The kernel aims at detecting local similarities within the 8 bars surrounding each bar. The more similar this surrounding is, the higher the score.

In addition, we combine the kernel score with a regularity penalty $p(n)$, depending on the size n of the segment. Indeed, in pop music in general (and in the MIREX10 RWC Pop annotations in particular [12]), the distribution of musical segment sizes (in bars) tend to be centered around 8, and they are more likely to be even than odd. In the experiments reported in the next section, we set empirically, $p(8) = 0$, $p(n) = \frac{1}{4}$, if n is a multiple of 4, $p(n) = \frac{1}{2}$ if n is a multiple of 2, and $p(n) = 1$ if n is odd. This penalty modifies the raw convolution score as

Figure 5: Barwise l_1-normalized autosimilarity matrices for "Come Together" (0: white - 1: black). Left: barwise chromagram autosimilarity - Right: autosimilarity of $\tilde{Q}$ matrix from Figure 4b. Grey horizontal and vertical lines represent the segmentation annotation.

follows:

$$c'_{b_1,b_2} = c_{b_1,b_2} - \lambda p(n) c_{k8}^{max} \qquad (6)$$

where c_{k8}^{max} is the maximum of the raw convolution score over all restrictions of size 8 bars within the piece, in order to cope with potential discrepancies in sparsity across autosimilarity matrices for different pieces. In practice, λ is fitted by cross-validation.

Finally, segment boundaries are found by a dynamic programming algorithm, inspired from [13]: it keeps the sequence of segments maximizing the global cost defined as the sum of all segment costs.

5. EXPERIMENTS

The proposed method was applied to the $\tilde{Q}^T$ representation and tested on the "structural segmentation" task, as defined in the MIREX campaigns [14], on the 100 songs from the RWC Pop database [2]. MIREX10 annotations [12] serve as the reference segmentation (1680 segments). We compare our results with state-of-the-art methods listed below.

5.1 Related Work

In the context of structural segmentation, numerous methods try to detect segment boundaries from the autosimilarity matrix, or from an "affinity matrix" derived from it.

The use of autosimilarity for segmenting music structure probably traces back to Foote [15]. In this work, structural boundaries are detected by applying a kernel along the diagonal, as described above. Foote's kernel though aims at detecting "novelty" in the signal's autosimilarity matrix, by comparing inter-similarity between the near past and near future at the current point. A high novelty should indicate a low inter-similarity between past and future, hinting towards a boundary between segments.

More recently, convex NMF was used for segmenting a pre-processed autosimilarity matrix [16]. A variant of NMF decomposition is used to enforce the feature space

(here, similarity between different bars) to be contracted in convex combinations of columns of the autosimilarity matrix. Factorization results are thus interpreted as the most similar bars, which can then be processed into sections.

Spectral clustering can also be used. In [17], an affinity matrix is computed from the signal, where the similarity is obtained with k-nearest neighbors and time-proximity rules. Then, interpreting this matrix as a graph, and its values as vertices connectivity, this method studies the eigenvectors of its Laplacian. These eigenvectors can be interpreted as principally connected vertices, forming cluster classes for segmentation.

We primarily compare the NTD method with these techniques for two reasons. First, they are implemented in the MSAF toolbox [20]. Second, they reach state-of-the-art performance among "blind" methods for structural segmentation, *i.e.* methods which, like NTD, do not resort to extensive training from examples. Note that the segmentation results we obtained with MSAF, though, are slightly worse ($\approx 3/4\%$) than those obtained at MIREX 2016 [21], possibly due to evolutions of the toolbox itself in the interval. We did not tune any of the default parameters.

As current state-of-the-art, we selected the algorithm from [18] since it ranked first in this task in the last MIREX campaigns. However, as opposed to the previous methods, it requires supervised training from many examples.

5.2 Downbeat-Synchronous Alignment

By construction, the boundaries estimated by the NTD-based approach are aligned on downbeats, which is not the case for the techniques we use as baseline comparisons. As segments generally start and end on downbeats of the song, this alignment could induce a bias favouring our technique. To compensate for this, in addition to the segmentation scores computed with the original boundaries, we compute the scores after having aligned boundaries on the closest downbeat. We call this condition "Aligned on downbeats".

Algorithm		$P_{0.5}$	$R_{0.5}$	$F_{0.5}$	P_3	R_3	F_3
NTD-based autosimilarity		53.3%	62.1%	56.6%	66.8%	78.1%	71.1%
Barwise chromagram autosimilarity		43.1%	45.7%	43.9%	64.8%	68.0%	65.8%
Foote Novelty [15]	Original	29.7%	22.3%	25.1%	63.9%	48.6%	54.5%
	Aligned on downbeats	42.0%	30.0%	34.5%	67.1%	47.7%	55.0%
CNMF [16]	Original	22.8%	21.5%	21.5%	46.8%	45.1%	44.7%
	Aligned on downbeats	31.6%	28.1%	28.8%	50.7%	45.4%	46.5%
Spectral Clustering [17]	Original	31.2%	30.5%	29.4%	60.7%	60.8%	58.1%
	Aligned on downbeats	49.2%	45.0%	45.0%	65.5%	60.6%	60.3%

Table 1: Averaged segmentation scores, and their comparison with several "blind" reference methods.

Algorithm	$P_{0.5}$	$R_{0.5}$	$F_{0.5}$	P_3	R_3	F_3
NTD, with "oracle ranks" for each song	67.1%	78.2%	71.5%	78.5%	90.2%	83.1%
Neural Networks [18], results from MIREX 2015 [19]	80.4%	62.7%	69.7%	91.9%	71.1%	79.3%

Table 2: Averaged segmentation scores in the "oracle ranks" condition, compared to the current state-of-the-art (non-blind) method.

In addition, we also processed the barwise autosimilarity obtained directly from the chromagram, in order to measure the impact of the NTD-derived representation vs the raw time-frequency representation.

5.3 Implementation Details

RWC Pop signals are sampled at 44100Hz. Bars were estimated by the madmom toolbox [22]. Chromas were extracted from the Constant-Q Transform of the signal with 32-sample hop using Librosa [23], then mapped to 96 equally spaced chroma vectors per bar. This results in a chromagram X with 12 rows and $96 \times B$ columns. Tensors were handled with the Tensorly toolbox [11]. We use our own implementation of the NTD algorithm (see Section 3.1). Segmentation performance was computed with the mir_eval toolbox [24].

5.4 Results

Segmentation performance is evaluated with metrics based on "hit-rate". The hit-rate considers a boundary as correct if it coincides with a boundary in the reference segmentation within some time window. From the count of correct and incorrect segment boundaries, we compute Precision, Recall and F-measure. Tolerance windows were chosen to be 0.5s and 3s, in line with MIREX standards.

As mentioned in Section 3.3, the ranks of the NTD strongly influence the decomposition and, consequently, the segmentation results. Ranks T' and B' are treated as adjustable parameters, and can vary between 12 to 48, with a step of 4. W is fixed to the 12-size identity matrix. The impact of T' and B' is investigated under two rank selection conditions.

In the first condition (Table 1), the RWC Pop data set is divided in two subsets (songs with odd vs even ID number), which are alternatively used as tuning (for global optimization of the ranks and the penalty parameter λ) and test data sets, in a 2-fold cross-validation fashion. Results shown in the table are averaged over the two folds. Hence, in this condition, all songs of a test data subset are decomposed with the same ranks, namely $T', B' = 40, 28$ for odd songs, and $48, 24$ for even ones.

In the second condition, presented in Table 2, the NTD ranks are fitted a posteriori on each song individually: for each tolerance value, separately, we select the ranks leading to the best F-measure for the given song. This is called the "oracle ranks" condition, corresponding to the situation where a "perfect" rank selection procedure would exist. Resulting scores provide an (optimistic) performance upper bound.

These two tables exhibit very competitive results. In the first (and most realistic) condition, NTD-based segmentation performance exceeds those of the reference "blind" methods segmentation. In the "oracle ranks" condition, the NTD provides higher F-measures than the state-of-the-art, showing strong potential for the technique, provided an efficient rank selection method is eventually developed.

6. CONCLUSION AND FUTURE WORK

Designing relevant audio features from music remains one of the key questions in many MIR tasks. In this paper, we have proposed a three-way tensor representation of music in frequency, short-term (frames) and mid-term (bars), and means to decompose it under the low-rank Nonnegative Tucker Decomposition (NTD) model. This decomposition turns out to be able to provide a compressed representation of interest, capturing salient patterns in music.

We have illustrated the benefits of the method in a structural segmentation task. The NTD-based representation allows to compute a new type of autosimilarity matrix which exhibits a better contrast than those directly computed on 2D time-frequency representations, and seems well-suited to identify musical patterns at the "right" time-scale for the task. Experimental results are promising and show a potential to compete with state-of-the-art approaches, may they be "blind", or greedier on training data.

Additional research is required to consolidate the technique. First, as our experiments show, a rank selection criterion would drastically improve segmentation performance. Second, the model does not yet incorporate the notion of proximity between patterns themselves. In parallel, a number of theoretical questions on model identifiability and algorithmic convergence also remain open.

ABSTRACT

"Maracatu de baque solto" is a Carnival performance combining music, poetry, and dance, occurring in the Zona da Mata Norte region of Pernambuco (Northeast Brazil). Maracatu percussive music is strongly repetitive, and is played as loud and as fast as possible. Both from an MIR and ethnomusicological perspective this makes a complex musical scene to analyse and interpret. In this paper we focus on the extraction of microtiming profiles towards the longer term goal of understanding how rhythmic performance in Maracatu is used to promote health and well-being. To conduct this analysis we use a set of recordings acquired with contact microphones which minimise the interference between performers. Our analysis reveals that the microtiming profiles differ substantially from those observed in more widely studied South American music. In particular, we highlight the presence of dynamic microtiming profiles as well as the importance of the choice of time-keeper instrument, which dictates how the performances can be understood. Throughout this work, we emphasize the importance of a multidisciplinary approach in which MIR, audio engineering, and ethnomusicology must interact to provide meaningful insight about this music.

1. INTRODUCTION

"Maracatu de baque solto", also known as "Maracatu rural", is a Carnival performance combining music, poetry, and dance, occurring in the Zona da Mata Norte region of Pernambuco (Northeast Brazil). Most inhabitants of this region, dominated by the sugar cane monoculture, are rural workers with very modest income, who invest most of

Figure 1: Maracatu de baque solto "Leão de Ouro de Condado" during a Carnival parade in Tupaoca (Pernambuco), Feb. 28th, 2017. Photo credit: Filippo Bonini Baraldi.

their time and money to participate in the Carnival "desfile" (parade), taking place every year in Recife, the state capital. More than 100 groups of Maracatu de baque solto, of different sizes (ranging from 15-20 members up to 200 members) are currently active, each with their own headquarters ("sede") which are generally linked to individual families. A Maracatu performance is shown in Fig. 1.

Maracatu de baque solto differs from another Carnival performance with a similar name, Maracatu "de baque virado," not only in terms of its musical and choreographic features, but also because it has remained a very local cultural practice. Indeed, while Maracatu de baque virado, like other music from Pernambuco (e.g., forró, coco de roda, ciranda), has recently spread out nationally and internationally, Maracatu de baque solto (hereafter shortened to Maracatu) is only performed within a radius of about $100\,\mathrm{km}^2$ and is strongly linked to the local afro-indigenous spiritual and religious practices, specifically, the jurema-umbanda worship [1]. This local dimension explains why, barring a few exceptions, it remains a largely understudied cultural expression. To the best of our knowledge no in-depth analysis of its music has ever been realised.

Previous field research conducted in Condado, a small city located in the Zona da Mata Norte region, suggests that

the protective function of Maracatu is locally expressed by two key concepts: "consonância" (consonance) and "fechar" (closure) [2, 3]. Consonance points to a particular way of behaving, of dancing together, and of producing sounds. It is associated with an idea of high interpersonal coordination, as opposed to the idea of "desmantelo" (fracture and breaking up). The expression "fechar o Maracatu" (closing the Maracatu) refers to various aesthetic strategies used to protect the individual and the community from the threats that are at stake during Carnival. The percussive nucleus of Maracatu plays as fast and loud as possible, saturating the acoustical space and "filling" each metrical position in order to avoid any silence. To this end, the study of systematic microtiming, i.e., intentional deviations from strict metronomic timing, can be a promising first step towards understanding Maracatu performances.

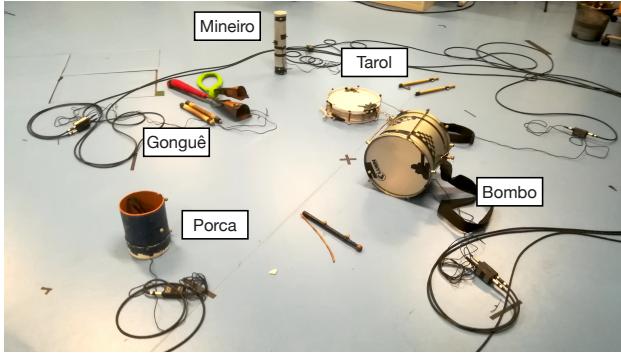
In December 2019, 13 members of a Maracatu group "Leão de Ouro de Condado" were invited to Lisbon. Several public performances were organised which culminated in a two-part event: a parade in which musicians and dancers moved through the streets, followed by a fixed location, outdoor performance. We focus on the recordings obtained from the latter, and perform an exploratory analysis of the microtiming in the percussionists' performances.

Our research is part of the emerging topic of computational ethnomusicology [4, 5], and falls within a growing body of work examining the role of microtiming and rhythmic structure and its relationship to groove and musical embodiment [6–10]. It also intersects with the existing MIR literature on the analysis of rhythm in South American music [11–16]. In our specific context, we face two prominent, interconnected challenges. In the absence of formal theories about Maracatu, there is little basis on which to pose research questions that computational analysis (e.g., using MIR techniques) could address. From a more practical perspective, the very nature of Maracatu performance: musicians in tight proximity to one another, playing very loudly, and moving between multiple ad-hoc external locations, creates technical difficulties for the high-quality signal acquisition necessary for temporally-precise analysis of musical timing.

Our methodology to address these challenges is to conduct the research from a strongly multidisciplinary perspective. We directly leverage technical expertise in audio engineering for signal acquisition, music signal processing and machine learning for computational rhythm analysis, and ethnomusicology to guide the interpretation of the findings based on long-term field research. By necessity, this leads to an exploratory approach concerning the presence and use of microtiming in Maracatu, where the computational analysis can be used as a means to infer new understanding about the musical practice.

To enable the isolated analysis of the microtiming of each percussionist, we use contact microphones attached to each individual instrument. We adapt a state-of-the-art approach for microtiming analysis [12] and investigate both "within-instrument" microtiming, where onset and beat information are specific to a given instrument,

and "between-instrument" microtiming, where a "time-keeping" instrument provides the beat reference. Our main findings demonstrate that the choice of the time-keeper is critical and can change the interpretation of the performance. Furthermore, we observe microtiming profiles that change dynamically within given pieces of music, and between pieces of music. Thus, the notion of a single characteristic microtiming profile appears not to apply to the set of Maracatu recordings under investigation here.

The remainder of this paper is structured as follows. Section 2 provides an overview of the musical structure and instruments of Maracatu. Section 3 describes the signal acquisition process. Section 4 summarizes the microtiming modelling approach, with our main findings presented in Section 5. We conclude the paper in Section 6 with a reflection on the broader impact of the research.


2. MARACATU DE BAQUE SOLTO

Maracatu is a combination of various elements: two to four wind instruments (trumpet and trombone), played by "musicos" (musicians), and a nucleus of five percussionists called the "terno." During performances, the musicos and terno act in close cooperation with a poet (the "mestre de apito"). When the poet improvises short verses about 30 s in duration, the musicians remain silent and the dancers and public remain still. When the poet finishes his verses and blows his whistle ("apito"), the percussionists and the wind musicians play for about the same duration and everybody dances. During this time, the poet prepares his next verses. This alternating pattern remains throughout the performance, which may last up to eight hours.

Maracatu percussive music is highly repetitive, and played as loud and as fast as possible. These features give rise to a very strong euphoria in the dancers and the public. Just a few rhythmical patterns exist in Maracatu and depend on the metrical form that the poet is following: the main genres are "marcha" and "samba," although the samba of Maracatu has nothing to do with the well-known samba music of Brazil. In Maracatu, marcha and samba indicate both the metrical subdivision of the poet's couplets, the rhythm played by the terno, and the melodies played by the musicos. Various melodies may be associated to the marcha pattern and/or samba pattern, depending on the melodic line that the poet chooses to sing his verses.

In Maracatu, the five percussion instruments of the terno, shown in Fig. 2, are: *Bombo* – a bass drum-like instrument played with two sticks, one for each side. We refer to Bombo High as the upper skin, and Bombo Low as the lower. *Onguê* – an iron instrument comprised of two bells of different pitches. We refer to Gonguê High as the higher, and Gonguê Low as the lower pitched bell. *Porca* – a friction drum, played with a damp cloth holding the stick. *Tarol* – similar to a small snare drum, but thinner. *Mineiro* – a metal tube filled with beads or other small objects, which is shaken to create a rattle-type sound.

Following transcriptions in [17] for both the marcha and samba, the Porca plays a regular quarter note pattern. Likewise for the marcha, the lower bell of the Gonguê has

Figure 2: The instruments of the terno (with identifying labels overlaid) including the connection of the contact microphones.

the same pattern. Thus, for marcha we assume that either could provide a time-keeping role.

3. DATA ACQUISITION

In this work, we wished to analyse each percussionist's performance in isolation. While multiple microphone setups have been successfully used to acquire separated audio data for rhythmic and microtiming analysis [18], the physical arrangement of the Maracatu percussionists in a tight circle, together with the very loud playing style, makes this impractical and highly prone to "spillage." In turn, this would make any subsequent annotation and microtiming analysis extremely challenging. A promising alternative is to consider the use of contact microphones.

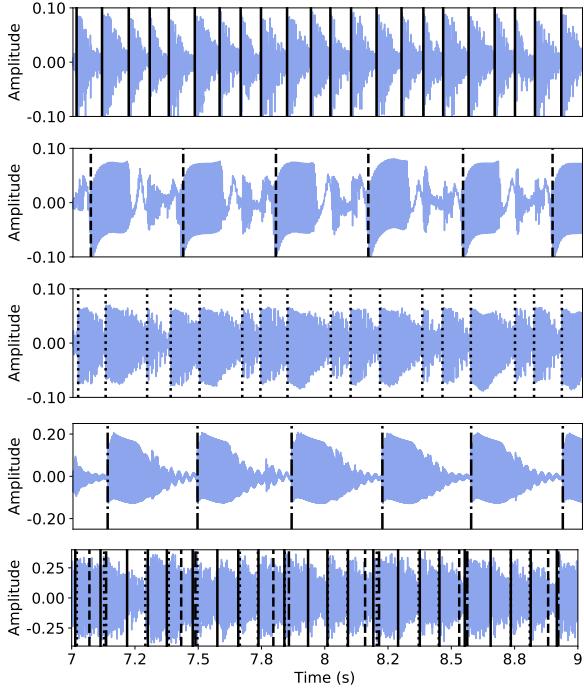
For this study, we used the Schertler Basik Set universal contact microphone. Each microphone includes a phantom-power adaptor box which delivers a line-level signal, with a 60 Hz–15 kHz frequency response. The sensitivity on the instrument is −34 dB (time-averaged sound level). We found these microphones provided high-quality audio recordings with minimal spillage and distortion.

For the microphone placement, we sought to balance the optimum location for sound capture while minimizing any impact to each musician's playing style. Given the small size of the Schertler pickup (less than 1 cm in diameter), this aspect was relatively straightforward.

We placed two pickups on the Gonguê – one per bell, and two on the Bombo – one per skin. For the remainder, the Tarol, Porca, and Mineiro we used a single pickup. The contact microphones were individually connected to a Motu UltraLite-mk3 Hybrid (USB/Firewire) with nominal gain at the input and no further processing. The recording session consisted of discrete, synchronised tracks, one per microphone, recorded in a Pro Tools 2019 mixing session configured to record at 44.1 kHz, with 16-bit depth.

We used this setup in the fixed location performance, rather than the parade. Over the total performance duration of 48 minutes, we partitioned the performance into 34 individual pieces (i.e., editing out the poetry), with a mean duration of 39.4 s. Of these 34 pieces, 28 were marcha, 5 were samba, and in one piece the percussionists played

samba, while the musicos played marcha.

4. MICROTIMING MODEL


In order to undertake any assessment of the microtiming present in recordings, we must obtain precise temporal markers which indicate the note onset positions. Following existing work in microtiming analysis [12, 14] it is necessary to create a reference beat grid against which to compare the locations of performed onsets with quantised beat and/or sub-beat positions. In this way, each beat interval can be assigned a normalised duration of 1, and thus a rhythmic pattern containing four equal sub-divisions would occur at normalised positions 0, 0.25, 0.50, and 0.75. When summarising this information over multiple beats, it is possible to observe systematic microtiming patterns–called microtiming profiles [12]–, where, in the case of Brazilian samba, the third and fourth sub-divisions of the beats have been shown to occur ahead of their quantised position [12, 14]. Note that because the relative position of onsets is normalized with respect to the beat interval, the modelling of microtiming profiles is independent of tempo changes, which allows us to visualise their change over time in a consistent manner. In this section, we first describe the means by which onsets and beat annotations were obtained, followed by the technique used to estimate microtiming profiles through time.

4.1 Onset Annotation

The 34 pieces in the Maracatu performance totalled approximately 22 minutes. Across all 7 channels, this led to a total of 238 contact microphone signals to be analysed. As shown in Fig. 3, even though the separation between channels is mostly very good, some spillage still occurred. This is especially prominent between the bells of the Gonguê which are physically connected. We also observed spillage where one instrument had yet to begin playing and the vibrations carried through the air were picked up thanks to the extremely high sensitivity of the contact microphones.

Given our proposed signal acquisition process using contact microphones, we assumed that largely isolated percussion tracks would be relatively straightforward for a well-known onset detection method using deep neural networks [19]. On this basis, we hoped to be able obtain reliable onset information in a semi-automatic way, where minor corrections (shifts, insertions, and deletions) could be performed. In practice, we found that the rather unusual waveform shapes of the Gonguê, Porca, and Mineiro events created numerous problems for the onset detection system and thus provided little benefit over manual annotation from scratch. Indeed, the recordings of the Mineiro were so challenging to annotate in a precise and consistent way, that we chose not to include them at this stage of our analysis. Ultimately, we selected four instruments: two instruments with time-keeping roles (Porca and Gonguê Low) and two rhythmically expressive instruments in which to observe microtiming (Tarol and Bombo High).

To provide the final onset annotations we followed the

Figure 3: Illustration of signals with annotated onsets in approximately one bar. Top to bottom: Tarol with annotations (solid line); Porca with annotations (dashed line); Bombo High with annotations (dotted line); Onguê Low with annotations (dash-dotted line); Audio mixture with overlaid onset times of the four instruments.

methodology applied to Brazilian samba [12] and adapted an existing deep neural network [20] and retrained it specific to each instrument using a subset of manually annotations. Even using *instrument-adapted* networks, some manual correction was required, both to contend with issues of temporal localization as well as extra and missed detections. As a coarse indication of the annotation effort, we highlight 51 onsets in just 2 s in the lowest plot of Fig. 3, with $\sim 45,000$ over the four instruments.

4.2 Microtiming Estimation

Our microtiming modelling is based on the approach in [12], which models microtiming profiles per beat as a multi-dimensional variable **m**, where each component m_i with $i = 1, ..., N$, with N the total number of onsets per beat, describes the evolution over time of the relative position of onset i with respect to the beat. The model in [12] estimates the beat and onset likelihoods, and infers the beat positions and associated microtiming profiles jointly using conditional random fields (CRFs). In this work we follow these ideas, but instead of inferring beat and microtiming profiles jointly with a CRF as in [12], we perform the beat and onset inference offline, and then group the onsets and beats using Algorithm 1. The reason for this is two-fold: our proposed approach is simpler and computationally cheaper than the CRF approach, with the limitation that it would not be robust in presence of noisy signals or mixtures, which is not the case here. Also, since we are in-

Algorithm 1: Microtiming modelling

terested in both within-instrument and between-instrument microtiming, we need a flexible model that allows changing the beat reference, which we can do since we compute beats and onsets offline and integrate them afterwards.

Algorithm 1 is structured as follows: for each beat b we obtain the onsets o_{beat} that fall within the beat interval $[t_{ini}, t_{end}]$ by a tolerance given by τ, and check if we have the expected number of onsets (denoted by r in Algorithm 1). If not, we deduce which onsets are missing by comparing the given onsets with a template containing evenly-distributed positions (0.25, 0.5 and 0.75 in the case of three expected onsets). Next, we interpolate the missing onsets for better visualisation of the microtiming pattern. Finally, we obtain the microtiming profile **m** by dividing all inter-onset-intervals by the beat interval length. We exclude beats with more than the expected number of onsets.

Microtiming deviations and their variation across time have been studied in the context of time-keeper instruments (e.g., in Brazilian samba [12], Uruguayan candombe [18], and jazz [21]). While previous approaches focus on within-instrument rhythmic patterns, we also explore the microtiming generated between time-keepers and non-time-keeper instruments. We apply a similar strategy to that in [12] to analyse the profiles visually.

Both existing work and Algorithm 1 assume that there is *one* main rhythmic pattern played during most of the recording. This hypothesis holds in most of the recordings we obtained, however, unlike other examples such as the BRID dataset [22] where it holds to a great extent, in Maracatu, it is not true for samba.

For the analysis of between-instrument microtiming de-

Figure 4: Comparison of Maracatu sub-genres and Tarol (Caixa) in Brazilian samba.

viations, we follow the existing literature about Maracatu [17] and use the Porca and Gonguê Low onsets as beat references for the other instruments since they play the role of time-keepers and are meant to play the beat. For the within-instrument analysis for Tarol and Bombo, we estimated the beats using the *madmom* library [23] [1], which performed well in the solo tracks, and we adjusted the final beat positions to the closest onset.

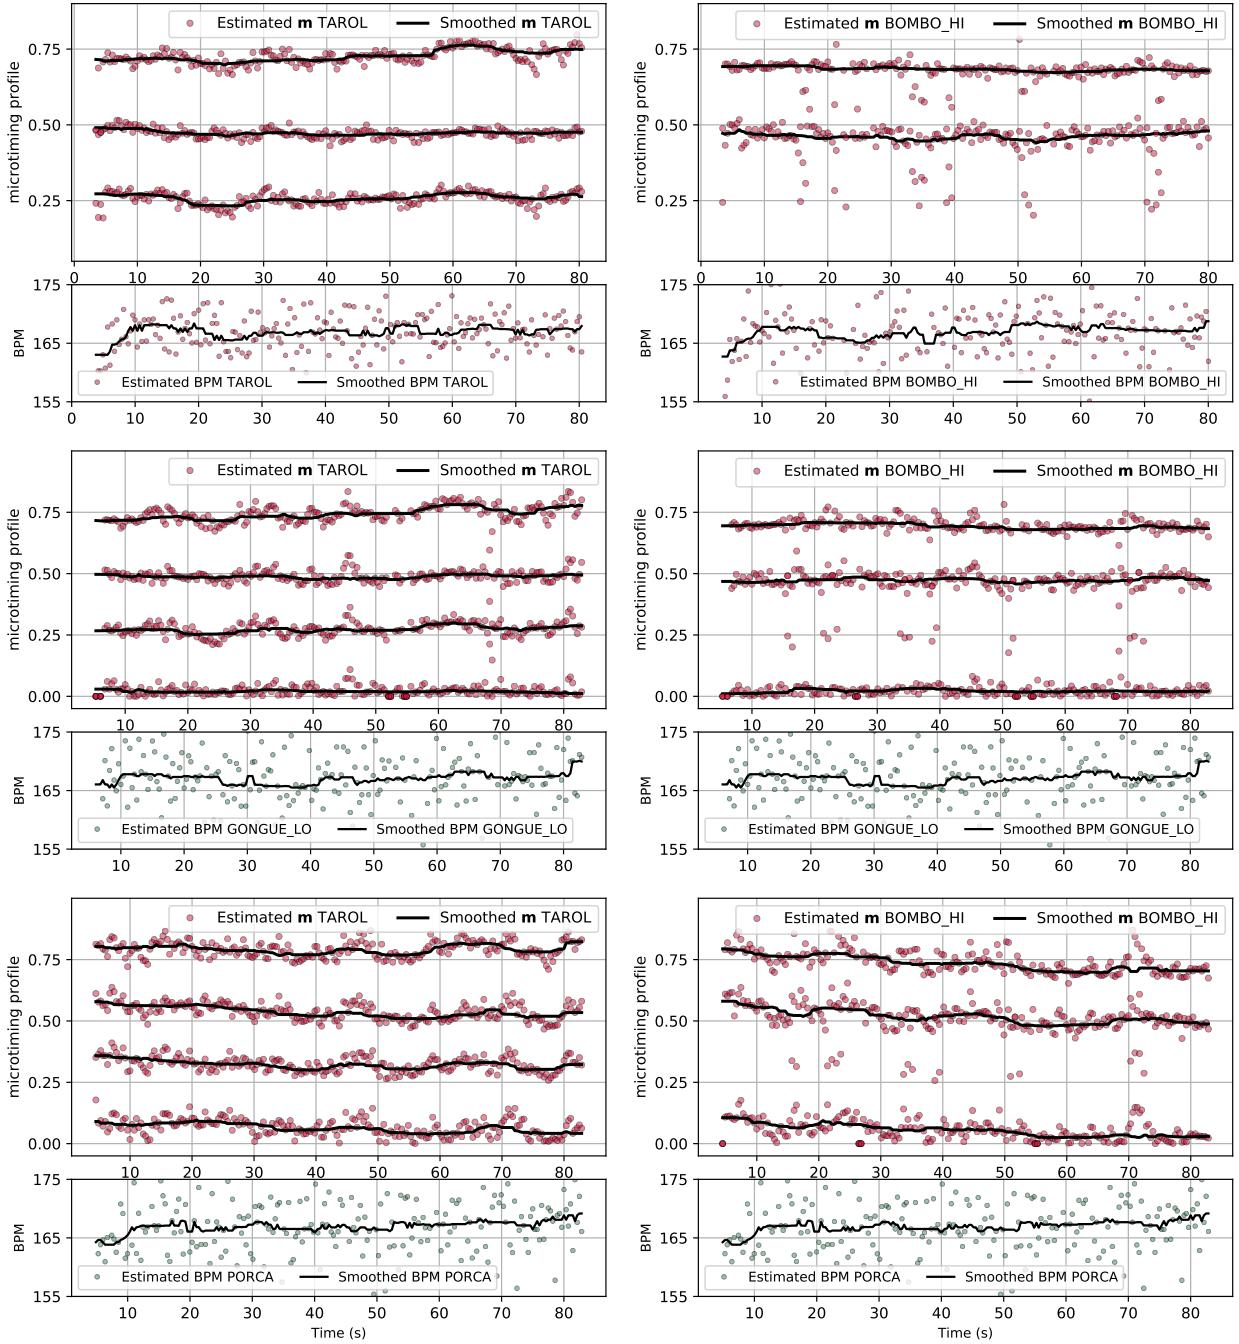
5. MICROTIMING ANALYSIS

Marcha vs. samba: Both by listening to the recordings and inspection of the microtiming profiles, we discovered that samba has far greater variation in rhythmic patterns than marcha. In addition, the beat estimation revealed a noticeable difference in tempo, with marcha approximately $165\,\mathrm{bpm}$ where as samba was faster at around $180\,\mathrm{bpm}$. Transcriptions from [17] also state that there is greater variation in the notated rhythmic patterns for samba compared to marcha. From the perspective of drawing robust conclusions about microtiming profiles, which, using our approach, rely quite strongly on a consistent rhythmic pattern, we were only able to conduct reliable analysis for Tarol within-instrument microtiming. To enable a high-level comparison, which also includes the use of Tarol (referred to as Caixa in [12]) in Brazilian samba we present a scatter plot of m_1 vs. m_2 vs. m_3 in Fig. 4. Perhaps the most striking observation is that for marcha, the Tarol shows a much wider variation in the m_1 and m_3 dimensions, where as the limited data we obtain for Maracatu samba occupies a tighter cluster, and Brazilian samba varies more prominently over m_2. This indicates a different use of microtiming for Tarol in our recordings both within Maracatu sub-genres and compared to Brazilian samba.

Microtiming profiles in marcha: In Fig. 5 we observe both the within- and between-instrument microtiming analysis for Tarol (left column) and Bombo High (right column) for recording #28. For the between-instrument

analysis we use the Gonguê Low and Porca as time-keepers (middle and bottom rows respectively). When comparing between-instrument and within-instrument profiles, we observe one additional trace for both instruments: the deviation at the beat level (which is normalised out for within-instrument analysis). Referring back to Fig. 3 we can see microtiming profiles consistent with a sub-division of the beat into four $1/16$th notes for Tarol, with the second $1/16$th note (m_1) not played for Bombo High.

Looking at the microtiming profiles through time, we see more fluctuation in Tarol compared to Bombo High. In particular for Tarol, the smoothed microtiming profiles move above and below the quantised positions indicating a dynamic use of microtiming. Furthermore, a direct comparison of Tarol with Bombo High illustrates different profiles. Across the entire set of recordings, we found the following median profiles: Tarol [0.25, 0.47, 0.715], and Bombo High [0.46, 0.69].

When contrasting the time-keepers, we observe much greater variation when the Porca beats are used as reference compared to Gonguê Low, including an unexpected downward trend for both Tarol and Bombo High. While not present in all marcha, we observed several similar instances, which can be attributed to the beats of the Porca being played *ahead* of the beat and slowly aligning in phase by the end. Looking again at Fig 3, we see the Porca annotations are earlier than the other instruments consistently by upto $20\,\mathrm{ms}$. A possible explanation may be that the Gonguê is louder and thus takes a more prominent time-keeping role, allowing the Porca to take a more expressive role. Regardless, we assert the importance of analysing the behaviour of the time-keeper instruments.


6. REFLECTIONS

One objective of current ethnomusicological research is to reveal how musicians of different cultures develop strategies for playing together that differ in subtle ways to those in Western culture. These strategies are often implicit, associated to verbal categories that express local views on how music "should sound" in a particular cultural context [25]. These verbal categories often rely on non-musical concepts and metaphors, often related to other sensorial domains (vision, taste, etc.) [26].

Ethnographic field research is a first, necessary step for unveiling subtle strategies of playing together that are at stake in a particular musical culture. Formal analysis of live performances is then needed to understand to what acoustic reality these local concepts refer. To this end, MIR techniques, such as microtiming analysis, can provide innovative solutions for exploring qualities of the music that would otherwise be hard to describe.

In the Zona da Mata region, Carnival is not a simple distraction but rather a ritual involving a complex set of mystical beliefs and social concerns. At this time of the year invisible negative "entidades" (entities) are believed to be more active and even dangerous, and interpersonal relations are marked by feelings of envy and jealousy. Carnival is therefore considered as a threat both for individuals and

[1] We used the model that implements Böck et al. [24] in version 0.16.1.

Figure 5: Microtiming profiles in recording #28 for Tarol and Bombo High, left and right respectively. The microtiming estimations use within-instrument, Gonguê Low and Porca beats as reference in top, middle and bottom plots respectively.

the community. Maracatu de baque solto is a performance-ritual that allows people to overcome these risks.

It is important to stress that the Maracatu musicians had never travelled outside of Brazil, and bringing them to Europe was logistically complicated. In addition, the signal acquisition and onset annotation were also non-trivial, meaning several challenges needed to be overcome before even beginning to analyse the microtiming in Maracatu in a computational way. Nevertheless, within the confines of a small dataset, limited to one set of musicians, our preliminary analysis revealed new findings on the use of microtiming, in particular its dynamic nature in Maracatu.

In the long term, our aim is to understand what it means to play in "consonance" and to "close the Maracatu." Both concepts point to subtle manners of producing sounds collectively, that differ form the ones observed in other musical contexts. Since no formal analyses of Maracatu music have been previously realised, this paper is a first attempt to understand how musicians rhythmically interact during a live performance. In future research, we intend to play back the recordings to the musicians to understand if "consonancia" and "closure" can be associated to the specific microtiming profiles highlighted in this paper.

MULTILINGUAL MUSIC GENRE EMBEDDINGS FOR EFFECTIVE CROSS-LINGUAL MUSIC ITEM ANNOTATION

ABSTRACT

Annotating music items with music genres is crucial for music recommendation and information retrieval, yet challenging given that music genres are subjective concepts. Recently, in order to explicitly consider this subjectivity, the annotation of music items was modeled as a translation task: predict for a music item its music genres within a target vocabulary or taxonomy (tag system) from a set of music genre tags originating from other tag systems. However, without a parallel corpus, previous solutions could not handle tag systems in other languages, being limited to the English-language only. Here, by learning multilingual music genre embeddings, we enable cross-lingual music genre translation without relying on a parallel corpus. First, we apply compositionality functions on pre-trained word embeddings to represent multi-word tags. Second, we adapt the tag representations to the music domain by leveraging multilingual music genres graphs with a modified retrofitting algorithm. Experiments show that our method: 1) is effective in translating music genres across tag systems in multiple languages (English, French and Spanish); 2) outperforms the previous baseline in an English-language multi-source translation task.

1. INTRODUCTION

Music genres are a key characteristic of music items [1, 2]. In music streaming services, user profiles and interests can be expressed through music genres, tracks and artists can be grouped in genre-specific collections, and content-based recommender systems frequently exploit music genres as item tags. However, music genres are difficult to infer due to their subjective nature. Based on their music preferences, musicological knowledge and culture, people inconsistently associate genres to music items [3–5]. Thus, annotating music items with genres for providing personalized recommendation and retrieval is challenging.

Acknowledging this subjectivity and the absence of a unique genre definition, recent works [6,7] framed the music genre annotation as a *translation*. More precisely, given

music items annotated with music genres originating from multiple source tag systems such as folksonomies, editorial vocabularies or taxonomies, the goal was to predict the equivalent music genres within a target tag system. In a supervised setup, the translation relied on a parallel corpus of music items jointly annotated with music genres from the source and target tag systems [6,7]. In an unsupervised setup, when the parallel corpus was unavailable, a solution centered on taxonomy alignment was proposed [6].

However, the translation of music genres between *multilingual* sources remains unaddressed when a parallel corpus is unavailable. The only past unsupervised solution [6] relied on heuristics specific to the English language, making its adaptation to multilingual tags a challenge. Here, we propose to perform the unsupervised cross-lingual translation by leveraging multilingual music genre embeddings. Also, our method to learn these embeddings could be straightforwardly applied to new languages.

The proposed method is further summarised. First, by acknowledging the compositional nature of music genres (i.e. the meaning of multi-word music genres can be often derived from the meaning of each word), we learn music genre embeddings by applying compositionality functions to pre-trained word vectors [8–10]. Moreover, as these pre-trained vectors are often trained on language-specific text, we need to align them across languages [11, 12].

Second, we fit the obtained music genre embeddings into the music domain. The embeddings learnt on general-language corpora could sometimes be semantically ambiguous. For instance, *house* is closer to *building* than to *music* and *jazz* is more similar to *folk* than to *bebop* in fast-Text [8]. To tackle this problem, we create a music genre knowledge graph from multilingual DBpedia [13] that contains multilingual genres as nodes and exhibits different types of music genre relations through its edges. Then, we use *retrofitting* [14] to encode the relational knowledge from the semantic graph in the embeddings. In this work, we modify the original retrofitting algorithm [14] to distinguish between two types of relations: equivalence (e.g. *dnb* and *drum'n'bass*) and other types of relatedness such as sub-genres, derivative genres, fusion genres, stylistic origins. Besides, we use retrofitting to learn embeddings for music genres that do not exist in the pretrained embedding vocabulary by exploiting their graph relations (e.g. *ethnotronica* and *chillstep* are not in the pretrained fastText vocabulary).

We evaluate the proposed method in two experiments.

First, we collect a new parallel corpus of music items annotated with music genres in three languages (English, French and Spanish) and demonstrate the effectiveness of our method for unsupervised cross-lingual music genre translation. Second, we show that using the embeddings learnt with our method outperforms the previous baseline [6] in a music genre translation task between multiple English-language tag systems.

2. PROBLEM FORMULATION AND RELATED WORK

Annotating music items from song lyrics or audio content has concentrated significant research efforts in the music information retrieval community [7, 15, 16]. Most existing works fix a tag system and focus on general music genres like *jazz* or *pop* [3–5]. Nonetheless, the dissimilarity of music genre tag systems and their use in annotations has been recently put forward for consideration, together with the need to take into account tags with increased granularity [15, 17]. In this direction, two previous works [6, 7] have framed the music genre annotation as a tag translation task between various music genre tag systems.

Specifically, given a set $\mathcal{S}$ of *source tag systems*, $S = \cup_{E \in \mathcal{S}} E$ the union of all tags across all source tag systems, $\mathcal{P}$ the partitions of S and T a *target tag system*, the goal is to define a translation scoring $f : \mathcal{P}(S) \to \mathbb{R}^{|T|}$ which estimates a score for each target tag from a set of source tags drawn from S. While in this notation a tag system refers to a set of tags, more general representations such as music genre graphs or taxonomies can also include relations between tags [18–20].

Hennequin et al. [7] proposed two translation strategies, both relying on the existence of a parallel corpus of music items annotated with music genres. Epure et al. [6] addressed also the unsupervised case, when such a parallel corpus was absent, and designed a knowledge-based method to learn tag embeddings. This method relied on multiple building blocks corresponding to tag normalization, the construction of an integrated music genre graph bringing together all source and target tag systems, and a taxonomy alignment algorithm mapping each music genre on DBpedia [13] tags. The DBpedia-related building block yielded music genre vectors quantifying the relatedness of the tag under consideration to each DBpedia music genre. For translation, considering $\{s_1, \ldots, s_K\}$ source tags and any target tag t, f was computed using cosine similarity:

$$f_t(\{s_1, s_2, \ldots, s_K\}) = \sum_{k=1}^{K} \frac{\mathbf{s}_k^T \mathbf{t}}{||\mathbf{s}_k||_2 ||\mathbf{t}||_2}, \qquad (1)$$

where $\mathbf{s}_k$ and $\mathbf{t}$ are the vectors corresponding to each s_k, respectively t and $|| \cdot ||_2$ is the Euclidian L2-norm.

In the previous unsupervised work, Epure et al. [6] focused on English-language music genres, claiming that the extension of the knowledge-based method to include multilingual tag systems was feasible since it relied on multilingual DBpedia. While we agree that it is feasible, the extent to which the introduced method could be easily

changed to support other languages is questionable. Both normalizing tags and mapping music genres into the DBpedia space rely on language-specific heuristics. For instance, in normalization, heuristics referring to the length of tokens were used. However, the average word length, hence what is considered as a short or medium-length token depends on the language [21]. Then, mapping music genres on English DBpedia genres is limiting because some tags may exist in two languages but not in the English DBpedia. Computing directly the degree of relatedness of a source tag to a target tag could be a better alternative.

3. A MULTI-STEP METHOD FOR LEARNING MUSIC GENRE EMBEDDINGS

In this work, we propose a method to learn multilingual music genre embeddings that can be easily extended to new languages and support cross-lingual translation. The first step is to deduce initial embeddings for multi-word music genres by leveraging pre-trained multilingual word embeddings (Section 3.1). However, directly using these music genre embeddings in cross-lingual translation is prone to under-perform because:

- the embeddings often correspond to the most common word senses (e.g. *country* can refer to *nations* or *rock* could be closer in meaning to *stone*) and they are not disambiguated against the music domain.

- some music genres could contain rare words which are absent from the pre-trained model vocabulary, resulting in potentially unknown tag embeddings.

To address these issues, we complement distributional concept representations with semantics from knowledge bases that expose concept relations. Thus, in a second step, we assemble a multilingual music genre graph (Section 3.2). Then, we adjust the initial tag embeddings to encode the tag relations from the collected graph, ensuring the domain adaptation. For this, but also to learn embeddings for concepts with unknown vocabulary words, we use *retrofitting* [14], which we modify to reflect the different types of music genre relations (Section 3.3).

3.1 Initializing Music Genre Embeddings

Under the music genre translation framework introduced in Section 2, the main goal boils down to quantifying the degree of relatedness of two textual tags. This task is widely popular in the natural language processing (NLP) community and contemporary approaches resort to expressing the relatedness as distance between corresponding word embeddings [8–10]. The mapping of words on embeddings is guided by the distributional hypothesis [22], which states that words in similar contexts are likely to have similar meanings. Word embeddings have been proven effective in capturing word syntactic and semantic similarities and in improving downstream NLP tasks such as natural language understanding [23] and information retrieval [24].

In order to measure the relatedness of multilingual words using embeddings learnt from monolingual corpora,

an alignment between the language-specific embedding spaces is required. Through the alignment [25], we ensure that multilingual word embeddings are projected into a common space where they are comparable. Practically, a mapping function between two monolingual word embedding spaces is learnt, for instance by using a bilingual lexicon [12]. Effective alignments have been also found using orthogonal Procrustes [11, 25].

Starting from multilingual word vectors, we discuss strategies to initialize the music genre embeddings. Music genres can contain multiple words. We claim that the compositionality principle, stating that the meaning of a multi-word expression is dictated by the meaning of each word, often holds for our case. For instance, *Dance pop* is related to *dance* and *pop* or *Balada romántica* is a type of *ballad* which is *romantic* [1]. The contemporary approach for compositional embeddings is to learn a function which derives the embeddings of a multi-word expression from the embeddings of its words [26]. The function is learnt by minimizing the distance for each multi-word expression between its distributional embedding and its embedding computed from its word embeddings. Obtaining the distributional embedding for multi-word music genres would be however challenging because sufficiently large corpora with all tags in multiple languages are required.

For this reason, the first music genre initialization strategy we propose consists of a simple compositionality function such as averaging word embeddings (*avg*). Let $V = \{c_1, c_2, ..., c_n\}$ be the multilingual vocabulary, c_i being a concept composed of at least one word. We aim to compute $\hat{\mathbf{Q}} \in \mathbb{R}^{n \times d}$, the embedding matrix for the vocabulary V, where $\hat{\mathbf{q}}_i \in \mathbb{R}^d$ denotes the embedding of concept c_i. If c_i is composed of the following words, $\{w_1, w_2, \ldots, w_M\}$, $\hat{\mathbf{q}}_i$ can be computed as $\frac{1}{M} \sum_{m=1}^{M} \mathbf{w}_m$, where $\mathbf{w}_m$ is the embedding of the word w_m. Of note is that if c_i contains words absent from the pretrained word embedding vocabulary, the d-dimensional null vector, $\mathbf{0}_d$, is used as a default.

The second music genre initialization strategy we propose exploits the fact that some words in a compounded expression may be more illustrative than others. The more frequently a word is observed in a corpus, the more likely it is that the word is common for a language and semantically less informative (e.g. *music* in *post industrial music*). Thus, the compositional embedding computation of a multi-word expression can be modified such that the contribution of each word embedding is inversely proportional to its frequency. Pre-trained word embeddings are generally released sorted by decreasing word corpus frequency. Let z_{w_m} be the rank of w_m in this vocabulary. Then, based on the Mandelbrot's generalization [27] of the Zipf's law [28], its frequency f_{w_m} can be estimated to $f_{w_m} = 1/(z_{w_m} + 2.7)$.

Further, we rely on the smooth inverse frequency (*sif*) based averaging proposed by Arora et al. [29] to compute the multi-word expression embeddings. This method is aligned with our previous observations and proven highly effective compared to more complex neural network-based

models on a large diversity of NLP tasks [29]. Given f_{w_m} the estimated frequency of the word w_m and a a fixed hyper-parameter [2], $\hat{\mathbf{q}}_i$ is computed as:

$$\overline{\mathbf{q}}_i = \frac{1}{M} \sum_{m=1}^{M} \frac{a}{a + f_{w_m}} \mathbf{w}_m \qquad (2)$$

$$\hat{\mathbf{q}}_i = \overline{\mathbf{q}}_i - \mathbf{u}\mathbf{u}^T \overline{\mathbf{q}}_i \qquad (3)$$

where $\mathbf{u}$ is the first singular vector from the singular value decomposition of $\overline{\mathbf{Q}}$ obtained with the Equation 2 [30].

3.2 Assembling a Multilingual Music Genre Graph

Previous related work [6] created a music genre graph by integrating multiple English-language music genre tag systems and a crawled sub-graph of DBpedia through a node English-language based normalization step. The other music genre tag systems were Lastfm, Tagtraum and Discogs, used in the 2018 MediaEval AcousticBrainz Genre Task [17]. Here, we bypass the language-specific heuristics normalization and propose a more robust alternative. We crawl a multilingual DBpedia music genre sub-graph and use its words as basis for normalizing new tag systems.

We further detail how we assemble the DBpedia-based music genres graph. We set the seeds for crawling from: 1) DBpedia entities of type *MusicGenre*, 2) the music genres of the multilingual DBpedia-based music item corpus (described in Section 4.1), 3) synonyms of the music genres of the previous two sources, linked through the *wikiPageRedirects* relation. We discover new potential music genres by crawling DBpedia entities linked to the seeds through one of the relations: *wikiPageRedirects*, *stylisticOrigin*, *musicSubgenre*, *derivative* and *musicFusionGenre* [3]. During crawling, seeds are updated with discovered entities that were not visited before, and the crawling goes on until no seeds are left. This is applied for each language. Finally, all music genres discovered as yet are connected to their equivalent tags in other languages, when possible (the DBpedia relation *sameAs*). In a post-processing step, we remove music genre nodes written as free-style text, which do not have DBpedia pages, and the connected components which do not contain at least one high-confidence music genre (empirically, we noticed that the highest-confidence tags were those from the music item corpus).

To ensure that tag systems with different music genre spellings benefit from the multilingual graph, we define a normalization which we apply to both the graph nodes and new tags. First, we tokenize each tag by non-alphanumeric characters. Further, as in [6], we create prefix trees to split multi-word tags such as *sludgemetal* or *indierock*. Nevertheless, we do not necessarily aim at a grammatically correct split, but at one based on lemmatized DBpedia music genre words [4]. Namely, if *sludgemetal* is already among

---

[1] Exceptions from the principle also exist (e.g. *hard rock*).

[2] Experimentally, it has been shown that $a = 10^{-3}$ is a suitable choice when using different types of pre-trained word embeddings [29].

[3] These relation names correspond to the English-language DBpedia. They have often translated versions in DBpedia in other languages.

[4] Through lemmatization, we retrieve the base form of inflected words using spacy (https://spacy.io). Most genre words are generally in their base form (e.g. *jazz*). However, some other words benefit from this (e.g. *Northern / North* or *children / child*)

the DBpedia music genre words, then there is no further split and we expect its initial embedding to be corrected though the embeddings of its graph neighbors as explained in the next section (Section 3.3).

3.3 Retrofitting Music Genre Embeddings

Retrofitting [14] has been proposed as a post-processing step to improve concept embeddings by leveraging existing semantic lexicons or knowledge graphs (e.g. WordNet [31]). More precisely, concept embeddings are modified to also encode concept relations [14, 32–34].

Let $G = (V, E)$ be the graph capturing the semantic relations between the nodes in V through a set of edges $E \subseteq V \times V$. The objective of retrofitting is to learn $\mathbf{Q} \in \mathbb{R}^{n \times d}$, the new concept embeddings, such that each new embedding $\mathbf{q}_i \in \mathbb{R}^d$ does not stray too far from the initial distributional embedding $\hat{\mathbf{q}}_i$, but also becomes closer to the new embeddings of the neighbour vertices $\mathbf{q}_j \in \mathbb{R}^d, j : (i, j) \in E$. The objective function to minimize is then [14]:

$$\Phi(\mathbf{Q}) = \sum_{i \in V} \left(\alpha_i ||\mathbf{q}_i - \hat{\mathbf{q}}_i||_2^2 + \sum_{j:(i,j) \in E} \beta_{ij} ||\mathbf{q}_i - \mathbf{q}_j||_2^2 \right) \tag{4}$$

where α_i and β_{ij} are positive scalars specifying the importance given to each component, the initial embedding and each graph neighbor. As Φ is convex with respect to $\mathbf{Q}$, a solution minimizing the objective function Φ is found in [14] via an iterative strategy derived from Jacobi iteration algorithm [35] that converges for such graph-based propagation problem [35, 36]. More precisely, until convergence, $\mathbf{q}_i$ is iteratively updated as follows:

$$\mathbf{q}_i \leftarrow \frac{\sum_{j:(i,j) \in E} (\beta_{ij} + \beta_{ji})\mathbf{q}_j + \alpha_i \hat{\mathbf{q}}_i}{\sum_{j:(i,j) \in E} (\beta_{ij} + \beta_{ji}) + \alpha_i} \tag{5}$$

where $\mathbf{Q}$ is initialized to $\hat{\mathbf{Q}}$. Equation (5) is not the same as the original one [14]. We observed that, when applying the Jacobi method to optimize equation (4), the contributing terms in the partial derivative with respect to the node i are those where i appears as source as well as target node in the inner sum, leading to a different update. In [36, 37], the same conclusion referring to a corrected update rule, different from the initial proposal, is reached.

Faruqui et al. [14] set $\alpha_i = 1$ and $\beta_{ij} = \frac{1}{\text{degree}(i)}$ for $(i, j) \in E$, where degree(i) is the number of neighbors i has in the graph G, or 0 for $(i, j) \notin E$. This choice was largely adopted in other related works [32, 38]. Speer and Chin [39] proposed to use a modified version of retrofitting to learn embeddings for unknown vocabulary concepts which are present in the knowledge graph. For this case, α_i is set to 0 for all unknown vocabulary concepts. This results in $\mathbf{q}_i$ being updated by averaging the embeddings of its neighbours at each iteration. Despite the change in the update rule we made, compared to the original work, we retain this choice of hyper-parameters as being a reasonable default, and defer the investigation of a more principled way to pick α_i and β_{ij} to future work.

We further modify retrofitting to take advantage of the different types of music genre relations. On one hand, mu-

sic genres can be semantically equivalent to other music genres (the relation types *wikiPageRedirects* and *sameAs*). On the other hand, music genres can be related to other music genres, but not semantically equivalent (e.g. *stylisticOrigin*). The change we propose for computing these new embeddings ($\mathbf{Q}_{\overline{\beta}}$) is through the coefficients β_{ij}, making them dependent on music genre relation types:

$$\overline{\beta}_{ij} = \begin{cases} 1 & \text{if } (i, j) \in E_\epsilon \subset E \\ \beta_{ij} & \text{if } (i, j) \in E - E_\epsilon \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

where E_ϵ contains edges which represent equivalence relations (*wikiPageRedirects*, *sameAs*); $E - E_\epsilon$ contains edges with the remaining relation types (*stylisticOrigin*, *musicSubgenre*, *derivative*, *musicFusionGenre*).

4. EXPERIMENTS

We evaluate the effectiveness of the learnt music genre embeddings, first, in a new cross-lingual music genre translation scenario (Section 4.3) and, second, in an existing English-language multi-source music genre translation task [6, 17] (Section 4.4). The languages we focus on for the cross-lingual annotation are English (**En**), French (**Fr**) and Spanish (**Es**). We start by presenting the parallel corpora used in the experiments (Section 4.1). Then, we discuss the detailed evaluation setup (Section 4.2). The results show that our music genre vectors are highly effective for cross-lingual translation and lead to improved results on the past unsupervised Enligh-language translation task [6].

4.1 Datasets

For the cross-lingual translation experiment, we relied on DBpedia [13] to collect a parallel corpus. During an initial manual analysis, we noticed that DBpedia music artists or works could have associated quite different music genres across languages. We present a few examples in Table 1. Also, when the tags used in annotations were equivalent, they were sometimes partially translated (e.g. *Rock_alternatif* in **Fr**), while other times they maintained the same form as in English (e.g. *Soft_rock* in **Es**). We collected DBpedia entities of type *MusicalArtist*, *Band*, or *MusicalWork* with music genres associated in at least two languages. Then, in a post-processing step, we filtered out the music items with tags that appeared less than 16 times.

For the English-language multi-source translation, we use an existing dataset [6, 17], which contains tracks annotated with English-language music genres from three sources. Discogs (**Dc**) tags are provided by editors per album, and automatically propagated to each track [17]. Lastfm (**Lf**) and Tagtraum (**Tt**) tags are created by Internet users per track. We show in Table 2 the number of music items and unique music genres in the new multilingual and the past English-language multi-source parallel corpora.

4.2 Evaluation Setup

We evaluated our models by translating music genre tags associated with tracks from multiple source tag systems to

Title	Type	En	Fr	Es
Morning View	Album	Alternative_metal, Funk_rock Alternative_rock, Post-grunge	Rock_alternatif	Metal_alternativo Rock_experimental
Jimi Hendrix	Artist	Hard_rock, Psychedelic_rock Blues, Rhythm_and_blues	Rock_psychédélique Blues_rock, Hard_rock	Blues_rock, Rock_psicodélico Hard_rock
Julio Iglesias	Artist	Dance-pop, Latin_music Adult_contemporary_music	Pop_française	Pop_latino, Balada_romántica Soft_rock, Adult_contemporary

Table 1. Examples of DBpedia music items annotated with music genres. The tag choices are inconsistent across sources. Tags may be adapted to a language (e.g. *Pop_latino* in **es**) or may keep the same form in all languages (e.g. *Hard_rock*).

	En	Fr	Es	Dc	Lf	Tt
Music items (tracks, albums, artists)	48 146	30 611	34 918	1 098 336	686 978	589 583
Unique music genres	489	338	491	315	327	296

Table 2. Number of music items and unique music genres in the multilingual and the English-language parallel corpora.

a target tag system. The translation scoring function computes a score for each tag of the target tag system as the degree of relatedness of the target tag to the input set of source tags. Compared to Equation 1, the translation scoring function we use here averages the cosine similarities between each source and target tag embeddings:

$$\hat{f}_t(\{s_1, s_2, \ldots, s_K\}) = \frac{1}{K} f_t(\{s_1, s_2, \ldots, s_K\}) \quad (7)$$

Like in other multi-label prediction tasks [15, 40], we use a ranking metric in evaluation, namely the area under the receiver operating characteristic curve (AUC). We macro-average the scores and report their mean and standard deviations computed over 4 folds. We split the multi-label data in a stratified way, balancing the overall number of music items and tag distribution across the folds [41].

For each experiment, English-language multi-source and cross-lingual, we have three input tag systems represented as partially aligned music genre graphs. For the multi-source translation, we assemble a graph from the English-language DBpedia music genre sub-graph and the input taxonomies, Discogs, Lastfm and Tagtraum. For the cross-lingual translation, the new music genre graph, which was assembled as described in Section 3.2, has 10748 tags in **En**, 2905 in **Fr** and 3988 in **Es**. The translation is performed using annotations from combinations of two out of three tag systems to the kept-out tag system. We also retain in evaluation annotations which are only from one of the two selected source tag systems.

In each experiment, we compare the *avg* and *sif* strategies to initialize the music genre vectors. We report results when using directly the initial embeddings ($\hat{\mathbf{Q}}$) in translation or retrofitted with the original method ($\mathbf{Q}$) or with our modified version ($\mathbf{Q}_{\bar{\beta}}$). As for the choice of pre-trained word embeddings, we use multilingual fastText [10] which we align with the method proposed by Joulin et al. [42].

4.3 Results on Cross-Lingual Genre Translation

In Table 3, we present the results of the cross-lingual music genre translation. The baseline we propose estimates the relatedness of two tags to be the length of their shortest

path in the multilingual DBpedia-based music genre graph. As a reminder, this graph is partially aligned, meaning that some music genres have equivalent tags in other languages. As shown in Table 3 in parentheses, the baseline scores are quite high proving that the graph is fairly effective for cross-lingual translation on this dataset. Even so, we are able to exceed these scores by a large margin with our music genre embeddings, initialized with *sif* and retrofitted to take into account the music genre relations.

When comparing the initialization strategies, we can observe that directly using *sif* embeddings in translation outperforms the baseline, while *avg* yields lower AUC scores. For all languages as targets, the *sif* initialization is consistently more effective than the *avg* initialization. A significant difference between the two types of retrofitting applied to both initialization strategies exists, our version resulting in higher AUC scores. By differentiating between the two relation types, equivalence and other relatedness, the music genre embeddings appear to encode more accurately their relations within and across languages.

4.4 Results on Multi-Source Genre Translation

In Table 4, we present the results of the English-language multi-source music genre annotation. We re-compute the baseline [6] results using Equation 7. Compared to the previously reported AUC scores [6], the re-computed ones are higher showing that the modified translation scoring function does not disadvantage the knowledge-based music genre embeddings derived with the baseline. In contrast to the baseline, our most effective method, using *sif* initialization and our version of retrofitting, yields consistently higher AUC scores. The increase in performance is of 11.3 percentage points for **Dc** as target, 5.9 points for **Lf** as target and 9.3 points for **Tt** as target.

The *sif* initialization of tag embeddings results in higher AUC scores than *avg* both when the embeddings are used directly as they are or retrofitted, in particular, when **Dc** is target. Also, let us notice that directly using the embeddings initialized with *sif* leads to an increased performance compared to the baseline for **Dc** and **Tt**. Retrofitting the embeddings significantly increases the AUC scores for all

	Baseline	$\hat{\mathbf{Q}}$ (*avg*)	$\mathbf{Q}$ (*avg*)	$\mathbf{Q}_{\overline{\beta}}$ (*avg*)	$\hat{\mathbf{Q}}$ (*sif*)	$\mathbf{Q}$ (*sif*)	$\mathbf{Q}_{\overline{\beta}}$ (*sif*)
En + Es $\Longrightarrow$ Fr	85.4 ± 0.4	73.7 ± 0.2	77.5 ± 0.1	87.0 ± 0.2	85.9 ± 0.1	87.7 ± 0.1	$\mathbf{92.3 \pm 0.1}$
En + Fr $\Longrightarrow$ Es	84.3 ± 0.2	73.6 ± 0.3	76.1 ± 0.2	84.9 ± 0.2	85.6 ± 0.0	86.3 ± 0.1	$\mathbf{91.3 \pm 0.1}$
Fr + Es $\Longrightarrow$ En	80.4 ± 0.1	76.7 ± 0.4	84.2 ± 0.2	87.0 ± 0.3	84.5 ± 0.2	88.4 ± 0.3	$\mathbf{90.2 \pm 0.2}$

Table 3. Macro-AUC (%) in cross-lingual music genre translation with standard deviation computed over 4 folds. Results are shown for different embedding initialization (*avg* and *sif*), used directly ($\hat{\mathbf{Q}}$) or retrofitted with the original retrofitting ($\mathbf{Q}$) or with our version ($\mathbf{Q}_{\overline{\beta}}$). The baseline is built on the shortest paths in the DBpedia-based multilingual graph.

	Baseline	$\hat{\mathbf{Q}}$ (*avg*)	$\mathbf{Q}$ (*avg*)	$\mathbf{Q}_{\overline{\beta}}$ (*avg*)	$\hat{\mathbf{Q}}$ (*sif*)	$\mathbf{Q}$ (*sif*)	$\mathbf{Q}_{\overline{\beta}}$ (*sif*)
Lf + Tt $\Longrightarrow$ Dc	76.2 ± 0.1	75.2 ± 0.2	82.0 ± 0.2	83.0 ± 0.2	81.3 ± 0.2	87.3 ± 0.1	$\mathbf{87.5 \pm 0.0}$
Dc + Tt $\Longrightarrow$ Lf	84.5 ± 0.2	81.6 ± 0.2	87.2 ± 0.1	88.0 ± 0.1	84.6 ± 0.1	90.1 ± 0.1	$\mathbf{90.4 \pm 0.1}$
Lf + Dc $\Longrightarrow$ Tt	82.5 ± 0.3	82.2 ± 0.3	87.8 ± 0.2	88.1 ± 0.2	86.4 ± 0.1	91.6 ± 0.2	$\mathbf{91.8 \pm 0.2}$

Table 4. Macro-AUC (%) in English multi-source music genre translation with standard deviation computed over 4 folds. Results are shown for different embedding initialization (*avg* and *sif*), used directly ($\hat{\mathbf{Q}}$) or retrofitted with the original retrofitting ($\mathbf{Q}$) or with our version ($\mathbf{Q}_{\overline{\beta}}$). The baseline consists in tag alignment against English DBpedia music genres [6].

tag systems as targets. Compared to the experiments reported in Section 4.3, this time, we observe only a marginal difference between the original retrofitting and our version.

Further, we give more details about the translations enabled by the baseline and our retrofitted *sif* embeddings. Often, we yield better music genre mappings (e.g. we map *Discogs:uk garage* on *Tagtraum:garagerock*, while the baseline maps it on *Tagtraum:dubstep*). However, there are also cases where the baseline leads to more accurate mappings (e.g. *Discogs:modal* is mapped on *Lastfm:cooljazz* compared to our best mapping on *Lastfm:jazz*). Finally, the baseline could not map at all some music genres, while we could (e.g. we map *Discogs:crunk* on *Tagtraum:gangstarap* and on *Lastfm:rap*).

To sum up, exploiting the semantics of the music genre graph edges leads to marginally improved results w.r.t. the original retrofitting in the English-language multi-source translation and significantly higher AUC scores in the cross-lingual translation. The *sif* initialization yields better translations than the *avg* initialization. Lastly, we outperform the baselines by large margins in both experiments.

5. CONCLUSION

In this paper, we presented a new multi-step method for multilingual music genre embeddings learning. This method combines pre-trained word embeddings, music genre graphs and a retrofitting method leveraging different types of music genre relations to adapt embeddings to the music domain and learn embeddings for music genres with unknown words in the pre-trained word embeddings vocabulary. Our experiments demonstrate the effectiveness of the proposed method, both in the English-language multi-source and the new cross-lingual translation tasks.

For future work, we plan to learn embeddings for each music genre relation type. Fang et al. [33] consider that each edge represents a linear translation from the embedding of one node to the embeddings of its neighbour. In a generalized setup, functional retrofitting proposed by Lengerich et al. [32] defines a linear relational penalty

function for each type of relation in the graph.

Then, we aim to address the incremental updates of the music genre graph in order to avoid re-applying retrofitting every time the graph is updated. Instead of relying on the constraints represented by the graph edges directly in retrofitting, Glavaš and Vulić [43] use them as training instances to learn an explicit retrofitting function, which can be after applied to new node embeddings.

Further, we want to apply our method to new languages, especially from other language families, as well as to investigate other pre-trained word embeddings and alternatives to embed multi-word concepts [26]. For this, the current music genre graph needs to be populated with new multilingual music genres and their relations, and a parallel corpus of music items covering new languages should be collected if further evaluation is required. Continuing to rely on the multilingual DBpedia is an option, though a limiting one, given that only some world languages are supported. Thus, music genre translation involving resource-poor languages remains a challenge. However, for the supported languages, our approach allows generating cross-lingual music genre annotations, which could be useful for other music information retrieval and recommendation tasks such as language-aware music genre autotagging, localized playlist captioning and music genre-driven recommendations, cross-cultural music genre perception modeling for user studies.

Finally, the multilingual data and the code to learn and evaluate music genre embeddings are made available to the community [5] . Also, a demo to visualize the music genre vector space and the cross-lingual translation results for DBpedia music items is available [44].

ABSTRACT

Musical form and syntax in Western classical music are hierarchically organised on different timescales. One of the most important features of this structure is the organisation of modulations between different keys throughout a piece. Music theoretical research has established taxonomies of prototypical modulation plans for different modes and musical forms. However, these prototypes still require empirical validation based on quantitative statistical methods and cannot be retrieved automatically so far.

In this paper, we present a novel method to infer prototypical modulation plans from musical corpora. A modulation plan is formalised as a transposition-invariant probabilistic model over the underlying pitch class distributions based on a hierarchical *pitch scape* representation. Prototypical modulation plans can be learned in an unsupervised manner by training a mixture model (similar to a Gaussian mixture model) on the data, so that different prototypes appear as distinct clusters.

We evaluate our approach by performing hierarchical clustering on a corpus of more than 150 Baroque pieces, with the extracted clusters showing excellent agreement with the most common prototypes postulated in music theory. Our method bears a great potential for modelling, analysis and discovery of hierarchical key structure and prototypes in corpora across a broad range of musical styles. An accompanying library is available at: github.com/robert-lieck/pitchscapes.

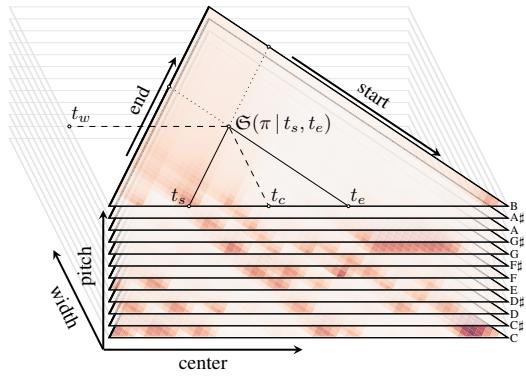
1. INTRODUCTION

The hierarchical structure of a piece in Western classical music is strongly determined by musical form [1] and harmonic syntax [2, 3], based on different aspects, such as repetition and variation of the rhythmic, melodic and harmonic content and hierarchical relations between different harmonies.

A central aspect that links musical form and harmonic syntax is the modulation plan of a piece. Western musicology assumes a number of prototypical modulation plans that describe the overarching tonal structure of a piece,

such as I–V–I for pieces in major or i–III–i for pieces in minor [1]. These prototypes have a long-standing history in musicology and have emerged from inspection of numerous individual pieces and agreement among experts. However, a quantitative validation based on statistical methods constitutes an important supplement to confirm and refine the music theoretic findings. Furthermore, they cannot be automatically retrieved from musical data, which impedes large-scale investigations and the application to other styles and genres of music.

In this paper, we present a method to retrieve prototypical modulation plans from large corpora of musical pieces in an unsupervised manner. This is achieved by modelling the overall corpus as a mixture of multiple prototypes, similar to how Gaussian mixture models [4] can be applied to clustering in Euclidean space. A prototype is represented by a transposition-invariant Bayesian model that describes the pitch content of a piece (pitch class distributions) on multiple time scales. Modelling is based on a novel *pitch scape* representation of the musical content, which allows to account for the hierarchical structure inherent to both musical form and harmonic syntax. We evaluate our model on a corpus of more than 150 Baroque pieces, with the extracted clusters showing excellent agreement with the most common prototypes postulated in music theory.

By providing a solid statistical approach to modelling prototypical modulation plans, we make an important contribution to connecting music theory and empirical science. Our approach relies on minimal prior assumptions, works on simple pitch data, and learns prototypes in an unsupervised manner, which bears a great potential for modelling, analysis and discovery of hierarchical key structure and prototypes in corpora across a broad range of musical styles.


In the remainder of the paper, we describe the underlying *pitch scape* representation in Section 2, introduce the probabilistic Bayesian model that is used to learn prototypes and prototype mixtures from musical corpora in Section 3, and present and discuss the results of our evaluation in Section 4.

2. PITCH SCAPES

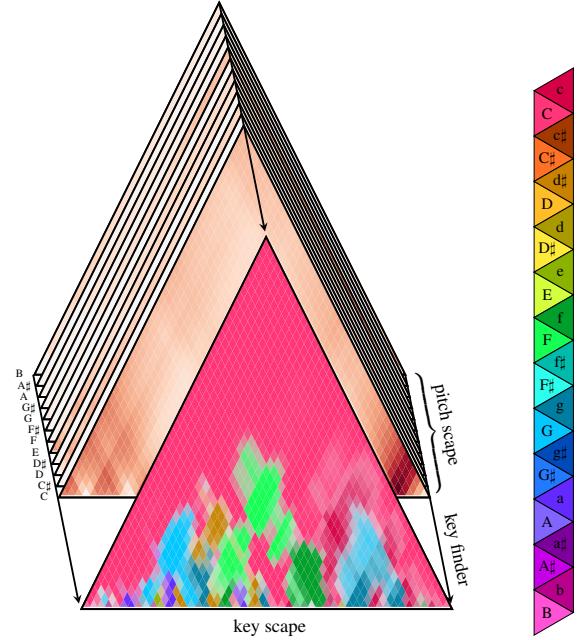
We model prototypical modulation plans based on a novel *pitch scape* representation of the musical content. Pitch scapes (see Figure 1 for an illustration) represent the pitch content of a piece on multiple time scales and can be for-

Figure 1. Pitch scape (Prelude in C major, BWV 846, Johann Sebastian Bach). The two time values can be specified in start-end-coordinates (t_s and t_e) or in center-width-coordinates (t_c and t_w).

mally defined as the conditional probability distribution of the pitch classes for a given section of the piece:

Definition 1 (Pitch Scape). *A pitch scape $\mathfrak{S}$ is a function that maps each proper time interval $[t_s, t_e]$ ($t_s < t_e$) to a pitch class distribution*

$$\mathfrak{S} : \mathbb{R} \times \mathbb{R} \to [0,1]^{12} , \quad \sum_{\pi=0}^{11} \mathfrak{S}(\pi \,|\, t_s, t_e) = 1 . \quad (1)$$

A pitch scape can equivalently be conceived as a conditional probability distribution $\mathfrak{S}(\pi \,|\, t_s, t_e)$ with three variables or a vector-valued function $\mathfrak{S}(t_s, t_e)$ in two variables.


Pitch scapes are inspired by scape plot visualisations, to which we draw the connection in Section 2.1, while Section 2.2 describes how to compute pitch scape estimates for a given piece.

2.1 Pitch Scape Visualisation

Scape plot visualisations were introduced in [5,6] to depict key estimates for different sections of a piece in a hierarchical triangular plot and have since been used for a variety of visualisation tasks [7–11].

Visualising the entire information contained in a three-dimensional pitch scape in a single two-dimensional plot is difficult. However, there are two convenient ways to visualise the relevant information. First, the 12 components can be visualised separately by creating one scape plot per pitch class. This preserves the entire information but does not foster musical intuition because information about simultaneous events is scattered across multiple plots. Alternatively, a key finding algorithm can be employed [12–15] to map the pitch class distribution of each point to a colour value. This corresponds to a key-scape plot of the pitch scape. For illustration, we show in Figure 2 an overlay of the 12 separate pitch-scape plots and the corresponding key-scape plot.

The colour mapping for a key-scape plot can be realised in different ways. We use a template-based key finder that

Figure 2. Separate pitch-scape plots and resulting key-scape plot for the prelude in C major, BWV 846, Johann Sebastian Bach (colour legend for keys on the right).

provides a score value for each major and minor key. The scores can be transformed into a probability distribution $p(k)$ using a soft-max function. After choosing a unique colour for each key, $p(k)$ can be used to interpolate between colours by computing their weighted average. To define the colour for each key, we let the hue value vary either along the circle of fifths or chromatically, which has complementary advantages. Fifth-based hue maps related keys to similar colours, while chromatic hue allows to better distinguish them. We add a lightness offset to distinguish major and minor keys and map the entropy of $p(k)$ to saturation. Entropy-based saturation allows to indicate regions with uncertain key classification and avoids uninterpretable colour blends.

2.2 Pitch Scape Estimates

The pitch scape of a piece is computed from its musical content and reflects the probability of a certain pitch class to occur within the specified time interval. As we are working in a Bayesian framework, we model the pitch scape of a piece as a posterior estimate given a prior distribution and the observed notes. To formally define the pitch scape estimate of a piece, we first define its pitch class density:

Definition 2 (Pitch Class Density). *The pitch class density $\delta(\pi \,|\, t)$ for pitch class π at time t corresponds to the normalised pitch class counts over all tones that sound at time t*

$$\delta(\pi \,|\, t) := \frac{1}{\max\{1, |T_t|\}} \sum_{\tau \in T_t} [\![\tau \bmod 12 = \pi]\!] , \quad (2)$$

where T_t is the multiset of all tones (as integers in MIDI pitch representation) sounding at time t; $[\![\cdot]\!]$ is the Iverson

bracket, which equals 1 if its argument is true and 0 otherwise; and the max *avoids division by zero for silent parts where $T_t = \emptyset$ is the empty set.*

Using the pitch class density, we define the pitch scape estimate as follows:

Definition 3 (Pitch Scape Estimate). *The posterior estimate of the pitch scape $\mathfrak{S}(\pi \,|\, t_s, t_e)$ for pitch class π and time interval $[t_s, t_e]$ is*

$$\mathfrak{S}(\pi \,|\, t_s, t_e) := \underbrace{\frac{1}{t_e - t_s + 12c}}_{\text{normalisation}} \left[c + \overbrace{\underbrace{\int_{t_s}^{t_e} \delta(\pi \,|\, t) \, dt}_{\text{overall pitch class counts}}}^{\text{prior counts}} \right], \quad (3)$$

where the integral over the pitch class density computes the overall pitch class counts, $c \geq 0$ specifies the prior counts, and the leading term ensures proper normalisation.

Using zero prior counts $c = 0$ thus corresponds to using the average pitch class density as pitch scape estimate (in Bayesian terms this would be a maximum likelihood estimate). In contrast, using a prior count of $c = 1$, which is done throughout the paper, corresponds to a Bayesian maximum posterior estimate with a uniform prior over pitch classes ($c = 1$ corresponds to a uniform Dirichlet distribution, which is the appropriate conjugate prior for the categorical distribution over pitch classes). Note that choosing $c > 0$ also circumvents the zero-count problem for silent parts.

The relative weight of the overall pitch class counts, computed in the integral in (3), depends on the scale on which time is measured. Throughout the paper, we measure time in quarter notes, so that a time interval of one quarter note has the weight of a single observation. That means, for instance, a single pitch sustained for two quarter note adds two to the respective overall pitch class counts; two different pitches sustained for one quarter note add half a count each; and three pitches sustained for an eight note add one sixth count each. Thus, for small time intervals the prior counts c introduce a significant bias towards a uniform pitch class distribution, while for large time intervals they have a vanishingly small weight relative to the overall pitch class counts (e.g. a 32-bar piece in 4/4 yields a total of 128 pitch class counts, so that the prior counts do not cause a major change of the estimated pitch class distribution for the entire piece).

3. MODELLING KEY STRUCTURE

We define our model for mixtures of prototypes in two steps. First, we define a probabilistic pitch scape model of a transposition-invariant modulation plan (Section 3.1). Based on this model for single prototypes, we define a mixture model (Section 3.2) that incorporates explicit transposition and models a musical corpus as a mixture of multiple prototypes.

3.1 Prototypes

The idea of a prototype is to specify an object that represents a subset of the data. In probabilistic modelling this corresponds to defining a probability distribution for which a subset of the data has a high likelihood. Additionally, this distribution should be unimodal so that its mode can be taken as a representative of all data points belonging to that prototype. In n-dimensional Euclidean space, prototypes can for instance be defined using multivariate Gaussian distributions.

When defining prototypes for pitch scapes, we are facing some additional challenges that will be addressed in the following. First, the output of a pitch scape is a categorical distribution (over pitch classes), which has to be normalised. Second, time is continuous so that a pitch scape itself is an inherently continuous object. Third, the prototypes postulated in music theory are formulated in terms of scale degrees, which makes them transposition-invariant (i.e. transposing a piece does not affect its relation to a specific prototype). The first two points will be addressed in the following Section 3.1.1, the third point is resolved in Section 3.1.3 and incorporated in the mixture model in Section 3.2.

3.1.1 Definition

We address the first two points by defining a prototype as a point-wise Dirichlet distribution with a time-dependent parameter vector α. The Dirichlet distribution is the conjugate prior of a categorical distribution and acts as a likelihood function if the observations themselves are categorical distributions, as it is the case for individual points in a pitch scape (first point). Making its parameter vector time-dependent additionally allows it to vary continuously over the pitch scape (second point). Formally, a prototype is defined as follows:

Definition 4 (Prototype). *Given a function*

$$\alpha : \mathbb{R} \times \mathbb{R} \to \mathbb{R}_+^{12} \qquad (4)$$

that maps each proper time interval $[t_s, t_e]$ ($t_s < t_e$) to a vector with positive entries, a prototype is defined as the point-wise Dirichlet distribution with parameter vector α. The likelihood of observing a pitch class distribution Π for the interval $[t_s, t_e]$ given α is

$$p(\Pi \,|\, \alpha, t_s, t_e) = \text{Dir}(\Pi; \alpha(t_s, t_e)) \,. \qquad (5)$$

The log-likelihood of observing a full pitch scape $\mathfrak{S}$ given α is

$$\log p(\mathfrak{S} \,|\, \alpha) = \frac{2}{T^2} \iint_{0 \leq t_s < t_e \leq T} \log \text{Dir}\big(\mathfrak{S}(t_s, t_e); \alpha(t_s, t_e)\big) dt_s dt_e \,,$$
$$(6)$$

where T is the duration of the piece.

The definition of the log-likelihood in (6) is equivalent to the (negative) cross-entropy of an infinite number of uniform samples from the pitch scape. It differs from a simple integration of (5) only by the normalisation $\frac{2}{T^2}$, which rescales it to the magnitude of a single observation and makes it invariant to the duration of the piece. Note that both (5) and (6) are probability *density* functions with the usual implications (i.e. they can be greater than 1; their log can be positive; their cross-entropy can be negative).

3.1.2 Proxy Function

To learn prototypes from data, we define α via a three dimensional real-valued proxy function $\widetilde{\alpha}$ that has a set of adjustable parameters θ and an open parameter τ

$$\widetilde{\alpha}^{(\theta,\tau)} : \mathbb{R} \times \mathbb{R} \times \mathbb{R} \to \mathbb{R} . \qquad (7)$$

The domain of interest is $[0, 1] \times [0, 1] \times \mathbb{Z}_{12}$ with the first two arguments specifying the time interval in normalised center-width-coordinates and the third specifying the pitch class. The πth component of α is then defined to be

$$\alpha_\pi^{(\theta,\tau)}(t_s, t_e) := e^{\widetilde{\alpha}^{(\theta,\tau)}(\bar{t}_c, \bar{t}_w, \pi)} \qquad (8)$$

with

$$\bar{t}_c = \frac{1}{2T}(t_s + t_e) \qquad \bar{t}_w = \frac{1}{T}(t_e - t_s) , \qquad (9)$$

where T is the duration of the piece that is to be modelled.

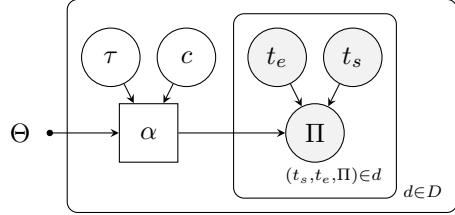
3.1.3 Fourier Representation

We parameterise $\widetilde{\alpha}$ as a Fourier series in three dimensions [16]

$$\widetilde{\alpha}^{(\theta,\tau)}(\mathbf{x}) = \sum_{\mathbf{n}} \theta_{\mathbf{n}} e^{2\pi i \mathbf{k_n} \cdot \mathbf{x}} , \qquad (10)$$

where π (only in this equation!) is the mathematical constant. The index vector $\mathbf{n}$, wave vector $\mathbf{k_n}$, and location vector $\mathbf{x}$ are

$$\mathbf{x} := (\bar{t}_c, \bar{t}_w, \pi) \qquad n_c \in \{-N_c, \dots, N_c\} \quad (11)$$

$$\mathbf{n} := (n_c, n_w, n_\pi) \qquad n_w \in \{-N_w, \dots, N_w\} \quad (12)$$


$$\mathbf{k_n} := \left(\sigma_c n_c, \sigma_w n_w, \frac{n_\pi + \tau}{12}\right) \quad n_\pi \in \{-6, \dots, 6\} . \quad (13)$$

N_c and N_w allow to independently control the smoothness (or bandwidth) of $\widetilde{\alpha}$ for the center and width dimension, respectively; $\tau \in \mathbb{Z}_{12}$ represents the transposition of the prototype (see below); and $\sigma = 1 - \frac{1}{2N}$ is a scaling factor. Scaling is required because we do not want $\widetilde{\alpha}$ to have periodic boundaries conditions in the time dimensions. The Nyquist frequency of the unscaled function is $2N$, the scaling factor thus stretches the function such that a critical fraction of $\frac{1}{2N}$ is moved out of the interval $[0, 1]$. This is not relevant for the pitch dimension because the space of pitch classes is inherently periodic and, moreover, we have a complete discrete Fourier series that allows to represent any function exactly. As $\widetilde{\alpha}$ is real-valued, $\theta_{\mathbf{n}}$ and $\theta_{-\mathbf{n}}$ are complex conjugates and (due to the properties of the discrete Fourier transform) all coefficients with $n_\pi = \pm 6$ are real-valued. We can thus store the parameters θ in a real-valued array of dimensions $(2N_c + 1, 2N_w + 1, 12)$.

As $\widetilde{\alpha}$ (and thus α) are periodic in the pitch dimension, the Fourier representation can be understood as a transposition-invariant formulation of a prototype. When creating a concrete instance of the prototype, τ needs to be specified and defines a specific transposition by inducing a corresponding phase shift through the cyclic pitch class space.

3.2 Mixture Model

In Section 3.1 we defined prototypes that have a point-wise Dirichlet distribution (Definition 4) and adjustable parameters θ. We will now build a transposition-invariant mixture

Figure 3. Graphical representation of our mixture model. Θ are the prototype parameters; c and τ the piece-specific cluster index and transposition; α the deterministically generated prototype instance; and $\Pi = \mathfrak{S}(t_s, t_e)$ the pitch scape values at intervals $[t_s, t_e]$ (see text for more details).

model using these prototypes. The overall structure of the model is shown in Figure 3 as a graphical model [17] and will be explained in detail below.

Our model is similar to classical topic models for corpora [18–20] with two nested levels. Each piece (or document) d in the data set D is generated independently from a specific prototype with parameters $\theta = \Theta_c$ and transposition τ (outer plate) and for a specific piece, each point Π in its pitch scape is generated independently (inner plate). [1]

3.2.1 Inference

We want to find parameters Θ^* that minimise the cross-entropy (i.e. maximise the likelihood) of our data D

$$\Theta^* = \text{argmin}_\Theta -\frac{1}{|D|} \log p(D \mid \Theta) , \qquad (14)$$

where

$$\log p(D \mid \Theta) = \sum_{d \in D} \log \sum_{c,\tau} p(d \mid \alpha^{(\Theta_c, \tau)}) \, p(c) \, p(\tau) , \quad (15)$$

is the data log-likelihood with the latent variables c and τ being marginalised out. The prior terms $p(c)$ and $p(\tau)$ are assumed to be constant so that a priori no specific prototype or transposition is preferred. We use

$$\log p(d \mid \alpha) = \frac{1}{|d|} \sum_{(t_s, t_e, \Pi) \in d} \log \text{Dir}\big(\Pi; \alpha(t_s, t_e)\big) \qquad (16)$$

to approximate the piece likelihood (6) based on a finite number of uniform samples. Marginalising out c and τ also readily yields the normalisation factor for the cluster and transposition probability for a piece

$$p(c, \tau \mid d) \propto p(d, c, \tau) = p(d \mid \alpha^{(\Theta_c, \tau)}) \, p(c) \, p(\tau) . \quad (17)$$

The optimal parameters Θ^* can be found by performing gradient descent on the cross-entropy (14).

---

[1] The assumption of different points in the pitch scape being generated independently is obviously incorrect, which is common to all topic models and the reason why they are not well suited to generate coherent data (e.g. text or music). In fact, in a pitch scape the values at different locations are highly correlated and would ideally be modelled as a single continuous latent function. One approach to achieve this are Gaussian processes (GPs) [21]. However, GPs are computationally expensive and GPs for multi-class classification have complex kernel functions and require approximations of the analytically intractable posterior distribution [21–23]. As we are primarily interested in extracting the mean pitch scape (corresponding to the GP prior), which represents a specific prototype, we therefore chose the simpler approach of defining prototypes as a point-wise Dirichlet distribution.

3.2.2 Hierarchical Clustering

Training the mixture model on a data set allows to perform unsupervised clustering with a fixed number of clusters. However, our motivation is a comparison with the prototypes described in the music theory literature. Instead of choosing a fixed number of clusters, we are rather interested in how clusters split hierarchically from more generic prototypes to more specific ones. We therefore take a hierarchical top-down clustering approach.

We start by training a single prototype on the whole corpus and perform a binary split of this cluster by using it to initialise a mixture of two prototypes, while adding minimal noise (10^{-8}) to the parameters θ to allow the clusters to properly split. This procedure is then recursively and *separately* applied to the resulting prototypes. To this end, the probability $p(d \,|\, c')$ of a piece d to fall into the parent cluster c' is used as a weight in (15) when training the two child clusters. This ensures a clear assignment between parent and child clusters and implies that only pieces that fell into the parent cluster influence the children.

After establishing a hierarchy of prototypes in this way, we perform a joint refinement of the resulting clusters. To this end, *all* final child clusters are combined in a single model while lifting the parent-specific piece weights. This serves a two-fold purpose. First, the prototypes may be sharpened as interactions between the clusters can now be exploited. Second, it acts as a sanity check for the established hierarchy: If the child clusters remain stable in the refinement phase, this indicates consistency of the hierarchical splitting.

4. EVALUATION

4.1 Experimental Setup

The model was implemented in `PyTorch` [24] and the parameters Θ were optimised via gradient descent using the Adam optimiser [25]. The "warm start" with pre-initialised clusters was realised by using a small initial learning rate (10^{-5}) to allow for the mean and variance estimators (internals of the Adam optimiser) to stabilise before reaching the normal learning rate (10^{-3}).

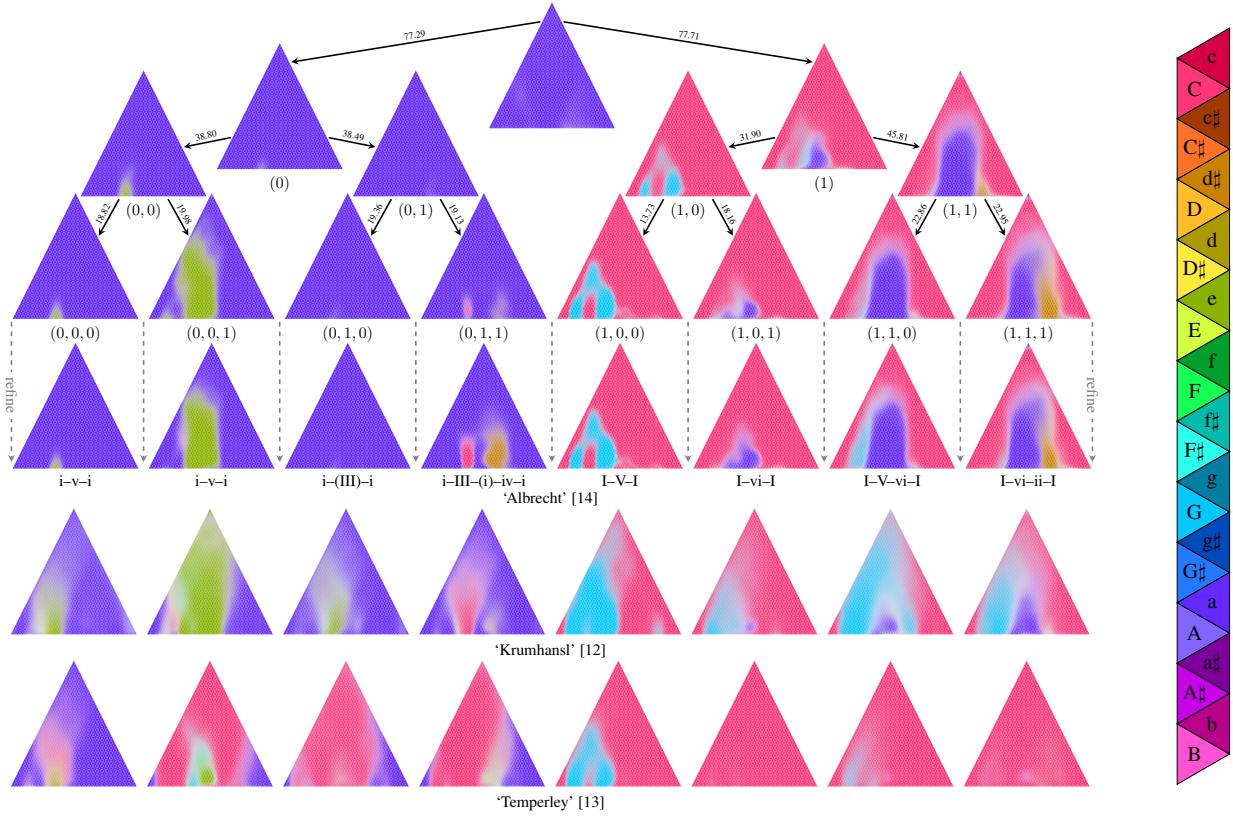
We trained our model on a corpus of 155 Baroque pieces in MIDI format by Johann Sebastian Bach (84%: WTK I/II; Brandenburgisches Konzert No. 5; Inventions and Sinfonias), Georg Friedrich Händel (4%: HWV 264, Movement 2, 4, 9, 10, 11, and 13; HWV 435), and Domenico Scarlatti (12%: Sonatas), see Appendix C for a complete list. As opposed to later periods with an increasing amount of chromaticism, the modulation plans of Baroque pieces are expected to more closely conform to the respective prototypes. Each piece was sampled by choosing interval start and end points on a uniform time grid of $n = 50$ points, resulting in $n(n-1)/2 = 1225$ samples per piece.

Hierarchical clustering was performed up to depth 3 (8 final clusters) with subsequent refinement (see Section 3.2.2). The hierarchy and final prototypes are shown in Figure 4 and discussed below.

4.2 Results and Discussion

The root cluster, which was trained on the entire corpus, represents a generic diatonic prototype. It does not unambiguously belong to a particular mode, being classified as minor based on 'Albrecht' profiles (as in Figure 4) and major based on 'Temperley' profiles. This is also reflected in the separate pitch-scape plots (Table 1 in Appendix B), which have strong weights for the entire pentatonic segment of the line of fifths (C–G–D–A–E). This can be interpreted as confirming the view that Baroque music is fundamentally diatonic.

The initial split results in a clear separation of major and minor keys, with cluster (0) and all its descendants being globally classified as minor pieces while (1) and its descendants are classified as major. From now on we can see a pronounced weight on the tonic pitch class (C for major, A for minor) at the beginning and end of a piece in the separate pitch-scape plots. This split into major and minor prototypes again is an important finding that confirms these two modes to be dominant in Baroque music.

4.2.1 Prototypes in Minor


The next split of the minor cluster separates the two most common prototypes. Prototypical minor-mode pieces are assumed to either modulate to the key of v (the dominant) or to the key of III (relative major) before returning to i (tonic), which corresponds to (0,0) and (0,1) and their descendants, respectively. Note that the cluster (0,1,0) also has a strong tendency to modulate to III, which becomes more apparent when using 'Temperley' profiles.

The i–v–i modulation plan of cluster (0,0,0) and (0,0,1) is one of the two standard prototypes for minor pieces. In (0,0,1), the v is more pronounced and the middle section also has a certain tendency to modulate to III, possibly even including a short VII passage (see 'Temperley' profiles). This corresponds to a i–III–(VII)–v–III–i modulation plan, which is a common subtype of the i–v–i prototype that features two fifth-related, modally distinct key pairs: i–v and III–VII.

Cluster (0,1,0) and (0,1,1) both fall under the general i–III–i prototype. The (0,1,0) cluster has a less pronounced III, which may be partly due to the III being at different locations in the corresponding pieces, thus leading to smoothing/averaging. According to 'Krumhansl' profiles, there is a tendency for modulation to v in the middle section and 'Temperley' profiles classify larger parts of the middle section as III. Cluster (0,1,1) has an additional modulation to the iv after the III, possibly with a short return to the i in between (again this could also be an effect of averaging over multiple pieces), representing the common subtype i–III–(i)–iv–i.

4.2.2 Prototypes in Major

Major pieces are generally assumed to modulate to V before going back to I. However, this general prototype can be elaborated in different ways. For the split of the major cluster (1), we see a very pronounced I–V–I prototype on the left with (1,0) and its child (1,0,0).

Figure 4. Results of hierarchical clustering with subsequent refinement. To visualise the prototypes, the transposition parameter τ was fixed to minimise the accidentals of the diatonic root cluster. The corresponding absolute keys are shown in the chromatic colour scale (right). However, only relative keys (scale degrees) bear interpretable meaning as the prototypes are inherently transposition-invariant. Prototypes are labelled with a hierarchical index; the final prototypes (after refinement) are labelled with the corresponding modulation plan in Roman numeral notation; numbers on the arrows indicate the number of pieces falling into the respective cluster. Key estimates for colouring are computed using 'Albrecht' [14] templates; the final prototypes are repeated using 'Krumhansl' [12] and 'Temperley' [13] templates to improve interpretability. For better disambiguation, Figure 5 and Figure 6 in Appendix A show chromatic and fifth-based colouring in comparison.

The remaining three clusters all belong to one of the most common elaborations of the I–V–I prototype with an additional vi (relative minor) passage after the V. The V passage is most clearly pronounced in the (1,1,0) cluster, to a lesser extent in the (1,1,1) and even less in the (1,0,1) cluster (see especially the 'Krumhansl' profiles). Notably, (1,1,1) has an additional ii passage after the vi.

The I–vi–I and the I–vi–ii–I cluster taken separately do not contradict expectations from music theory, but due to the missing V they are less typical than the other prototypes so far. However, when being combined with the I–V–vi–I cluster, theses clusters form the very common subtype I–V–vi–ii–I [1]. This is typical in Baroque music but also in modern Pop music, where on the chord-level this sequence is known as "the four chord song" (optionally with a IV as an equivalent pre-dominant replacement of the ii). This combination of multiple prototypes suggests the existence *prototype sub-spaces*.

5. CONCLUSION

To address the problem of modelling and automatic retrieval of prototypical modulation plans from a corpus of musical pieces, a probabilistic Bayesian model of transposition-invariant prototypes was introduced. This model was based on a novel hierarchical *pitch scape* representation of the musical content. We learned prototypical modulation plans from a corpus of Baroque pieces, empirically confirming common prototypes postulated in music theory. Extending the conventional music theoretical concepts, we found that continuous *prototype sub-spaces* can be generated as the superposition of multiple prototypes.

Our approach relies on minimal prior assumptions, works on simple pitch data and delivers robust results while being scalable to large data sets. It can therefore be applied to model, analyse and discover hierarchical key structures and prototypes in a wide range of musical styles and genres, including diachronic studies of musical form and syntax in Western classical music, the influence of style- and composer-specific elements, and the investigation of modulation plans in other genres such as Jazz, Pop and Rock music. Therefore, our approach is suited for numerous applications and contributes a valuable method for music information retrieval.

ABSTRACT

Informed source separation has recently gained renewed interest with the introduction of neural networks and the availability of large multitrack datasets containing both the mixture and the separated sources. These approaches use prior information about the target source to improve separation. Historically, Music Information Retrieval researchers have focused primarily on score-informed source separation, but more recent approaches explore lyrics-informed source separation. However, because of the lack of multitrack datasets with time-aligned lyrics, models use weak conditioning with non-aligned lyrics. In this paper, we present a multimodal multitrack dataset with lyrics aligned in time at the word level with phonetic information as well as explore strong conditioning using the aligned phonemes. Our model follows a U-Net architecture and takes as input both the magnitude spectrogram of a musical mixture and a matrix with aligned phonetic information. The phoneme matrix is embedded to obtain the parameters that control Feature-wise Linear Modulation (FiLM) layers. These layers condition the U-Net feature maps to adapt the separation process to the presence of different phonemes via affine transformations. We show that phoneme conditioning can be successfully applied to improve singing voice source separation.

1. INTRODUCTION

Music source separation aims to isolate the different instruments that appear in an audio mixture (a mixed music track), reversing the mixing process. Informed-source separation uses prior information about the target source to improve separation. Researchers have shown that deep neural architectures can be effectively adapted to this paradigm [1, 2]. Music source separation is a particularly challenging task. Instruments are usually correlated in time and frequency with many different harmonic instruments overlapping at several dynamics variations. Without additional knowledge about the sources the separation is often infeasible. To address this issue, Music Informa-

tion Retrieval (MIR) researchers have integrated into the source separation process prior knowledge about the different instruments presented in a mixture, or musical scores that indicate where sounds appear. This prior knowledge improves the performances [2–4]. Recently, conditioning learning has shown that neural networks architectures can be effectively controlled for performing different music source isolation tasks [5–10]

Various multimodal context information can be used. Although MIR researchers have historically focused on score-informed source separation to guide the separation process, lyrics-informed source separation has become an increasingly popular research area [10, 11]. Singing voice is one of the most important elements in a musical piece [12]. Singing voice tasks (e.g. lyric or note transcription) are particularly challenging given its variety of timbre and expressive versatility. Fortunately, recent data-driven machine learning techniques have boosted the quality and inspired many recent discoveries [13, 14]. Singing voice works as a musical instrument and at the same time conveys a semantic meaning through the use of language [14]. The relationship between sound and meaning is defined by a finite phonetic and semantic representations [15, 16]. Singing in popular music usually has a specific sound based on phonemes, which distinguishes it from the other musical instruments. This motivates researchers to use prior knowledge such as a text transcript of the utterance or linguistic features to improve the singing voice source sparation [10, 11]. However, the lack of multitrack datasets with time-aligned lyrics has limited them to develop their ideas and only weak conditioning scenarios have been studied, i.e. using the context information without explicitly informing where it occurs in the signal. Time-aligned lyrics provide abstract and high-level information about the phonetic characteristics of the singing signal. This prior knowledge can facilitate the separation and be beneficial to the final isolation.

Looking for combining the power of data-driven models with the adaptability of informed approaches, we propose a multitrack dataset with time-aligned lyrics. We explore then how we can use strong conditioning where the content information about the lyrics is available frame-wise to improve vocal sources separation. We investigate strong and weak conditioning using the aligned phonemes via Feature-wise Linear Modulation (FiLM) layer [17] in U-Net based architecture [18]. We show that phoneme conditioning can be successfully applied to improve standard

singing voice source separation and that simplest strong conditioning outperforms any other scenario.

2. RELATED WORK

Informed source separation use context information about the sources to improve the separation quality, introducing in models additional flexibility to adapt to observed signals. Researchers have explored different approaches for integrating different prior knowledge in the separation [19]. Most of the recent data-driven music source separation methods use weak conditioning with prior knowledge about the different instruments presented in a mixture [3, 5, 7–9]. Strong conditioning has been primarily used in score-informed source separation. In this section, we review works related to this topic as well as novel approaches that explore lyrics-informed source separation.

2.1 Score-informed music source separation

Scores provide prior knowledge for source separation in various ways. For each instrument (source), it defines which notes are played at which time, which can be linked to audio frames. This information can be used to guide the estimation of the harmonics of the sound source at each frame [2,4]. Pioneer approaches rely on non-negative matrix factorization (NMF) [20–23]. These methods assume that the audio is synchronized with the score and use different alignment techniques to achieve this. Nevertheless, alignment methods introduce errors. Local misalignments influence the quality of the separation [21, 24]. This is compensated by allowing a tolerance window around note onsets and offsets [20, 23] or with context-specific methods to refine the alignment [25]. Current approaches use deep neural network architectures and filtering spectrograms by the scores and generating masks for each source [2]. The score-filtered spectrum is used as input to an encoder-decoder convolutional neural network (CNN) architecture similar to [26]. [27] propose an unsupervised method where scores guide the representation learning to induce structure in the separation. They add class activity penalties and structured dropout extensions to the encoder-decoder architecture. Class activity penalties capture the uncertainty about the target label value and structured dropout uses labels to enforce a specific structure, canceling activity related to unwanted note.

2.2 Text-informed music source separation

Due to the importance of singing voice in a musical piece [12], it is one of the most useful source to separate in a music track. Researchers have integrated the vocal activity information to constrain a robust principal component analysis (RPCA) method, applying a vocal/non-vocal mask or ideal time-frequency binary mask [28]. [10] propose a bidirectional recurrent neural networks (BRNN) method that includes context information extracted from the text via attention mechanism. The method takes as input a whole audio track and its associated text information

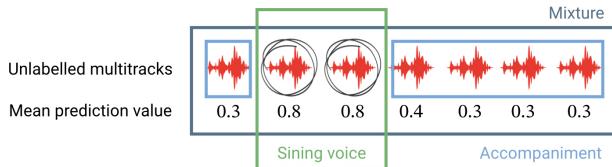
and learn alignment between mixture and context information that enhance the separation. Recently, [11] extract a representation of the linguistic content related to cognitively relevant features such as phonemes (but they do not explicitly predict the phonemes) in the mixture. The linguistic content guide the synthetization of the vocals.

3. FORMALIZATION

We use the multimodal information as context to guide and improve the separation. We formalize our problem satisfying certain properties summarized as [29]:

How is the multimodal model constructed? We divide the model into two distinct parts [30]: a *generic* network that carries on the main computation and a *control mechanism* that conditions the computation regarding context information and adds additional flexibility. The *conditioning* itself is performed using FiLM layers [17]. FiLM can effectively modulate a generic source separation model by some external information, controlling a single model to perform different instrument source separations [3, 5]. With this strategy, we can explore the *control* and *conditioning* parts regardless of the *generic* network used.

Where is the context information used? at which place in the *generic* network we insert the context information, and defining how it affects the computation, i.e. weak (or strong) conditioning without (or with) explicitly informing where it occurs in the signal.

What context information? We explore here prior information about the phonetic evolution of the singing voice, aligned in time with the audio. To this end, we introduce a novel multitrack dataset with lyrics aligned in time.


4. DATASET

The DALI (Dataset of Aligned Lyric Information) [31] dataset is a collection of songs described as a sequence of time-aligned lyrics. Time-aligned lyrics are described at four levels of granularity: **notes**, **words**, **lines** and **paragraphs**:

$$A_g = (a_{k,g})_{k=1}^{K_g} \text{ where } a_{k,g} = (t_k^0, t_k^1, f_k, l_k, i_k)_g \quad (1)$$

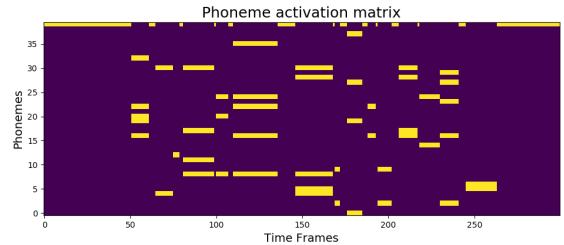
where g is the granularity level and K_g the number of elements of the aligned sequence, t_k^0 and t_k^1 being a text segment's start and end times (in seconds) with $t_k^0 < t_k^1$, f_k a tuple (f_{min}, f_{max}) with the frequency range (in Hz) covered by all the notes in the segment (at the note level $f_{min} = f_{max}$, a vocal note), l_k the actual lyric's information and $i_k = j$ the index that links an annotation $a_{k,g}$ with its corresponding upper granularity level annotation $a_{j,g+1}$. The text segment's events for a song are ordered and non-overlapping - that is, $t_k^1 \leq t_{k+1}^0 \forall k$.

There is a subset of DALI of 513 multitracks with the *mixture* and its separation in two sources, *vocals* and *accompaniment*. This subset comes from WASABI

Figure 1. Method used for creating the *vocals*, *accompaniment* and *mixture* version.

dataset [32]. The multitracks are distributed in 247 different artists and 32 different genres. The dataset contains 35.4 hours with music and 14.1 hours with vocals, with a mean average duration per song of 220.83s and 98.97s with vocals. All the songs are in English.

The original multitracks have the *mixture* decomposed in a set of unlabeled sources in the form track_1, track_2, ..., track_n. Depending of the songs, the files can be RAW (where each source is an instrument track e.g. a drum snare) or STEMS (where all the RAW files for an instrument are merged into a single file). In the following, we explain how the *vocals* and *accompaniment* tracks are automatically created from these unlabelled sources. The process is summarized in Figure 1.

For each track τ of a multitrack song, we compute a singing voice probability vector overtime, using a pretrained Singing Voice Detection (SVD) model [33]. We obtain then a global mean prediction value per tracks ϵ_τ. Assuming that there is at least one track with vocals, we create the *vocals* source by merging all the tracks with $\epsilon_\tau >= \max_\tau(\epsilon_\tau) \cdot \nu$ where ν is a tolerance value set to 0.98. All the remaining tracks are fused to define the *accompaniment*. We manually checked the resulting sources. The dataset is available at `https://zenodo.org/record/3970189`.


The second version of DALI adds the phonetic information computed for the word level [33]. This level has the words of the lyrics transcribed into a vocabulary of 39 different phoneme symbols as defined in the Carnegie Mellon Pronouncing Dictionary (CMUdict)[1]. After selecting the desired time resolution, we can derive a time frame based phoneme context activation matrix Z, which is a binary matrix that indicates the phoneme activation over time. We add an extra row with the 'non-phoneme' activation with 1 at time frames with no phoneme activation and 0 otherwise. Figure 2 illustrates the final activation matrix.

Although we work only with phonemes per word information, we can derive similar activation matrices for other context information such as notes or characters.

5. METHODOLOGY

Our method adapts the C-U-Net architecture [5] to the singing voice separation task, exploring how to use the prior knowledge defined by the phonemes to improve the vocals separation.

Input representations. Let $X \in \mathbb{R}^{T \times M}$ be the magnitude of the Short-Time Fourier Transform (STFT) with

---

Figure 2. Binary phoneme activation matrix. Note how words are represented as a bag of simultaneous phonemes.

$M = 512$ frequency bands and T time frames. We compute the STFT on an audio signal down-sampled at 8192 Hz using a window size of 1024 samples and a hop size of 768 samples. Let $Z \in \mathbb{R}^{T \times P}$ be the aligned phoneme activation matrix with $P = 40$ phoneme types and T the same time frames as in X. Our model takes as inputs two submatrix $x \in \mathbb{R}^{N \times M}$ and $z \in \mathbb{R}^{N \times P}$ of $N = 128$ frames (11 seconds) derived from X and Z.

Model. The C-U-Net model has two components (see [5] for a general overview of the architecture): a **conditioned network** that processes x and a **control mechanism** that conditions the computation with respect to z. We denote by $x_d \in \mathbb{R}^{W \times H \times C}$ the intermediate features of the **conditioned network**, at a particular depth d in the architecture. W and H represent the 'time' and 'frequency' dimension and C the number of feature channels (or feature maps). A *FiLM* layer conditions the network computation by applying an affine transformation to x_d:

$$FiLM(x_d) = \gamma_d(z) \odot x_d + \beta_d(z) \qquad (2)$$

where $\odot$ denotes the element-wise multiplication and $\gamma_d(z)$ and $\beta_d(z)$ are learnable parameters with respect to the input context z. A *FiLM* layer can be inserted at any depth of the original model and its output has the same dimension as the x_d input, i.e. $\in \mathbb{R}^{W \times H \times C}$. To perform Eqn (2), $\gamma_d(z)$ and $\beta_d(z)$ must have the same dimensionaly as x_d, i.e. $\in \mathbb{R}^{W \times H \times C}$. However, we can define them omitting some dimensions. This results in a non-matching dimensionality with x_d, solved by broadcasting (repeating) the existing information to the missing dimensions.

As in [5, 18, 34], we use the U-Net [18] as **conditioned network**, which has an encoder-decoder mirror architecture based on CNN blocks with skip connections between layers at the same hierarchical level in the encoder and decoder. Each convolutional block in the encoder halves the size of the input and doubles the number of channels. The decoder is made of a stack of transposed convolutional operation, its output has the same size as the input of the encoder. Following the original C-U-Net architecture, we insert the *FiLM* layers at each encoding block after the batch normalization and before the Leaky ReLU [5].

We explore now the different **control mechanism** we use for conditioning the U-Net.

5.1 Control mechanism for weak conditioning

Weak conditioning refers to the cases where

Model	U-Net	W_{si}	W_{co}	S_a	S_{a*}	S_c	S_{c*}	S_f	S_{f*}	S_s	S_{s*}
θ	$9.83 \cdot 10^6$	$+14,060$	$+2.35 \cdot 10^6$	$+1.97 \cdot 10^6$	$+327,680$	$+80,640$	$+40,960$	$+40,320$	$+640$	$+480$	$+80$

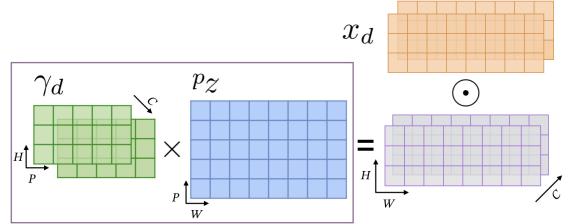
Table 1. Number of parameters (θ) for the different configurations. We indicate increment to the U-Net architecture.

- $\gamma_d(z)$ and $\beta_d(z) \in \mathbb{R}^1$: they are scalar parameters applied independently of the times W, the frequencies H and the channel C dimensions. They depend only on the depth d of the layer within the network [5].

- $\gamma_d(z)$ and $\beta_d(z) \in \mathbb{R}^C$: this is the original configuration proposed by [17] with different parameters for each channel $c \in 1, ..., C$.

We call them *FiLM simple* (W_{si}) and *FiLM complex* (W_{co}) respectively. Note how they apply the same transformation without explicitly informing where it occurs in the signal (same value over the dimension W and H).

Starting from the context matrix $z \in \mathbb{R}^{N \times P}$, we define the **control mechanism** by first apply the autopool layer proposed by [35] [2] to reduce the input matrix to a timeless vector. We then fed this vector into a dense layer and two dense blocks each composed by a dense layer, 50% dropout and batch normalization. For *FiLM simple*, the number of units of the dense layers are 32, 64 and 128. For *FiLM simple*, they are 64, 256 and 1024. All neurons have ReLU activations. The output of the last block is then used to feed two parallel and independent dense layer with linear activation which outputs all the needed $\gamma_d(z)$ and $\beta_d(z)$. While for the *FiLM simple* configuration we only need 12 γ_d and β_d (one γ_d and β_d for each of the 6 different encoding blocks) for the *FiLM complex* we need 2016 (the encoding blocks feature channel dimensions are 16, 32, 64, 128, 256 and 512, which adds up to 1008).

### 5.2 Control mechanism for strong conditioning


In this section, we extend the original *FiLM* layer mechanism to adapt it to the strong conditioning scenario.

The context information represented in the input matrix z describes the presence of the phonemes $p \in \{1, \ldots, P\}$ over time $n \in \{1, \ldots N\}$. As in the popular Non-Negative Matrix factorization [36] (but without the non-negativity constraint), our idea is to represent this information as the product of tensors: an activation and two basis tensors.

The **activation tensor** z_d indicates which phoneme occurs at which time: $z_d \in \mathbb{R}^{W \times P}$ where W is the dimension which represents the time at the current layer d (we therefore need to map the time range of z to the one of the layer d) and P the number of phonemes.

The **two basis tensors** γ_d and $\beta_d \in \mathbb{R}^{H \times C \times P}$ where H is the dimension which represents the frequencies at the current layer d, C the number of input channels and P the number of phonemes. In other words, each phoneme p is represented by a matrix in $\mathbb{R}^{H \times C}$ derived from Eqn (1). This matrix represents the specific conditioning to apply

Figure 3. Strong conditioning example with $(\gamma_d \times z_d) \odot x_d$. The phoneme activation z_d defines how the basis tensors (γ_d) are employed for performing the conditioning on x_d.

to x_d if the phoneme exists (see Figure 3). These matrices are learnable parameters (neurons with linear activations) but they do not depend on any particular input information (at a depth d they do not depend on x nor z), they are rather "activated" by z_d at specific times. As for the 'weak'conditionning, we can define different versions of the tensors

- the **all-version** (S_a) described so far with three dimensions: $\gamma_d, \beta_d \in \mathbb{R}^{H \times C \times P}$

- the **channel-version** (S_c): each phoneme is represented by a vector over input channels (therefore constant over frequencies): $\gamma_d, \beta_d \in \mathbb{R}^{C \times P}$

- the **frequency-version** (S_f): each phoneme is represented by a vector over input frequencies (therefore constant over channels): $\gamma_d, \beta_d \in \mathbb{R}^{H \times P}$

- the **scalar-version** (S_s): each phoneme is represented as a scalar (therefore constant over frequencies and channels): $\gamma_d, \beta_d \in \mathbb{R}^P$

The global conditioning mechanism can then be written as

$$FiLM(x_d, z_d) = (\gamma_d \times z_d) \odot x_d + (\beta_d \times z_d) \quad (3)$$

where $\odot$ is the element-wise multiplication and $\times$ the matrix multiplication. We broadcast γ_d and β_d for missing dimensions and transpose them properly to perform the matrix multiplication. We test two different configurations: inserting FiLM at each encoder block as suggested in [5] and inserting FiLM only at the last encoder block as proposed at [3]. We call the former 'complete' and the latter 'bottleneck' (denoted with $*$ after the model acronym). We resume the different configurations at Table 1.

6. EXPERIMENTS

DATA. We split DALI into three sets according to the normalized agreement score η presented in [31] (see Table 2). This score provides a global indication of the global alignment correlation between the annotations and the vocal activity.

---

[2] The auto-pool layer is a tuned soft-max pooling that automatically adapts the pooling behavior to interpolate between mean and max-pooling for each dimension

Table 4. Median performance in dB of the different models on the DALI test set. In bold are the results that significantly improve over the U-Net (p < 0.001) and inside the circles the best results for each metric.

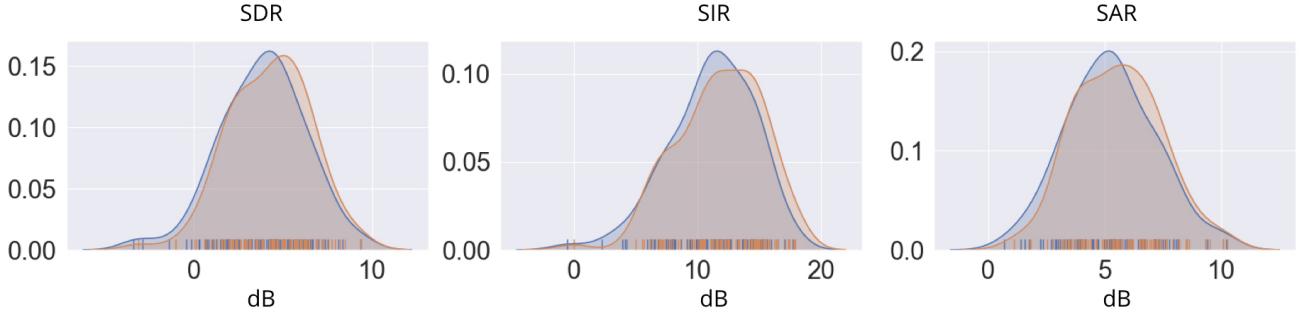
DETAILS. We train the model using batches of 128 spectrograms randomly drawn from the training set with 1024 batches per epoch. The loss function is the mean absolute error between the predicted vocals (masked input mixture) and the original vocals. We use a learning rate of 0.001 and the reduction on plateau and early stopping callbacks evaluated on the validation set, using patience of 15 or 30 respectively and a min delta variation for early stopping to $1e-5$. Our output is a Time/Frequency mask to be applied to the magnitude of the input STFT mixture. We use the phase of the input STFT mixture to reconstruct the waveform with the inverse STFT algorithm.

For the strong conditioning, we apply a `softmax` on the input phoneme matrix z over the phoneme dimension P to constrain the outputs to sum to 1, meaning it lies on a simplex, which helps in the optimization.

6.1 Evaluation metrics

We evaluate the performances of the separation using the mir evaltoolbox [37]. We compute three metrics: Source-to-Interference Ratios (SIR), Source-to-Artifact Ratios (SAR), and Source-to-Distortion Ratios (SDR) [38]. In practice, SIR measures the interference from other sources, SAR the algorithmic artifacts introduce in the process and SDR resumes the overall performance. We obtain them globally for the whole track. However, these metrics are ill-defined for silent sources and targets. Hence, we compute also the Predicted Energy at Silence (PES) and Energy at Predicted Silence (EPS) scores [10]. PES is the mean of the energy in the predictions at those frames with silent target and EPS is the opposite, the mean of the target energy of all frames with silent prediction and non-silent target. For numerical stability, in our implementation, we add a small constant $\epsilon = 10^{-9}$ which results in a lower boundary of the metrics to be -80 dB [3]. We consider as silent segments those that have a total sum of less than -25 dB of the maximum absolute in the audio. We report the **median** values of these metrics over the all tracks in the DALI test set. For SIR, SAR, and SDR larger values indicate better performance, for PES and EPS smaller values, mean better performance.

6.2 Data augmentation

Similarly as proposed in [39], we randomly created 'fake' input mixtures every 4 real mixtures. In non-augmented training, we employ the mixture as input and the vocals as a target. However, this does not make use of the accompaniment (which is only employed during evaluation). We can integrate it creating 'fake' inputs by automatically mixing (mixing meaning simply adding) the target vocals to a random sample accompaniment from our training set.


We test the data augmentation process using the standard U-Net architecture to see whether it improves the performance (see Table 3). We train two models on DALI and Musdb18 dataset [40] [3]. This data augmentation enables models to achieve better SDR and SAR but lower SIR. Our best results (4.96 db SDR) are not state-of-the-art where the best-performing models on Musdb18 achieve (approximately 6.60 db SDR) [41].

This technique does not reflect a large improvement when the model trained on DALI is tested on DALI. However, when this model is tested on Musdb18, it shows a better generalization (we have not seen any song of Musidb18 during training) than the model without data augmentation (we gain 0.36 dB). One possible explanation for not having a large improvement on DALI testset is the larger size of the test set. It also can be due to the fact that vocal targets in DALI still contain leaks such as low volume music accompaniment that come from the singer headphones. We adopt this technique for training all the following models.

Finally, we confirmed a common belief that training with a large dataset and clean separated sources improves the separation over a small dataset [42]. Both models trained on DALI (with and without augmentation) improve the results obtained with the models trained on Musdb18.

Since we cannot test the conditioning versions on Musdb (no aligned lyrics), the results on the DALI test (4.05 dB SDR) serves as a baseline to measure the contribution of the conditioning techniques (our main interest).

---

[3] We use 10 songs of the training set for the early stopping and reduction on plateau callbacks

Figure 4. Distribution of scores for the the standar U-Net (Blue) and S_s (Orange).

7. RESULTS

We report the median source separation metrics (SDR, SAR, SIR, PES, ESP) in Table 4. To measure the significance of the improvement differences, we performed a paired t-test between each conditioning model and the standard U-Net architecture, the baseline. This test measures (p-value) if the differences could have happened by chance. A low p-value indicates that data did not occur by chance. As expected, there is a marginal (but statistical significance) improvement over most of the proposed methods, with a generalized $p < 0.001$ for the SDR, SIR, and PES, except for the versions where the basis tensors have a 'frequency' H dimension. This is an expected result since when singing, the same phoneme can be sung at different frequencies (appearing at many frequency positions in the feature maps). Hence, these versions have difficulties to find generic basis tensors. This also explains why the 'bottleneck' versions (for both S_{f*} and S_{a*}) outperforms the 'complete' while this is not the case for the other versions. Most versions also improve the performance on silent vocal frames with a much lower PES. However, there is no difference in predicting silence at the right time (same EPS). The only metric that does not consistently improve is SAR, which measures the algorithmic artifacts introduced in the process. Our conditioning mechanisms can not reduce the artifacts that seem more dependent on the quality of the training examples (it is the metric with higher improvement in the data augmentation experiment Table 3). Figure 4 shows a comparison with the distribution of SDR, SIR, and SAR for the best model S_s and the U-Net. We can see how the distributions move toward higher values.

One relevant remark is the fact that we can effectively control the network with just a few parameters. S_s just adds 480 (or just 80 for S_{s*}) new learnable parameters and have significantly better performance than S_a that adds $1.97 \cdot 10^6$. We believe that the more complex control mechanisms tend to find complex basis tensors that do not generalize well. In our case, it is more effective to perform a simple global transformation. In the case of weak conditioning, both models behave similarly although W_{si} has $1.955 \cdot 10^6$ fewer parameters than W_{co}. This seems to indicate that controlling channels is not particularly relevant.

Regarding the different types of conditioning, when repeating the paired t-test between weak and strong models only S_s outperforms the weak systems. We believe that

strong conditioning can lead to higher improvements but several issues need to be addressed. First, there are misalignments in the annotations that force the system to perform unnecessary operations which damages the computation. This is one of the possible explanations of why models with fewer parameters perform better. They are forced to find more generic conditions. The weak conditioning models are robust to these problems since they process z and compute an optimal modification for a whole input patch (11s). We also need to "disambiguate" the phonemes inside words since they occur as a bag of phonemes at the same time (no individual onsets per phonemes inside one word, see Figure 2). This prevents strong conditioning models to properly learn the phonemes in isolation, instead, they consider them jointly with the other phonemes.

8. CONCLUSIONS

The goal of this paper is twofold. First, to introduce a new multimodal multitrack dataset with lyrics aligned in time. Second, to improve singing voice separation using the prior knowledge defined by the phonetic characteristics. We use the phoneme activation as side information and show that it helps in the separation.

In future works, we intend to use other prior aligned knowledge such as vocal notes or characters also defined in DALI . Regarding the conditioning approach and since it is transparent to the conditioned network, we are determined to explore recent state-of-the-art source separation methods such as Conv-Tasnet [43]. The current formalization of the two basis tensors γ_d and β_d does not depend on any external factor. A way to exploit a more complex control mechanisms is to make these basis tensors dependent on the input mixture x which may add additional flexibility. Finally, we plan to jointly learn how to infer the alignment and perform the separation [44, 45].

The general idea of lyrics-informed source separation leaves room for many possible extensions. The present formalization relies on time-aligned lyrics which is not the real-world scenario. Features similar to the phoneme activation [46, 47] can replace them or be used to align the lyrics as a pre-processing step. This two options adapts the current system to the real-world scenario. These features can also help in properly placing and disambiguating the phonemes of a word to improve the current annotations.

ABSTRACT

A major bottleneck in the evaluation of music generation is that music appreciation is a highly subjective matter. When considering an average appreciation as an evaluation metric, user studies can be helpful. The challenge of generating personalized content, however, has been examined only rarely in the literature. In this paper, we address generation of personalized music and propose a novel pipeline for music generation that learns and optimizes user-specific musical taste. We focus on the task of symbol-based, monophonic, harmony-constrained jazz improvisations. Our personalization pipeline begins with BebopNet, a music language model trained on a corpus of jazz improvisations by Bebop giants. BebopNet is able to generate improvisations based on any given chord progression[1] . We then assemble a personalized dataset, labeled by a specific user, and train a user-specific metric that reflects this user's unique musical taste. Finally, we employ a personalized variant of beam-search with BebopNet to optimize the generated jazz improvisations for that user. We present an extensive empirical study in which we apply this pipeline to extract individual models as implicitly defined by several human listeners. Our approach enables an objective examination of subjective personalized models whose performance is quantifiable. The results indicate that it is possible to model and optimize personal jazz preferences and offer a foundation for future research in personalized generation of art. We also briefly discuss opportunities, challenges, and questions that arise from our work, including issues related to creativity.

1. INTRODUCTION

Since the dawn of computers, researchers and artists have been interested in utilizing them for producing different forms of art, and notably for composing music [1]. The explosive growth of deep learning models over the past several years has expanded the possibilities for musical generation, leading to a line of work that pushed forward the state-of-the-art [2–6]. Another recent trend is the development and offerings of consumer services such as Spotify, Deezer and Pandora, aiming to provide personalized streams of existing music content. Perhaps the crowning achievement of such personalized services would be for the content itself to be generated explicitly to match each individual user's taste. In this work we focus on the task of generating user personalized, monophonic, symbolic jazz improvisations. To the best of our knowledge, this is the first work that aims at generating personalized jazz solos using deep learning techniques.

The common approach for generating music with neural networks is generally the same as for language modeling. Given a context of existing symbols (e.g., characters, words, music notes), the network is trained to predict the next symbol. Thus, once the network learns the distribution of sequences from the training set, it can generate novel sequences by sampling from the network output and feeding the result back into itself. The products of such models are sometimes evaluated through user studies (crowd-sourcing). Such studies assess the quality of generated music by asking users their opinion, and computing the mean opinion score (MOS). While these methods may measure the overall quality of the generated music, they tend to average-out evaluators' personal preferences. Another, more quantitative but rigid approach for evaluation of generated music is to compute a metric based on musical theory principles. While such metrics can, in principle, be defined for classical music, they are less suitable for jazz improvisation, which does not adhere to such strict rules.

To generate personalized jazz improvisations, we propose a framework consisting of the following elements: (a) BebopNet: jazz model learning; (b) user preference elicitation; (c) user preference metric learning; and (d) optimized music generation via planning.

As many jazz teachers would recommend, the key to attaining great improvisation skills is by studying and emulating great musicians. Following this advice, we train BebopNet, a harmony-conditioned jazz model that composes entire solos. We use a training dataset of hundreds of professionally transcribed jazz improvisations performed by saxophone giants such as Charlie Parker, Phil Woods and

---

[1] Supplementary material and numerous MP3 demonstrations of jazz improvisations of jazz standards and pop songs generated by BebopNet are provided in `https://shunithaviv.github.io/bebopnet`.

Figure 1. A short excerpt generated by BebopNet.

Cannonball Adderley (see details in Section 4.1.1). In this dataset, each solo is a monophonic note sequence given in symbolic form (MusicXML) accompanied by a synchronized harmony sequence. After training, BebopNet is capable of generating high fidelity improvisation phrases (this is a subjective impression of the authors). Figure 1 presents a short excerpt generated by BebopNet.

Considering that different people have different musical tastes, our goal in this paper is to go beyond straightforward generation by this model and optimize the generation toward personalized preferences. For this purpose, we determine a user's preference by measuring the level of their satisfaction throughout the solos using a digital variant of continuous response interface (CRDI) [7]. This is accomplished by playing, for the user, computer-generated solos (from the jazz model) and recording their good/bad feedback in real time throughout each solo. Once we have gathered sufficient data about the user's preferences, consisting of two aligned sequences (for the solos and feedback), we train a user preference metric in the form of a recurrent regression model to predict this user's preferences. A key feature of our technique is that the resulting model can be evaluated *objectively* using hold-out user preference sequences (along with their corresponding solos). A big hurdle in accomplishing this step is that the signal elicited from the user is inevitably extremely noisy. To reduce this noise, we apply selective prediction techniques [8, 9] to distill cleaner predictions from the user's preference model. Thus, we allow this model to abstain whenever it is not sufficiently confident. The fact that it is possible to extract a human continuous response preference signal on musical phrases and use it to train (and test) a model with non-trivial predictive capabilities is interesting in itself (and new, to the best of our knowledge).

Equipped with a personalized user preference metric (via the trained model), in the last stage we employ a variant of beam-search [10], to generate optimized jazz solos from BebopNet. For each user, we apply the last three stages of this process where the preference elicitation stage takes several hours of tagging per user. We applied the proposed pipeline on four users, all of whom are amateur jazz musicians. We present numerical analysis of the results showing that a personalized metric can be trained and then used to optimize solo generation.

To summarize, our contributions include: (1) a useful monophonic neural model for general jazz improvisation within any desired harmonic context; (2) a viable methodology for eliciting and learning high resolution human preferences for music; (3) a personalized optimization process of jazz solo generation; and (4) an objective evaluation method for subjective content and plagiarism analysis for the generated improvisations.

2. RELATED WORK

Many different techniques for algorithmic musical composition have been used over the years. For example, some are grammar-based [11], rule-based [1, 12], use Markov chains [13–15], evolutionary methods [16, 17] or neural networks [18–20]. For a comprehensive summary of this broad area, we refer the reader to [21]. Here we confine the discussion to closely related works that mainly concern jazz improvisation using deep learning techniques over symbolic data. In this narrower context, most works follow a generation by prediction paradigm, whereby a model trained to predict the next symbol is used to greedily generate sequences. The first work on blues improvisation [22] straightforwardly applied long short-term memory (LSTM) networks on a small training set. While their results may seem limited at a distance of nearly two decades [2], they were the first to demonstrate long-term structure captured by neural networks.

One approach to improving a naïve greedy generation from a jazz model is by using a mixture of experts. For example, Franklin et al. [23] trained an ensemble of neural networks were trained, one specialized for each melody, and then selected from among them at generation time using reinforcement learning (RL) utilizing a handcrafted reward function. Johnson et al. [24] generated improvisations by training a network consisting of two experts, each focusing on a different note representation. The experts were combined using the technique of product of experts [25] [3]. Other remotely related non-jazz works have attempted to produce context-dependent melodies [2, 3, 5, 26–30].

A common method for collecting continuous measurements from human subjects listening to music is the continuous response digital interface (CRDI), first reported by [7]. CRDI has been successful in measuring a variety of signals from humans such as emotional response [31], tone quality and intonation [32], beauty in a vocal performance [33], preference for music of other cultures [34] and appreciation of the aesthetics of jazz music [35]. Using CRDI, listeners are required to rate different elements of the music by adjusting a dial (which looks similar to a volume control dial present on amplifiers).

3. PROBLEM STATEMENT

We now state the problem in mathematical terms. We denote an input $x_t = (s_t, c_t)$ consisting of a note s_t and its context c_t. Each note $s_t \in \mathcal{S}$, in turn, consists of a pitch and a duration at index t and $\mathcal{S}$ represents a predefined set of pitch-duration combinations (i.e., notes). The context $c_t \in \mathcal{C}$ represents the chord that is played with note s_t, where $\mathcal{C}$ is the set of all possible chords. The context may contain additional information such as the offset of the note within a measure (see details in Section 4). Let $\mathcal{D}$ denote a training dataset consisting of M solos. Each

---

[2] Listen to their generated pieces at www.iro.umontreal.ca/~eckdoug/blues/index.html.

[3] Listen to the generated solos at www.cs.hmc.edu/~keller/jazz/improvisor/iccc2017/

solo is a sequence $X_\tau = x_1 \cdots x_\tau \in (\mathcal{S} \times \mathcal{C})^\tau$ of arbitrary length τ. In our work, these are the aforementioned jazz improvisations.

We define a context-dependent jazz model f_θ (Eq. 1), as the estimator of the probability of a note s_t given the sequence of previous inputs X_{t-1} and the current context c_t, where θ are the parameters of the model. This is similar to a human jazz improviser who is informed of the chord over which his next note will be played.

$$f_\theta(X_{t-1}, c_t) = Pr(s_t | X_{t-1}, c_t) \qquad (1)$$

For any solo X_τ, we also consider an associated sequence of annotation $Y_\tau = y_1 \cdots y_\tau \in \mathcal{Y}^\tau$. An annotation $y_t \in \mathcal{Y}$ represents the quality of the solo up to point t by some metric. In our case, y_t may be a measure of preference as indicated by a user or a score measuring harmonic compliance. Let $\widetilde{\mathcal{D}}$ denote a training dataset consisting of N solos. Each solo X_τ of arbitrary length τ is labeled with a sequence Y_τ. Given $\widetilde{\mathcal{D}}$, we define a metric g_ϕ (Eq. 2) to predict y_τ given a sequence of inputs X_τ. g_ϕ is the user-preference model and ϕ are the learned parameters.

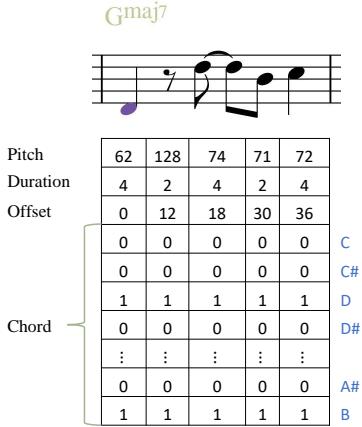
$$\hat{y}_\tau = g_\phi(X_\tau) \qquad (2)$$

We denote by ψ a function that is used to sample notes from f_θ to generate solos. In our case, this will be our beam-search variant. The objective here is to train viable models, f_θ and g_ϕ, and then to use ψ to sample solos from f_θ while maximizing g_ϕ.

4. METHODS

In this section we describe the methods used and implementation details of our personalized generation pipeline.

4.1 BebopNet: Jazz Model Learning

In the first step of our pipeline, we use supervised learning to train BebopNet, a context-dependent jazz model f_θ from a given corpus of transcribed jazz solos.


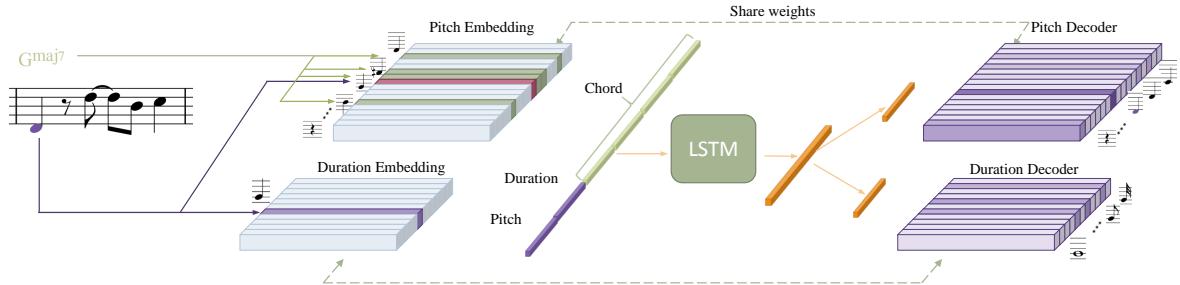
4.1.1 Dataset and music representation

Our corpus $\mathcal{D}$ consists of 284 professionally transcribed solos of (mostly) Bebop saxophone players of the early 20th century. These are Charlie Parker, Sonny Stitt, Cannonball Adderley, Dexter Gordon, Sonny Rollins, Stan Getz, Phil Woods and Gene Ammons. We consider only solos that are in 4/4 metre and include chords in their transcription. The solos are provided in musicXML format. As opposed to MIDI, this format allows the inclusion of chord symbols[4]. We represent notes using a representation method inspired by sheet music (see Figure 2).
Pitch The pitch is encoded as a one-hot vector of size 129. Indices 0—127 match the pitch range of the MIDI standard.[5] Index 128 corresponds to the *rest* symbol.

---

[4] The solos were purchased from SaxSolos.com [36]; we are thus unable to publish them. Nevertheless, in the supplementary material we provide a complete list of solos used for training, which are available from the above vendor.

[5] The notes appearing in the corpus all belong to a much smaller range; however, the MIDI range standard was maintained for simplicity.

Figure 2. An example of a measure in music notation and its vector representation. Integers are converted to one-hot representations.


Duration The duration of each note is encoded using a one-hot vector consisting of all the existing durations in the dataset. Durations smaller than $1/24$ are removed.
Offset The offset of the note lies within the measure and is quantized to 48 "ticks" per (four-beat) measure. This corresponds to a duration of 1/12 of a beat. This is similar to the learned positional-encoding used in translation [37].
Chord The chord is represented by a four-hot vector of size 12, representing the 12 possible pitch classes to appear in a chord. As common in jazz music, unless otherwise noted, we assume that chords are played using their 7th form. Thus, the chord pitches are usually the 1st, 3rd, 5th, and 7th degrees of the root of the chord. This chord representation allows the flexibility of representing rare chords such as sixth, diminished and augmented chords.

4.1.2 Network Architecture

BebopNet, as many language models, can be implemented using different architectures such as recurrent neural networks (RNNs), convolutional networks (CNNs) [5, 26, 38] or attention-based models [39]. BebopNet contains a three-layer LSTM network [40]. Recent promising results with attention based models enabled us to improve BebopNet by replacing the LSTM with Transformer-XL [41]. The architecture of the network used to estimate f_θ is illustrated in Figure 3. The network's input x_t includes the note s_t (pitch and duration) and context c_t (offset and chord). The pitch, duration and offset are each represented by learned embedding layers. The chord is encoded by using the embedding of the pitches comprising it. While notes at different octaves have different embeddings, the chord pitch embeddings are always taken from the octave in which most notes in the dataset reside. This embedded vector is passed to the LSTM network. The LSTM output is then passed to two heads. Each head consists of two fully-connected layers with a sigmoid activation in-between. The output of the first layer is the same size as the embedding of the pitch (or duration), and the second output size is the number of possible pitches (or durations).

Figure 3. The BebopNet architecture for the next note prediction. Each note is represented by concatenating the embeddings of the pitch (red bar), the duration (purple bar) and the four pitches comprising the current chord (green bars). The output of the LSTM is passed to two heads (orange bars), one the size of the pitch embedding (top) and the other the size of the duration embedding (bottom).

Following [42, 43], we tie the weights of the final fully-connected layers to those of the embedding. Finally, the outputs of the two heads pass through a softmax layer and are trained to minimize the negative log-likelihood of the corpus. To enrich our dataset while encouraging harmonic context dependence, we augment our dataset by transposing to all 12 keys.

4.2 User Preference Elicitation

Using BebopNet, we created a dataset to be labeled by users, consisting of 124 improvisations. These solos were divided into three groups of roughly the same size: solos from the original corpus, solos generated by BebopNet over jazz standards present in the training set, and generated solos over jazz standards not present in the training set. The length of each solo is two choruses, or twice the length of the melody. For each standard, we generated a backing track in MP3 format that includes a rhythm section and a harmonic instrument to play along the improvisation using Band-in-a-Box [44]. This dataset amounts to approximately five hours of played music.

We created a system inspired by CRDI that is entirely digital, replacing the analog dial with strokes of a keyboard moving a digital dial. A figure of our dial is presented in the supplementary material. While the original CRDI had a range of 255 values, our initial experiments found that quantizing the values to five levels was easier for users. We recorded the location of the dial at every time step and aligned it to the note being played at the same moment.

4.3 User Preference Metric Learning

In the user preference metric learning stage we again use supervised learning to train a metric function g_ϕ. This function should predict user preference scores for any solo, given its harmonic context. During training, for each sequence X_τ we estimate y_τ, corresponding to the label the user provided for the last note in the sequence. We choose the last label of the sequence, rather than the mode or mean, because of delayed feedback. During the user elicitation step, we noticed that when a user decides to change the position of the dial, it is because he has just heard a sequence of notes that he considers to be more (or less)

pleasing than those he heard previously. Thus, the label indicates the preference of the past sequence. The labels are linearly scaled down to the range $[-1, 1]$. Since the data in $\widetilde{\mathcal{D}}$ is small and unbalanced, we use stratified sampling over solos to divide the dataset into training and validation sets. We then use bagging to create an ensemble of five models for the final estimate.

4.3.1 Network Architecture

We estimate the function g_ϕ using transfer learning from BebopNet. The user preference model consists of the same layers as BebopNet without the final fully-connected layers. Next, we apply scaled dot-product attention [45] over τ time steps followed by fully-connected and tanh layers. The transferred layers are initialized using the weights θ of BebopNet. Furthermore, the weights of the embedding layers are frozen during training.

4.3.2 Selective Prediction

To elevate the accuracy of g_ϕ, we utilize selective prediction whereby we ignore predictions whose confidence is too low. We use the prediction magnitude as a proxy for confidence. Given confidence threshold parameters, $\beta_1 < 0, \beta_2 > 0$, we define $g'_{\phi,\beta_1,\beta_2}(X_t^i)$ in Eq. 3.

$$g'_{\phi,\beta_1,\beta_2}(X_t^i) = \begin{cases} 0 & \text{if } \beta_1 < g_\phi(X_t^i) < \beta_2 \\ g_\phi(X_t^i) & \text{else} \end{cases} \quad (3)$$

The parameters β_1 and β_2 change our coverage rate and are determined by minimizing error (risk) on the risk-coverage plot along a predefined coverage contour. More details are given in Section 5.2.

4.4 Optimized Music Generation

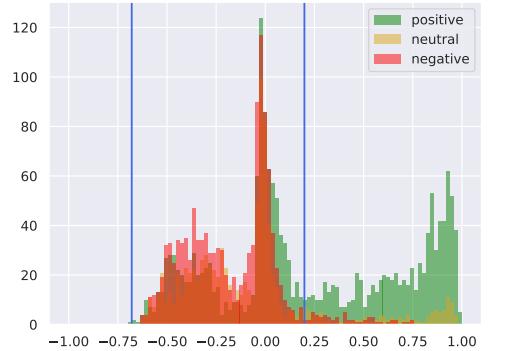
To optimize generations from f_θ, we apply a variant of beam-search, ψ, whose objective scores are obtained from non-rejected predictions of g_ϕ. Pseudocode of the ψ procedure is presented in the supplementary material. We denote by $V_b = [X_t^1, X_t^2, ..., X_t^b]$ a running batch (beam) of size (beam-width) b containing the most promising candidate sequences found so far by the algorithm. The sequences are all initialized with the starting input sequence. In our

Name	Adderley	Gordon	Getz	Parker	Rollins	Stitt	Woods	Ammons	**BebopNet (Heard)**	**BebopNet (Unheard)**
Chord	0.50	0.54	0.53	0.52	0.52	0.53	0.50	0.54	**0.53**	**0.52**
Scale	0.78	0.83	0.81	0.80	0.81	0.83	0.78	0.83	**0.82**	**0.81**

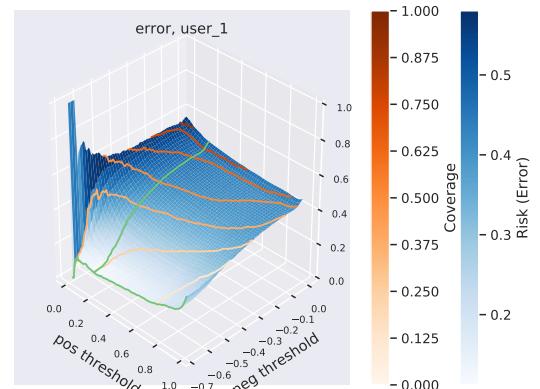
Table 1. Harmonic coherence: The average chord and scale matches computed for artists in the dataset and for BebopNet. A higher number indicates a high coherency level. BebopNet is measured separately for harmonic progressions heard and not heard in the training dataset.

case, this is the melody of the jazz standard. At every time step t, we produce a probability distribution of the next note of every sequence in V_b by passing the b sequences through the network $f_\theta(X_t^i, c_{t+1}^i)$. As opposed to typical applications of beam-search, rather than choosing the most probable notes from $Pr(s_{t+1}|X_t^i, c_{t+1}^i)$, we independently and randomly sample them. We then calculate the score of the extended candidates using the preference metric, g_ϕ.

Every δ steps, we perform a beam update process. We choose the highest scoring k sequences calculated by g_ϕ. Then we duplicate these sequences b/k times to maintain a full beam of b sequences. Choosing different values of δ allows us to control a horizon parameter, which facilitates longer term predictions when extending candidate sequences in the beam. The use of larger horizons may lead to sub-optimal optimization but increases variability.

5. EXPERIMENTS


We start the experimental process by training BebopNet as described in Section 4. After training, we use BebopNet to generate multiple solos over different jazz standards[6]. To verify that BebopNet can generalize to harmonic progressions of different musical genres, we also generate improvisations over pop songs (see supplementary material).

This section has two sub-sections. First, we evaluate BebopNet in terms of harmonic coherence (5.1). Next, we present an analysis of our personalization process (5.2). All experiments were performed on desktop computers with a single Titan X GPU. Hyperparameters are provided in the supplementary material.


5.1 Harmonic Coherence

We begin by evaluating the extent to which BebopNet was able to capture the context of chords, which we term *harmonic coherence*. We define two harmonic coherence metrics using either scale match or chord match. These metrics are defined as the percent of time within a measure where notes match pitches of the scale or the chord being played, respectively. We rely on a standard definition of matching scales to chords using the chord-scale system [46]. While most notes in a solo should be harmonically coherent, some non-coherent notes are often incorporated. Common examples of their uses are chromatic lines, approach notes and enclosures [47]. Therefore, as we do not expect a perfect harmonic match according to pure music rules, we

take as a baseline the average matching statistics of these quantities for each jazz artist in our dataset. The harmonic coherence statistics of BebopNet are computed over the dataset used for the preference metric learning (generated by BebopNet), which also includes chord progressions not heard during the jazz modeling stage. The baselines and results are reported in Table 1. It is evident that our model exhibits harmonic coherence in the 'ballpark' of the jazz artists even on chord progressions not previously heard.

i Histogram of predictions

ii Risk-coverage plot

Figure 4. 4i Predictions of the preference model on sequences from a validation set. Green: sequences labeled with a positive score ($y_\tau > 0$); yellow: neutral ($y_\tau = 0$); red: negative ($y_\tau < 0$). The blue vertical lines indicate thresholds β_1, β_2 used for selective prediction. 4ii Risk-coverage plot for the predictions of the preference model. β_1, β_2 (green lines) are defined to be the thresholds that yield a minimum error on the contour of 25% coverage.

---

[6] To appreciate the diversity of BebopNet, listen to seven solos generated for user-4 for the tune Recorda-Me in the supplementary material.

5.2 Analyzing Personalized Models

We applied the proposed pipeline to generate personalized models for each of the four users, all amateur jazz musicians. All users listened to the same training dataset of solos to create their personal metric (see Section 4). Each user provided continuous feedback for each solo using our CRDI variant. In this section, we describe our evaluation process for user-1. The evaluation results for the rest of the users are presented in the supplementary material.

We analyze the quality of our preference metric function g_ϕ by plotting a histogram of the network's predictions applied on a validation set. Consider Figure 4i. We can crudely divide the histogram into three areas: the right-hand side region corresponds to mostly positive sequences predicted with high accuracy; the center region corresponds to high confusion between positive and negative; and the left one, to mostly negative sequences predicted with some confusion. While the overall error of the preference model is high (0.4 MSE where the regression domain is [-1,1]), it is still useful since we are interested in its predictions in the positive (green) spectrum for the forthcoming optimization stage. While trading-off coverage, we increase prediction accuracy using selective prediction by allowing our classifier to abstain when it is not sufficiently confident. To this end, we ignore predictions whose magnitude is between two rejection thresholds (see Section 4.3.2). Based on preliminary observations, we fix the rejection thresholds to maintain 25% coverage over the validation set. In Figure 4ii we present a risk-coverage plot for user-1 (see definition in [8]). The risk surface is computed by moving two thresholds β_1 and β_2 across the histogram in Figure 4i, and at each point, for data not between the thresholds, we calculate the risk (error of classification to three categories: positive, neutral and negative) and the coverage (percent of data maintained).

We increase the diversity of generated samples by taking the score's sign rather than the exact score predicted by the preference model g_ϕ. Therefore, different positive samples are given equal score. For user-1, the average score predicted by g_ϕ for generated solos of Bebop-Net is **0.07**. As we introduce beam-search and increase the beam width, the performance increases up to an optimal point from which it decreases (see supplementary material). User-1's scores peaked at **0.8** with $b = 32, k = 8$. Anecdotally, there was one solo that user-1 felt was exceptionally good. For that solo, the model predicted the perfect score of 1. This indicates that the use of beam-search is indeed beneficial for optimizing the preference metric.

6. PLAGIARISM ANALYSIS

One major concern is the extent to which BebopNet plagiarizes. In our calculations, two sequences that are identical up to transposition are considered the same. To quantify plagiarism in a solo with respect to a set of source solos, we measure the percentage of n-grams in that solo that also appear in any other solo in the source. These statistics are also applied to any artist in our dataset to form a baseline for the typical amount of copying exhibited by humans.

Another plagiarism measurement we define is the largest common sub-sequence. For each solo, we consider the solos of other artists as the source set. Then, we average the results per artist. Also, for every artist, we compare every solo against the rest of his solos to measure self-plagiarism. For BebopNet, we quantify the plagiarism level with respect to the entire corpus. The average plagiarism level of BebopNet is 3.8. Interestingly, this value lies within the human plagiarism range found in the dataset. This indicates that BebopNet can be accused of plagiarism as much as some of the famous jazz giants. We present the extended results in the supplementary material.

7. CONCLUDING REMARKS

We presented a novel pipeline for generating personalized harmony-constrained jazz improvisations by learning and optimizing a user-specific musical preference model. To distill the noisy human preference models, we used a selective prediction approach. We introduced an objective evaluation method for subjective content and numerically analysed our proposed pipeline on four users.

Our work raises many questions and directions for future research. While our generated solos are locally coherent and often interesting/pleasing, they lack the qualities of professional jazz related to general structure such as motif development and variations. Preliminary models we have trained on smaller datasets were substantially weak. Can a much larger dataset generate a significantly better model? To acquire such a large corpus it might be necessary to abandon the symbolic approach and rely on raw audio.

Our work emphasizes the need to develop effective methodologies and techniques to extract and distill noisy human feedback that will be required for developing many personalized applications. Our proposed method raises many questions. To what extent does our metric express the specifics of one's musical taste? Can we extract precise properties from this metric? Additionally, our technique relies on a sufficiently large labeled sample to be provided by each user, a substantial effort on the user's part. We anticipate that the problem of eliciting user feedback will be solved in a completely different manner, for example, by monitoring user satisfaction unobtrusively, e.g., using a camera, EEG, or even direct brain-computer connections.

The challenge of evaluating neural networks that generate art remains a central issue in this research field. An ideal jazz solo should be creative, interesting and meaningful. Nevertheless, when evaluating jazz solos, there are no mathematical definitions for these properties—as yet. Previous works attempted to define and optimize creativity [48], but no one has yet delineated an explicit objective definition. Some of the main properties of creative performance are innovation and the generations of patterns that reside out-of-the-box— namely, the extrapolation of outlier patterns beyond the observed distribution. Present machine learning regimes, however, are mainly capable of handling interpolation tasks and not extrapolation. Is it at all possible to learn the patterns of outliers?

HOW MUSIC FANS SHAPE COMMERCIAL MUSIC SERVICES: A CASE STUDY OF BTS AND ARMY

ABSTRACT

Much of the existing research on user aspects in the music information retrieval field tends to focus on general user needs or behavior related to music information seeking, music listening and sharing, or other use of commercial music services. However, we have a limited understanding of the personal and social contexts of music fans who enthusiastically support musicians and are often avid users of commercial music services. In this study, we aim to better understand the contextual complexities surrounding music fans through a case study of the group BTS and its fan community, ARMY. In particular, we are interested in discovering factors that influence the interactions of music fans with music services, especially in the current environment where the prevalence of social media and other tools/technologies influences musical enjoyment. Through virtual ethnography and content analysis, we identified four factors that affect music fans' interactions with commercial music services: 1) perception of music genres, 2) participatory fandom, 3) desire for agency and transparency, and 4) importance of non-musical factors. The discussion of each aspect is followed by design implications for commercial music services to consider.

1. INTRODUCTION

Understanding users' motivations, needs, and behavior related to music is fundamental in designing commercial music services that will be well-received by users. Since the early 2000s, a steady stream of user studies has been conducted in the field of music information retrieval (MIR) [1]. These studies have investigated a variety of user aspects, such as their information needs and searching behavior [2], perception of music genres and moods [3], [4], and social music behavior [5], [6]. Some of these studies have focused on improving our understanding of MIR issues related to specific populations, such as youth [7], music creators [8], members of certain cultures [9], or people who use streaming, cloud, or recommender services [6], [10], [11].

One user group that has not been studied much in past MIR user studies are music fans. The term "fan," as an abbreviation for "fanatic," first appeared in a religious context in late 17th-century England, and became significant in the United States as it started to be used to describe passionate sports enthusiasts and later "dedicated audiences

for film and recorded music" [12, p.28]. Understanding what motivates and influences fans' behavior is important since they are often avid users of systems and services designed to provide access to media. Their digital touchpoints subsequently shape the design of these systems and services. While much of the current research involving user elements investigates user interactions with MIR systems and services, such as their usage of music and playlists [6], [10], [13], fewer works explore users more holistically or the characteristics of unique user groups. This work aims to fill this gap by 1) investigating the contextual factors that influence users' engagement with music services, and 2) attending more closely to music fans as an important subset of users. We conducted an empirical study of music fans to reveal the underlying motivations and reasons explaining why we see certain user behavior in commercial music services. The particular case we examined was a fandom called ARMY, consisting of supporters of the music group BTS and considered to be one of the largest pop music fandoms today [14]. BTS ARMY is an excellent case to study not only due to the sheer size of the fandom, but also because of its diversity and impact. ARMY is known to be an extremely dedicated fan base that actively participates in numerous initiatives to support BTS and relevant causes globally [15], [16].

In this paper, we aim to answer the following research questions: What does the case of BTS and ARMY tell us about the current landscape of music fans, specifically related to how they interact with commercial music services? Subsequently, what are the implications for designing and providing commercial music services for these fans?

2. RELATED WORK

2.1 Music Fans and Participatory Culture

Over the past two decades, user studies in MIR have shown that the way users interact with music has significantly changed. During this time, a majority of users moved from sharing actual music files and listening to personal collections to using streaming or subscription-based models and sharing YouTube links and music metadata [10]. Additionally, social media has become an important venue for people to share and discuss music [11]. These cultural and technological shifts have changed the ways people consume, create, and share music [17], and have altered the role of music users from passive listeners to more active participants, indicative of a larger trend in media use [18], [19]. Recent MIR user studies point out that users are not merely consumers of music but also shapers of music services. For instance, Lee and Price [20] observe that music users are getting increasingly savvy about the tools and

technologies available to them—rather than using only a single platform, music users very intentionally choose particular platforms that work well for specific purposes [10]. Contextual factors, sometimes unrelated to music itself, were also found to influence people's interaction with music services, such as their decisions about whether to listen to music recommendations [21]. These factors, of course, included reasons such as convenience or being in the mood to listen to recommendations, but interestingly, they also related to personal values. For instance, researchers learned that some participants actively "refused" to listen to certain songs based on how well their personal values aligned with those of the artist or their perception of the artist's ethical stance [21]. These findings imply the complexity of users' engagement with music services: they are often motivated by contextual factors going beyond preference for music based on musical attributes. In addition, many users have embraced participatory culture and contribute user-generated content related to music on social media, especially streaming venues like YouTube [22].

Music fans are at the center of this technological and cultural landscape and often drive trends taken up by other music users. Jenkins [18] discusses how in "convergence culture," fans play a central role in how culture operates, demonstrating the influence of an active audience in contemporary popular culture. While fandom suffered from stigma in earlier media studies, participatory culture has now become central in understanding fans and fan-based online communities in popular culture [18]. Users actively engage in online communities, produce creative works, and develop new knowledge [23], especially in the context of games [24], [25] and YouTube [26], [27]. Researchers also started investigating the participatory nature of user involvement related to music in certain contexts. For instance, Waldron [28] discusses how user-generated content in YouTube is used for music learning and teaching in online participatory communities. Schneider [22] uses qualitative media analysis to examine audience engagement with music videos on YouTube.

While it is important to understand how fans interact with music in commercial music services, it is also critical to consider the broader context in which users are situated to understand what factors may impact how they engage with commercial music services. Jenkins [23, p.7] emphasizes various aspects such as "the social, cultural, legal, political and economic institutions, practices, and protocols" that shape the communication technologies in media systems.

2.2 BTS and ARMY

Before Korean pop (Kpop) music became a global sensation, the Korean Wave, also known as "Hallyu," popularized Korean culture in media channels such as television dramas and digital games [15]. As it emerged alongside social media, Hallyu was able to reach audiences beyond East Asia including Latin America, Europe, and North America [29], [30]. While Hallyu became popular through various mediums, one of the driving forces behind its success is Kpop [15]. Artists such as Psy and BTS have collectively gained billions of views on YouTube, bringing Hallyu music fandom to North America.

BTS is a South Korean band with seven male musicians, managed by their entertainment agency, Big Hit, since June 2013. The abbreviation stands for "Bangtan Sonyeondan" or "Bulletproof Boy Scouts," which depicts the challenges that the younger generations face in modern social life [31]. A large part of BTS's success is its high engagement with fans on social media where band members share visual stories of their lives, aesthetic preferences, and commentary on their work. Tweets, Instagram posts, and other social media updates also enable fans from all over the world to connect with the band members [15].

Additionally, BTS engages with global campaigns to digitally connect with youth culture around the world. In November 2017, BTS launched a two-year anti-violence campaign called "Love Myself" in partnership with UNICEF that raised over $2,000,000 (USD) [32]. In 2018, the band delivered a speech at the United Nations General Assembly in New York to launch the "Generation Unlimited," a global partnership of UNICEF [32].

BTS's popularity has reached a global scale thanks to the unity of its fandom, ARMY, which has bonded through the band members' story of growth, authenticity, and determination to pursue musical careers. The influence of ARMY is massive in its own right [16], [33]. When the band's scheduled tour was cancelled in Korea due to COVID-19, ARMY followed the lead of one BTS member, Suga, by donating their refunds to disaster relief organization Hope Bridge—amounting to over $300,000 in just a few days [34]. In another instance, after ARMY learned that BTS and Big Hit Entertainment donated $1,000,000 to support Black Lives Matter, they organized a campaign to match the donation and raised another million dollars in a little over 24 hours [35]. The campaign is still ongoing on the One In An Army website (https://www.oneinanarmy.org/), along with many other campaigns for social good across the globe. These are just a few of numerous examples illustrating the power and impact the fandom has.

3. STUDY DESIGN AND METHODS

We employed a multimethod approach of virtual ethnography and content analysis. While traditional ethnography focuses on observing the interactions among individuals situated in a particular setting, as technologically mediated communications and online communities become ubiquitous, virtual ethnography is becoming increasingly common [36], [37]. Virtual ethnography explores social interactions taking place in virtual environments and emphasizes the immersion of the researcher in the setting for extended periods of time for a holistic understanding of the culture [38]. Beneito-Montagut [36] points out that applying physical boundaries in the context of the Internet during virtual ethnography provides limited understanding of everyday life in the Internet, as the various intersections between different sites are lost. For this reason, the researchers chose to examine multiple online websites and venues, including a swath of social media (such as Twitter, Facebook, Instagram, Reddit, and TikTok), YouTube, Daum BTS fan café, which used to be the official fan community, and Weverse, the current official channel for in-

teractions between BTS and ARMY. The first author observed the interactions among the fans for approximately a year from April 13, 2019, to March 30, 2020. During this phase, the researcher generated field notes documenting reflections and questions, while being cautious to minimize bias in collecting and interpreting the data.

In order to complement the ethnographic approach, the researchers also collected user data from Twitter and a subreddit, r/Bangtan. A total of 3,195 recent tweets (the maximum number allowed in the API policy) were pulled from the bts_twt timeline on Twitter. The tweets, along with the field notes generated from the observation phase, informed some of the prominent themes to be further investigated (e.g., streaming, radio play, award, donation). Additionally, discussion threads were scraped from r/Bangtan, and the second author, taking a deductive approach [39], qualitatively examined and coded the data into categories representing prominent themes identified in the observation phase. Here, we present selected user quotes that are helpful for discussing four aspects that commercial music services should consider to better cater to music fans.

This research investigates a single case study of BTS and its fandom, ARMY, to examine the current landscape of the music listening environment and the role of music fans in shaping it. Yin [40] describes a case study as "an empirical inquiry that investigates a contemporary phenomenon in depth and within its real-life context, especially when the boundaries between phenomenon and context are not clearly evident" (p. 18). Single case studies and multiple case studies have their own merits. While studying multiple cases may help with generalizing the data, delving deeply into a single case can provide a richer understanding of the context that is being studied. In this paper, we selectively chose to study the case of BTS and ARMY for two reasons. First, BTS/ARMY is a unique case because it demonstrates an exemplary manifestation of the fandom phenomenon—ARMY could be seen as an outstanding success as it is often characterized as the most powerful, dedicated, and organized fandom in the world [14], [41]. Second, BTS/ARMY presents a longitudinal case where a single case is examined across time to demonstrate how situations and processes change. Indepth observation of user interactions over an extended period of time and examination of artifacts on various media channels enabled the researchers to have a better understanding of how ARMY might react to certain situations due to historical reasons. The case overall serves as an excellent candidate to examine the complexity of the user's context, which affects how fans engage with commercial music services.

4. FINDINGS AND DISCUSSION

4.1 Perception of Music Genres

Kpop is a prime example of how the boundaries of music genres are becoming increasingly blurry. The hybridity of Kpop music has been noted in prior research [15] and discussed in relation to the popularity of "idol" groups, often strategically created to consist of members with different musical strengths [42]. As a result, the music they produce tends to have elements accentuating the diverse strengths

of the members, embodying a fusion of multiple music styles [42]. This is also true in the case of BTS—in a recent interview about its latest album, *Map of the Soul: 7*, one BTS member actually stated that "the genre is BTS," and "it's less and less meaningful to divide music into genres now" [43]. Fans on the BTS subreddit also discuss this genre issue, as shown in the following quotes:

""bts is the genre" wasn't them saying they're not kpop, they were saying that their music is diverse and that putting it into a box is pointless."

"I love how he tried to highlight artistry and talent instead of focusing on artificial (and unrealistic) plastic subgenres like kpop. I am one of those firm believers that kpop (much like *pop*) is not a music genre but an industry with specific practices."

Beyond discussing the specific label "Kpop," which is already problematic given that it often refers to all music originating from Korea regardless of style, users also recognize the limitation of genre labels in general. They comment on the difficulty of applying one set of genre labels, commonly used in a certain culture, to all music.

"Yoongi [one of the BTS members] *said stop limiting south korea to a single genre when genre itself is meaningless as music continues to mix and evolve and we love to see it. Let's appreciate the artist no matter the genre!"*

"I don't know of one western equivalent in terms of the genre since BTS has a lot of different styles to their music."

Considering the wide range of artists who collaborate with BTS makes the band's music further challenging to label. For instance, its recent collaborators have ranged from vocalists such as Zara Larsson and Halsey to rappers like Desiigner and Nicki Minaj, who have very different music styles.

While BTS well exemplifies how different music genres and styles can be successfully mashed up to create hybrid music styles, this trend is also becoming increasingly popular among other Kpop groups and genres of music. Hybridity, fueled by increasing global collaboration among musicians and producers around the world, is becoming more prevalent in the music industry in general. "Genres have blended together so completely and seamlessly" that it is "almost impossible to label a lot of popular music as any one thing" [44].

Design Implication: Think of alternative means to show the connections of music, rather than relying on music genres, especially genres represented in a hierarchical structure.

For MIR researchers and designers of commercial music services, the blurred boundaries of genres raise an interesting question about how to best categorize music to support and improve users' access and discovery. The limitation of genre labels has been noted in previous MIR user research, especially with regards to users' perception of genres and the lack of consistency in their description in

cross-cultural contexts [42]. The trend of hybrid genres supports the importance of exploring other metadata elements that can be used to organize music, such as mood and suitable contexts (e.g., accompanying activities, users' biological rhythm). It also highlights the limitation of a hierarchical structure in organizing music, as it becomes increasingly difficult to find a single appropriate category for these kinds of music in a tree-like structure. Rather, a faceted approach may be more suitable, in which different musical styles can be described as a collection of organized tags, which avoids the pitfall of having to categorize the music with one *correct* label. In addition, a network-based approach (such as MusicLynx (http://www.semanticaudio. ac.uk/demonstrators/16-musicweb/) or Mora-Mcginity et al. [45]) could also complement a more traditional hierarchical organizational structure, as networks can represent the relationships and influences among artists that are often meaningful to the music fans. For instance, mapping the influences between BTS and other music groups based on their collaboration would probably generate a more interesting social network for users to explore than simply categorizing the music as Kpop.

4.2 Participatory Fandom

Our observation of fan activities on social media showed that fans engage in a wide variety of activities in addition to simply listening to and enjoying music from the artists they support. These additional activities include not only appreciating non-music content related to the artists (such as documentary films or books), but also interacting with the artists and other fans through social media and offline events. For example, a substantial number of user-generated videos, featuring reactions, theory (analytical videos examining music videos or lyrics), cover dances, unboxing, lyrics, and remixing, are regularly uploaded to YouTube [16], [46]. Many fans also donate a significant amount of time and resources to helping other fans or supporting various causes that the artists support [16]. For instance, much of the BTS content is translated by fans who volunteer their time—the massive followings on translation team and individual accounts on Twitter (e.g., @BTS_Trans with 1.5 million followers; @btstranslation7 with 340,700; @doolsetbangtan with 316,600; and many more) demonstrate their impact. Yoon [46] discusses how youths took on these roles as cultural translators and how they engage transnationally with digital media.

ARMY also showcases how to effectively use social media for participatory fandom, including Twitter, Facebook, Vlive, Reddit, etc. [46]. The various streaming, donation, and hashtag campaigns in which fans participate require them to utilize these apps and services to organize. While there is an app called Weverse, established by Big Hit as the official communication channel for BTS and fans, due to the volume of daily posts and the lack of organization, it is not an effective venue for systematically organizing these efforts. Instead, it primarily serves as a venue where the artists can directly communicate with fans by sharing posts and responding to fans' posts.

While globally there is no central coordinating organization within ARMY, the fan group is still extremely successful in coordinating to support the artists despite its loose structure—for instance, there are various accounts that provide streaming guides (e.g., @AllForARMY, @BTS_graphs, @BTS_Billboard, @ARMY52Hz) that recommend strategically curated streaming lists in specific music streaming services to enhance the band's rankings in various charts [15], [16]. The big BTS Fan Twitter accounts (Twitter accounts with a lot of followers) often follow these streaming guide accounts and retweet these messages so they can quickly and efficiently reach a large number of fans. Lee [16] and Lee [33] also discuss in depth how international ARMY, coordinating its efforts on Twitter and other social media, worked systematically to translate and distribute BTS content to get BTS to debut on US radio and television by providing ARMY members with instructions for requesting BTS's songs and actions to take if a request is rejected.

Sometimes fans actively use commercial music services to make a statement—in the case of BTS, when the People's Choice Awards awarded another band Group of 2019, Music Video of 2019, and Concert of 2019 despite BTS receiving the largest number of Twitter votes in all three categories (according to data collected and tracked by accounts like @ResearchBTS), fans protested by banding together on social media and re-charting BTS's entire discography (20 albums including solo mixtapes and two Japanese repackage albums) in iTunes in less than 24 hours [47]. This happened again when BTS did not receive any Grammy nominations despite having a huge success with its *Persona: Map of the Soul* album in 2019, with the hashtag #ThisIsBTS trending in Twitter [48]. The purpose of these organized movements is partly to show support and appreciation for the artists, but also to express listeners' discontent and disapproval of outdated customs and systems, such as the management of music awards.

Design Implication: Consider ways to promote artist and fan interactions in a two-way communication model and features that can support fans' activities to achieve group goals.

The active, participatory nature of fans should prompt designers of commercial music services to think about features they might employ to support fans' activities and maintain strong communities. One idea might be to explore features within commercial music services where fans and artists can have interactions. While existing social media platforms already offer venues for artist-fan interactions and community discussions, commercial music services can offer other unique types of interactions. For instance, Spotify for Artists allows artists to put together and share their own playlist through their profile page. This enables fans to feel closer to artists they like, as they can better understand artists' tastes and know what they are currently listening to. Furthermore, this feature has an additional benefit of encouraging listeners to venture out of their typical music realm and discover new songs and artists, as prior research suggests people tend to be more receptive to music recommendations coming from people who are experts or those they trust to have good music taste [21]. One suggestion is to expand this feature by turning it into a two-way interaction, in which fans can also suggest

music to artists. We observed that this occasionally happens in social media such as Twitter or Weverse, especially when fans want the artist to collaborate with another artist. A voting mechanism could be implemented so that fans could collectively put together a playlist for the artists, which would increase user engagement and provide a sense of bonding. Another idea is to consider features that better support group activities among fans. While sharing music and playlists is already a feature in many commercial music services, tweaking these features so that they can support group goals may appeal to fans. For instance, the streaming guide account's use of playlists is unique compared with other use scenarios in that the goal is not to enable group members to collaboratively create or modify the queue. Rather, it is to effectively distribute a specific playlist—created by a small team of users—that has been deemed most efficient to support the artists. Gifting music or codes for streaming to fans who cannot afford access to music also frequently occurs within the fan community, which can potentially be supported in commercial music services.

4.3 Desire for Agency and Transparency

During our observation of ARMY's interactions in online communities and our examination of tweets and reddit posts, we noticed a strong desire among users to have more agency in how they interact with music. For many BTS fans, the act of streaming is not only to simply listen to and enjoy music but also to strategically support the artist. As discussed above, sometimes streaming can also be an act of resistance against the existing social structure and systems that fans feel are unjust. These fans' selection of music services is often driven by their desire to maximize the impact of their streaming on the rankings of artists' albums in various charts.

A recent event that well illustrates this desire for agency among fans concerns the lack of radio play BTS received in Western radio stations after the release of its latest album, *Map of the Soul: 7*. Despite the group's past success in album sales, sold-out stadium tours worldwide, and participation in various promotional events in the US organized by radio stations, BTS received almost no radio play for its latest album [49], [50]. This led to many fans speculating why, resulting in discussion of multiple factors including payola (the illegal practice of payment from record companies in exchange for more radio exposure for their artists, discussed extensively in Leight [51]), DJs' perception that ARMY consists exclusively of teenage girls, the public's perception of BTS as "foreign" artists, and xenophobia [49], [50]. While we do not have space for a full discussion of all of these factors here, what is clear is that many fans expressed frustration and actively boycotted radio, opting to use music streaming services as a result. Many believed that their participation would matter and that they would have more control over how they interacted with music on streaming services, as opposed to radio, in which gatekeepers control what is played. Fans on Bangtan subreddit share:

"Ugh it's 2020. Traditional radio just needs to die and make way for streaming. I know radio matters for charting

and GP exposure, etc but ever since we proved BTS can chart well without it, the tiny bit of interest I have in it has all but evaporated. If anything, I would rather they continue to succeed without it. Especially if getting on radio still means they have to play their ridiculous games (interviews, payola)."

"People in radio here who don't play BTS, that's why I use Spotify AND buy BTS albums. Living in the past, these radio people are. That's what Freddie Mercurys "Radio Gaga" was about. Barely anything has changed. Look, most of the world, their first language isn't English anyway. You know? Thanks to internet, people are waking up. These people in the industry continuing to sleep screams hello, boomer. They do their thing, I'll continue to support BTS."

"why is radio so important still in terms of charting, i feel my generation doesn't even listen to it in the car or whatever, we all just use our spotify etc. bc it's more personalized playlist and u don't have to sit thru annoying ads every 2 or 3 songs."

Hertweck [50] points out that "streaming's prevalence creates an avenue to success in the music industry, and artists are no longer required to rely on Big Radio to reach mainstream." In addition to streaming services' access and convenience, the desire for user agency is a critical reason why certain streaming services have become increasingly relevant and supported by users. Fans are now much more aware of potential issues that traditional media carry due to abundant information shared on social media. Furthermore, listeners now have a legitimate alternative option to support their artists and still make the impact they want by focusing "efforts on streaming and purchasing digital/physical albums to make sure that BTS charts well" [49]. Indeed, BTS's latest album debuted as number one in the US Billboard 200, with the lead single "On" debuting at number four on the Billboard Hot 100 even with almost no radio play [52]. Some fans, however, noted that Billboard also potentially made mistakes in its calculation and wanted clarification on how it arrived at the final numbers. Transparency is extremely important for these fans, as shown in the following tweets:

"I think the ranking of no. 4 is amazing, but the calculation seems very suspect. At very least, Billboard should clarify how it arrived at those numbers because they are not adding up, and it doesn't seem like they counted other streams outside of Spotify and YT. #billboardrecalculate."

"You tweeted the wrong date representing an incorrect tracking week, then made a new tweet, still claiming 18.3M US streams when the true figures show 18.9M streams in the US on Spotify and YouTube ALONE. Please hear us and recalculate @billboardcharts."

Design Implication: Recognize that users want more agency and provide transparency in how usage and popularity are measured.

Streaming services in fact benefit to some degree from fans' desire to have more agency, as fans intentionally choose streaming services over traditional models of music access like radio. Interestingly, streaming services are

also attempting to adopt a model similar to radio's as they seek to expand their revenue sources by asking artists to pay to advertise their songs within the app. Spotify's Marquee, for example, notifies listeners about new songs/albums for artists who pay $5,000 or more, but Shaw warns that "the effort is controversial because it's complicating wider talks over long-term music rights between Spotify and the record companies" [53]. As music services try to balance meeting user needs and ensuring revenues, it is difficult to say which model is in the best interests of all stakeholders. Regardless of the final decisions made by music services, at the minimum, it is important to recognize fans will continue to demand more agency, the ability to see the impact of their efforts, and transparency in how various statistics are collected and shared.

4.4 Importance of Non-musical Factors

One of the reasons for BTS's massive success is often attributed to the group's abundant visual content, such as high-quality music videos and choreography videos [31]. Music listeners' consumption and appreciation of music is changing as they consider more non-musical factors such as visual elements or information about the artists or labels when deciding what to listen to [37].

In addition to publishing various types of non-music materials, the transmedia storytelling BTS does through these different works is impressive. In order to truly understand the whole narrative created by the band, fans not only have to listen to the music and decipher the lyrics, but also connect the clues hidden in the music video, choreography, performances from concerts and award shows, and printed books and webtoons containing episodes from the fictional narrative. In fact, there are numerous "theory" videos on YouTube analyzing the music of BTS in depth, connecting the symbols embedded in various creative works and explaining the ideas behind them [31].

The visual elements that accompany music do not merely serve to enhance individuals' experiences. Prior research also shows that users watching the music videos with friends and family and engaging with other people around music videos or user-generated videos (such as reaction or theory videos) are important and memorable social experiences [44]. This community connection is also evident for many reaction videos related to BTS, as researchers have observed these videos generate substantial numbers of views and user comments.

Jenkin [24] also discusses the importance of recognizing the interrelationship among different technologies and thinking beyond the affordances of individual technologies or tools, stating:

> Rather than dealing with each new technology in isolation, we would do better to take an ecological approach, thinking about the interrelationship among different communication technologies, the cultural communities that grow up around them, and the activities they support. (p. 8)

This assertion hints at the importance of exploring how tools and technologies that were not necessarily designed to support music listening or sharing music information could be used to complement the activities in commercial music services.

Design Implication: Consider incorporating more visual and non-musical content, along with metadata pointing to related works, to promote fans' engagement.

In MIR user studies, YouTube consistently ranks very highly as the most used music service, often above services that are specifically designed for music [10], [20], [54]. While providing album art or sharing links to relevant music videos are already basic features in many existing commercial music services, we can envision more features that creatively incorporate visual elements. Spotify's Enhanced Albums (which BTS used for its *Map of the Soul: 7* album) or Pandora Stories, which allow artists to add video messages explaining the album concept, other visual materials, or voice commentaries, are good examples. These kinds of features not only enrich the music listening experience by adding a visual layer, but also provide more information about the music and the artist, which helps fans understand the context of creation and the creator's intent. One suggestion for expanding this feature is to allow users to interpret the music and related materials and share their perspectives, or share stories about what the music means to them individually, which would contribute to the sense of bonding. This currently happens mainly in Twitter, YouTube, or online forums for fans, but it could be interesting to foster the conversation within commercial music services, alongside the artist's expression of the original intention. Additionally, providing metadata that links users to related non-music materials would allow fans to more easily access a variety of materials to assist their analysis and interpretation of creative works.

5. CONCLUSION AND FUTURE WORK

In this paper, we investigated a case study of BTS and ARMY to better understand the contextual complexities that drive music fans' perceptions and behavior in commercial music services. Through a case study of BTS and its fandom, ARMY, we derived and described four design implications for commercial music services to consider.

This study examines only a single case study of BTS and ARMY; thus, there could potentially be additional factors that are missing in our discussion. As previously stated, this is an intentional methodological choice, given that the aim of the study is not to produce generalized findings, but to gain insights from a deep investigation of a highly impactful single case study to help us think about design ideas related to commercial music services.

The bonding experience created in these fan communities is increasingly important in our current situation, where most people are practicing some degree of social distancing due to COVID-19. In our future work, we plan to continue our research on fan communities and investigate the underlying social structure and practices of the ARMY fandom. Additionally, we are interested in exploring how fans are finding ways to connect with one another through music in this unprecedented situation by co-listening, participating in streaming events, and collaboratively creating and sharing playlists.

THE MIDI DEGRADATION TOOLKIT:
SYMBOLIC MUSIC AUGMENTATION AND CORRECTION

ABSTRACT

In this paper, we introduce the MIDI Degradation Toolkit (MDTK), containing functions which take as input a musical excerpt (a set of notes with pitch, onset time, and duration), and return a "degraded" version of that excerpt with some error (or errors) introduced. Using the toolkit, we create the Altered and Corrupted MIDI Excerpts dataset version 1.0 (ACME v1.0), and propose four tasks of increasing difficulty to detect, classify, locate, and correct the degradations. We hypothesize that models trained for these tasks can be useful in (for example) improving automatic music transcription performance if applied as a post-processing step. To that end, MDTK includes a script that measures the distribution of different types of errors in a transcription, and creates a degraded dataset with similar properties. MDTK's degradations can also be applied dynamically to a dataset during training (with or without the above script), generating novel degraded excerpts each epoch. MDTK could also be used to test the robustness of any system designed to take MIDI (or similar) data as input (e.g. systems designed for voice separation, metrical alignment, or chord detection) to such transcription errors or otherwise noisy data. The toolkit and dataset are both publicly available online, and we encourage contribution and feedback from the community.

1. INTRODUCTION

Music language models (MLMs) have been the subject of much research in recent years. In the most general terms, their goal is to learn the structure of a typical piece of music, usually in symbolic form, as either a piano roll or a (monophonic or polyphonic) sequence of notes. Such models can be designed either as a stand-alone system (i.e. to perform a specific task such as voice separation, metrical alignment, or chord detection), or as part of an automatic music transcription (AMT) system along with an acoustic model.

In AMT systems, MLMs have thus far led to only small increases in performance compared to state-of-the-art acoustic models by themselves [9]. One possible reason

is that such MLMs are typically run at the frame-level [1], rather than at the note-level or the beat-level [20]. Regardless, even beat- or note-level MLMs have not led to very large improvements by themselves (e.g. [19,21]). One approach to solving this issue has been proposed in [22], where a separate "blending model" is used to combine the acoustic model with the MLM. The blending model leads to a small but significant increase in performance over using the acoustic model only.

Another possible reason for their minimal improvement is that such MLMs are not directly trained to solve the task at hand—to correct errors produced by the acoustic model. That is, they are not *discriminative* models taking data with errors as input and producing the correct transcription as output. Instead, they are typically trained to model the distribution of clean (usually MIDI) data, and used to alter the probabilistic predictions of the acoustic model. The integration of such an MLM into an AMT system usually involves searching through a large space of possible output transcriptions. One potential solution to this problem (at least when using an RNN-based MLM), is to train the model with scheduled sampling [3], which uses its own (noisy) outputs during training, teaching it to recover from such mistakes. In fact, the MLM from [22] is trained using scheduled sampling. However, this training strategy is only designed to allow the MLM to recover after a mistake, rather than to recognize and correct a mistake directly.

Training a discriminative model which "cleans" the output of an acoustic model is only feasible in the presence of a dataset mapping degraded data to clean data. Whilst this dataset could be produced by running an acoustic model on a dataset mapping audio to the correct transcription, such datasets are small relative to the amount of clean MIDI data available elsewhere. Our MDTK package allows the user to take any clean data and degrade it to have musical errors of their choosing. The pool of clean MIDI data is many orders of magnitude larger than that which maps audio to transcription data. For example, MAESTRO [7] has aligned MIDI and audio data of ~1 300 performances totalling ~200 hours. In comparison, the Lakh MIDI Dataset [14] comprises ~175 000 MIDI files [2] totalling ~9 000 hours. This is over 40 times the size, and

---

[1] It is debatable as to whether frame-based models should be called "language" models, since they do not work at a step related to the language (e.g. musical notes or beats), but rather the frames of the acoustic model. However, such a distinction is not the focus of this work.

[2] The true number of files is slightly smaller than this as it is known that some of these MIDI files are corrupted.

additionally spans diverse genres. Using a dataset such Lakh MIDI, MDTK allows for the creation of datasets large enough to make the direct discriminative task feasible. In addition, as we will discuss later in Section 2.2, there is no need to restrict learning capability by explicitly creating a degraded dataset: MDTK's `Degrader` objects can be used to degrade clean input dynamically when loading it into the model, thus providing on-the-fly data augmentation, enabling the model to be trained on a degraded dataset which is essentially unlimited in size.

This process is analogous to performing learned data augmentation—MDTK makes the discriminative task of correcting errors feasible by increasing the effective size of the dataset. Data augmentation has proved essential in other fields. In [5], the authors advocate the automated application of data augmentation for the ImageNet task [6], a classification task for image data. They find that by automatically tuning the type of data augmentation they apply for each task, they can attain a significant improvement over the state-of-the-art. In [1], the authors explicitly investigate the effects of generating augmented data in low-data regimes, advocating the use of learned generators—essentially what MDTK's `Degrader` objects are—using GANs. Finally, in [17], the authors solve their low-data regime issue for environmental sound classification by using data augmentation, finding that performing augmentations such as pitch shifting and time stretching leads to a 6 percentage point boost in classification accuracy. MDTK enables similar such data augmentation techniques to be performed easily for AMT.

For non-AMT tasks, standalone MLMs typically take as input MIDI files and output some alignment or label, depending on the task. To our knowledge, the robustness of these MLMs to noisy or incorrect data is rarely if ever analysed. This is not necessarily an important factor when clean MIDI files are used as input, but when such a MIDI file is the result of noisy process such as AMT or Optical Music Recognition (OMR; e.g. [18]), a model's robustness to noise becomes an important piece of information.

We propose that both of these shortcomings—poor AMT post-processing, and that MLMs' robustness to noise has not been analysed—can be addressed using excerpts of music to which noise is added. In an AMT system, a post-processing model which is trained directly to identify and correct similar noise should be better able to correct noisy acoustic model outputs than a generic MLM. Likewise, the robustness of a standalone MLM to noisy input can be analyzed with such noisy data, allowing the MLM to be evaluated for its potential usefulness in downstream tasks such as those involved in creating a complete piece of sheet music given an audio signal.

In this paper, we introduce the MIDI Degradation Toolkit (MDTK), a set of tools to easily introduce controlled noise into excerpts automatically extracted from a set of MIDI files. MDTK is similar to the Audio Degradation Toolbox [11] for audio, but to the authors' knowledge, ours is the first toolkit of its kind for MIDI data. The controlled noise includes (1) shifting the pitch of a note; (2) lengthening, shortening, or shifting a note in time;

(3) adding or removing a note; and (4) splitting or joining notes.

We also introduce the Altered and Corrupted MIDI Excerpts dataset version 1.0 (ACME v1.0), containing MIDI excerpts which have been degraded (and some which have not been degraded) using the toolkit, and four new tasks of increasing difficulty: to (1) detect whether each excerpt has been degraded; (2) if so, classify what degradation has been applied and (3) locate where a degradation has taken place; and (4) recover the original excerpt.

We present a simple baseline model for each task and analyse its performance. These baselines are provided as an easy starting point for researchers wanting to attempt our proposed tasks or post-process their own AMT data. We provide evaluation metrics for assessment and postulate that, if high performance were achieved, we would be able to improve AMT output using models trained for these tasks. We can easily swap out ACME v1.0 for a dataset matching the errors for a specific AMT system using a provided script.

2. THE TOOLKIT

The MIDI Degradation Toolkit (MDTK) is a python package, installable with pip, which can be used to introduce errors to MIDI excerpts. The code is released open source under an MIT License, and is available online. We encourage feedback and contribution from the community in its continued development.

Internally, MDTK stores each excerpt as a set of notes in a Pandas [12] DataFrame with columns pitch (MIDI pitch, with C4=60), onset (the onset time of the note, in milliseconds), track, and dur (the duration of the note, in milliseconds), all integers. It contains functionality to load an excerpt from a MIDI file (using pretty_midi [15]), as well as to read from and write to a CSV file.

2.1 Degradations

Each degradation provided in MDTK takes as input a pandas DataFrame of an excerpt of music, and returns a DataFrame with the given degradation. Some degradations (e.g. removing a note from an empty excerpt) are not always possible. In such cases, a warning is printed and None is returned. Care is also taken to ensure that no overlaps on the same pitch are introduced by a degradation. There are a total of 8 degradations in MDTK, each of which is described below.

The `pitch_shift` degradation changes the pitch of a random note. By default, the new pitch is chosen uniformly at random from all possible pitches (a minimum and maximum pitch can be given, and the valid range defaults to 21–108 inclusive). It can also be drawn from a weighted distribution of intervals around the original pitch, for example to emphasize octave errors from overtones. We also include a flag to force the new pitch to align with the pitch of some other note in the excerpt, to reduce out-of-key shifts, if desired.

Three degradations shift a random note in time in some way: `onset_shift` changes the note's onset time, leaving its offset time unchanged; `offset_shift` changes

the note's offset time, leaving its onset time unchanged; and `time_shift` changes the note's onset and offset times by the same amount, leaving its duration unchanged. For all of these degradations, care is taken to ensure that the shifted note does not lie outside the excerpt's initial time range. A minimum and maximum resulting duration can be specified, as well as a minimum and maximum shift amount. We also include flags to align some combination of the shifted note's onset or duration with those of other notes from the excerpt, ensuring the note lies on some metrical grid, if desired.

Two degradations can be used to either add a random note to an excerpt (`add_note`), or remove a random note from an excerpt (`remove_note`). Flags to align an added note's pitch, onset, or duration to those of existing notes are included.

Two degradations can be used either to split a note into multiple shorter consecutive notes or to combine consecutive notes at the same pitch into a single longer note. Specifically, `split_note` will cut a random note into some number of consecutive notes of shorter duration (the first of which begins at the original note's onset time and the last of which ends at the original note's offset time). By default the note is split into two shorter notes, but this—as well as a minimum allowable duration for the resulting notes—can be set with a parameter. Similarly, `join_notes` takes two or more consecutive notes at the same pitch (with a maximum allowable gap—set with a parameter—allowed between them), and joins them into a single note with onset time equal to that of the first note and offset time equal to that of the last.

2.2 Other Tools

2.2.1 Dynamically degrading clean data

MDTK includes the `Degrader` class, which can be used to degrade excerpts dynamically. When instantiating a `Degrader` object, the proportion of excerpts that should remain undegraded is set with a parameter (which can be 0). The probability of each degradation being performed on an excerpt (if it is to be degraded) can also be set at this time. Then, each time `Degrader.degrade(excerpt)` is called, a randomly degraded version of the input excerpt is generated according to the proportions set during object creation. The `Degrader` class can be easily inserted into any model training procedure in order to dynamically create new degraded excerpts during each epoch, dramatically increasing the amount of data available for training.

2.2.2 Automatically matching model errors

MDTK includes a `measure_errors.py` script, which can be used to estimate the types of errors (specifically, as degradations) typical to a particular AMT system, given a set of transcriptions and ground truths from that system. Note that there is no unique set of degradations which reproduce the errors that a transcription system has made (e.g., any `shift` degradation can be trivially replaced by a `remove_note` and an `add_note`).

We make no claim that the degradations found by the script correspond to the exact causes of the errors made by the AMT system. Rather, only that the distribution of degradations produces excerpts with similar properties to those transcribed by that system. Nonetheless, the script finds what we believe are a *reasonable* set of degradations to have produced those errors using a simple heuristic-based approach. Notes are first matched as correct if possible (same pitch, and onset and offset within a changeable threshold), and the remaining notes are checked for the various degradations in the following order: (1) `join_notes` and `split_note`, either of which may include an additional `offset_shift` or `onset_shift`; (2) `offset_shift`, if the pitch and onset time match; (3) `onset_shift`, if the pitch and offset time match; (4) `time_shift`, but only if the transcribed note overlaps the position of the corresponding ground truth note; and (5) `pitch_shift`, which must match in onset time, although an additional `offset_shift` can be added. Finally, any remaining unmatched notes are counted as `add_note` and `remove_note`.

The output of the script is a json file containing the estimated proportion of each degradation in the given set of transcriptions. It does not yet include values for the various degradation parameters (though this is planned for a future update to MDTK). This output file can be used, for example, to create a custom-tuned, static, degraded dataset for training a model. However, the two tools can also be combined in powerful ways. By passing this json file to the `Degrader` constructor, a `Degrader` object can be instantiated that generates degradations exactly matching the estimated proportions. This could then be used to train a model to correct the errors of that specific AMT system using a relatively small amount of raw data.

3. THE DATASET

3.1 ACME version 1.0

The Altered and Corrupted MIDI Excerpts dataset v1.0 (ACME v1.0) is a dataset of 5 second excerpts with degradations implemented by MDTK. It is not intended to emulate the errors of any specific AMT system, but rather serve as a starting point for the modelling tasks we introduce below.

The dataset is taken from two sources: (1) the piano-midi dataset [3] , which contains 328 MIDI files of pseudo-live performance [4] piano pieces of various styles (generally classical); (2) the 22194 primes from the small, medium, and large sections of the monophonic and polyphonic Patterns for Prediction Development Datasets (PPDD-Sep2018) [5] , which contain excerpts drawn randomly from the Lakh MIDI Dataset (LMD) [14]. We remove track information, flattening each excerpt to a single track, simplifying the modelling tasks [6] ; analysis

---

[3] http://www.piano-midi.de

[4] The files are quantized and beat-aligned, but their tempo curves were manually edited by their creator to sound more like live performance.

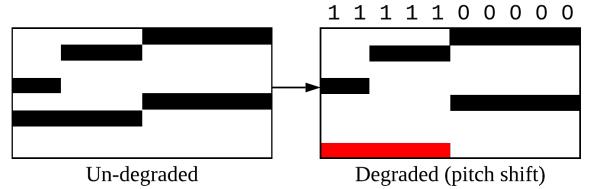
[5] https://www.music-ir.org/mirex/wiki/2019: Patterns_for_Prediction

[6] The use of tracks is not standard our different data sources.

of multi-track MIDI files will be addressed in future work. We then fix any pair of overlapping notes of the same pitch by cutting the first note at the onset time of the second. We additionally set the offset time of the second note to the maximum of the original offset times of the two notes, such that no sustain is removed.

Once this pre-processing is complete, we select a ~5 second excerpt from each piece by choosing a random note and all notes beginning in the subsequent 5 seconds, but require that at least 10 notes be present. The excerpt ends when the last held note is released. This duration is approximately 2 bars for most songs so is small enough for the models proposed in section 4 to train quickly. We degrade $\frac{8}{9}$ of the excerpts, selecting the degradation uniformly at random from the set of 8 defined degradations, and leave the remaining $\frac{1}{9}$ undegraded. For ACME v1.0, we use default parameter settings for all degradations, although we intend to investigate the effect of different settings in future work (and future releases of ACME datasets).

The excerpts and degraded excerpts are split randomly into training, validation, and test sets of proportion 0.8, 0.1, and 0.1, creating the official splits for ACME v1.0. The canonical form is available online as a set of CSV files. Additionally, the MDTK package includes the `make_dataset.py` script which we used to create the dataset from scratch—including the automatic downloading of the raw data—and thus serves as a record of how it was created.

3.2 Custom Dataset Creation


The `make_dataset.py` script can also be used to generate an ACME-style dataset from a user-provided set of MIDI or CSV files. The user can specify custom sizes for the excerpts, a custom distribution of the various degradations, as well as custom parameters for each. The script can be given the json output of the `measure_errors.py` script in order to match the properties of the generated dataset with those measured from an AMT result. Alternatively, a user can simply choose to degrade individual excerpts from their own training set by calling MDTK during the training process, either manually or randomly using the `Degrader` class.

4. PROPOSED TASKS

4.1 Motivation

These tasks are performed on ACME v1.0, and proposed in lieu of taking existing AMT systems and measuring their improvement when trained with the assistance of MDTK. It is proposed that the *output* of arbitrary AMT systems could be improved with models that can solve these tasks.

For instance, we could use a model trained to classify the error contained within a given excerpt to call out for human intervention. We could also train models to perform the actual fix; however, we show that, with the models we have chosen for our baseline, this problem is far from solved.

Figure 1. Example piano rolls of a clean excerpt (left) being degraded with pitch_shift (right), including the labels for Error Location (top right).

4.2 Tasks

We propose four tasks of increasing difficulty. Figure 1 shows a simple toy data point which has been pitch shifted (changed note in red). We will use it as an example when necessary throughout this section. We should note that the tasks we introduce here are not in any way trivial, but represent significant steps towards successful AMT postprocessing.

1. Error Detection: detect whether a given excerpt has been degraded. This is a binary classification task with a skewed distribution: $\frac{8}{9}$ excerpts are degraded (the positive class), and $\frac{1}{9}$ are not degraded (the negative class). We evaluate performance using F-measure but, since the negative class is the minority, for the purposes of F-measure evaluation, we treat those as positives. Thus, a model which always outputs "degraded" achieves a "reverse F-measure" of 0.00 (with precision and recall both 0) rather than its F-measure of 0.94 (with precision $\frac{8}{9}$ and recall 1).

2. Error Classification: specify which degradation (if any) was performed on each excerpt. This is a multi-class classification problem, and since ACME v1.0 contains a uniform distribution of each class, we evaluate performance using accuracy and a confusion matrix to show specific error tendencies for each degradation.

3. Error Location: assign a binary label to each (40 ms) frame of input identifying whether it contains an error i.e. whether this frame contains a degradation. We evaluate performance using the standard F-measure. The labels for this task are shown in the top right of Figure 1.

4. Error Correction: output the original, un-degraded version of each excerpt. In Figure 1, a model is given the degraded excerpt (right) and expected to output the original excerpt (left). For this task, we define our own metric, helpfulness (H), based on two F-measures proposed by [2]: frame-based F-measure with 40ms frames, and note-based onset-only F-measure. We use the `mir_eval` [16] implementation of note-based F-measure (with 50ms onset tolerance) to evaluate both the given excerpt and the system's output compared to the original excerpt. We take the average between the two F-measures for each excerpt, which we denote F_g (for the given excerpt) and F_c (for the system's corrected output). If $F_g = 1$ (the given excerpt was not degraded), $H = F_c$. If the given excerpt was degraded, however ($F_g < 1$), H is calculated as in Equation (1). An intuition for this calculation is as follows: $H = 0.5$ represents an output which is exactly as accurate as the given excerpt (the error correction system has neither helped nor hurt), and H scales linearly up to 1

and down to 0 from there. For example, $H = 0.75$ represents an output which is in some sense twice as accurate as the given excerpt (its error, $1 - F_c$, is half of the given excerpt's error, $1 - F_g$). Similarly, $H = 0.25$ represents an output which has twice as many errors as the input.

$$H = \begin{cases} 1 - \frac{1}{2}\frac{1-F_c}{1-F_g} & F_c \geq F_g \\ \frac{1}{2}\frac{F_c}{F_g} & F_c < F_g \end{cases} \quad (1)$$

4.3 Baseline Models

4.3.1 Data Formats

For input into our baseline models, we first quantize each excerpt onto 40 ms frames, rounding note onsets and offsets to the nearest frame. We use two different input formats for our baseline models, and provide data conversion and loading functions for each of them.

The *command format* is based on the one designed by [13]. Each excerpt is converted into a sequence of one-hot vectors representing commands from a pre-defined vocabulary of 356 commands: $note\_on(p)$, $note\_off(p)$, and $shift(t)$ ($p \in [0, 127]$, $t \in [1, 100]$). The note on and off commands represent note onsets and offsets at the current frame, and the shift command skips t frames. Longer shifts are represented by multiple shift commands.

The *piano roll format* represents each excerpt as two binary piano rolls: one representing pitch presence in each frame, and another represent pitch onsets in each frame. These two piano rolls are concatenated together frame-wise to form the model's input.

4.3.2 Model details

The details for the models provided in this paper are brief. For code which fully defines the models and the code used to train and evaluate them, see the repo[7]. Our choice of models was relatively arbitrary; they are easy to implement with existing open source packages and easy to improve upon.

Our baseline for **Error Detection** uses the *command format* as input. It consists of an embedding layer of size 128, followed by a basic Long Short-Term Memory (LSTM) [8]. A dropout of 0.1 is applied to the final LSTM state's output, which is then passed to a fully-connected layer of size 2 with softmax activation, resulting in a single output for each input sequence.

Our **Error Classification** baseline uses the same design, but with output dimensionality 9 for the final layer (one for each degradation plus one for no degradation).

For **Error Location**, we use the *piano roll format*. We first feed the input frames into a bi-directional LSTM (Bi-LSTM), and send the output of each Bi-LSTM state (with dropout 0.1) into 3 linear layers, each with dropout 0.1 and ELU activation. These are each fed into a final fully-connected layer of size 2 with softmax activation, resulting in one output per input frame.

For **Error Correction**, we use the *piano roll format*, and base our network on a basic Encoder-Decoder structure [4], where both the encoder and the decoder are Bi-LSTMs. The input is passed directly into the encoder Bi-LSTM, and the output at each frame is passed through a

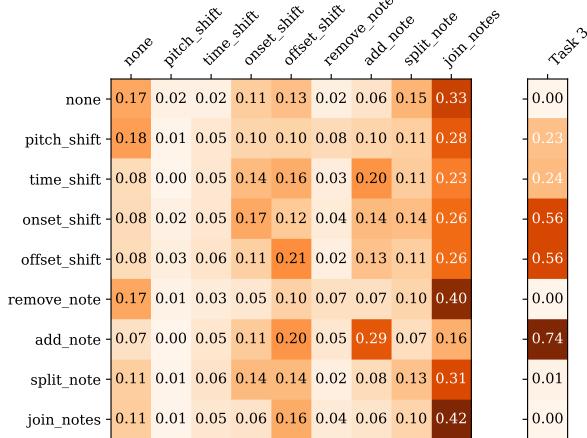
Table 1. Loss and evaluation metric for the baseline and rule-based models for each task on the ACME v1.0 test set. Each task's metric is different, as explained in the text.

single fully connected layer with dropout 0.1. This sequence is input into the decoder Bi-LSTM, each output of which is fed into 4 linear layers which output a vector of the same length as the input.

The models were trained using the Adam optimizer [10], and a grid search was performed for weight decay, learning rate, LSTM hidden-unit size, and linear layer sizes (for full details, see the code). The model with the lowest validation loss on each task is used as the baseline.


4.4 Analysis

To gauge the difficulty of each task, we compare each of the baseline models to a simple rule-based approach. Like our baseline models, the rule-based systems output probability values $\in [0, 1]$. For Error Detection, the rule-based system returns an $\frac{8}{9}$ probability of each data point being degraded. For Error Classification, the rule-based system outputs a $\frac{1}{9}$ probability for each class. For Error Location, the rule-based system outputs a 0.06 probability that each frame has been degraded (the proportion of frames that are degraded in the training set is 0.06). Finally, for Error Correction, we calculate $p(1|0) = 0.01$ and $p(1|1) = 0.96$ from the training set[8] and have the system output these values for each cell in a given piano roll.

The results for each task on the ACME v1.0 test set are shown in Table 1. From the losses, it is clear that the baseline models have learned something, since all of their losses are lower than the rule-based losses except for in Error Correction. However, from the metrics, it is also clear that there is much room for improvement on each of the proposed tasks (as we would hope).

For Error Detection, the baseline predicts 1 (degraded) for every data point, just like the rule-based system, likely because of the skew of the training data. As a simple attempt to overcome this tendency, we trained another model identical to the baseline which weights the loss of each data point inversely proportional to that label's frequency in the training set. This results in a model with greater overall loss (as expected), but which outputs some 0s, achieving a

---

[8] That is, for the degraded piano rolls from the training set, 1% of cells with a 0 and 96% of cells with a 1 map to a value of 1 in the corresponding cell of the clean piano roll.

Figure 2. Left: Confusion matrix showing the distribution of the baseline Error Classification model's classifications, normalized by true label. Rows show the true label, and columns show the predicted label. Right: The baseline Error Location model's F-measure for each degradation type.

reverse F-measure of 0.155. Overcoming the skew of the dataset may prove to be a challenge for this task.

For Error Classification, the baseline achieves an accuracy of greater than that of the rule-based system. The baseline's confusion matrix is shown in Figure 2 (left), where rows represent the ground truth label and columns represent its output. This shows error tendencies, and (more importantly) gives an idea of the general difficulty of detecting each degradation. Here, it can be seen that the maximum point in each column is always on the diagonal, showing that the model does seem to have learned something sensible. It performs well on the add note degradation, classifying 32% of those data points correctly. Pitch shift, time shift, and remove note seem to be the most difficult, while join notes is a common target for false positives. We are interested to see whether the above trends continue in future work on Error Classification, and intend to further investigate their causes.

The Error Location baseline outperforms the rule-based system in terms of both loss and F-measure by wide margins. It achieves this F-measure with a precision of 0.844 and a recall of 0.381, so although it rarely guesses that a frame has been degraded, it is usually correct when it does. Figure 2 (right) presents the baseline's F-measure split by degradation type, which shows the model performing best on add_note, but also well for onset and offset shifts (precision is over 0.9 for all three). It is slightly worse with pitch and time shifts (precision over 0.6 for both), and performs poorly on the other degradations (the value for "none" will always be 0 since it has no positives). Given the relative success of this model compared to the other tasks' baselines, pre-training a model for this task before continuing to train it for another task might be an avenue for improved performance. Another strategy could be to use a model trained for this task as an attention mechanism for some of the other tasks.

Error Correction is clearly the most difficult task of the four, and the baseline model's performance reflects this.

Although its loss is similar to that of the rule-based system, its helpfulness lags clearly behind. The rule-based model's strategy of (essentially) reproducing the input turns out to be a strong baseline. Our baseline, on the other hand, almost always outputs empty piano rolls, no matter the input. The difficulty of this task might require a more modular approach than the presented end-to-end baseline, perhaps combining the results of models from tasks 2 and 3 with a system designed to correct a specific degradation affecting a specific set of frames.

5. CONCLUSION

In this paper, we have introduced the MIDI Degradation Toolkit (MDTK), which contains tools to "degrade" (introduce errors to) MIDI excerpts. The toolkit is publicly available online [9] under an MIT License, and we encourage contributions and feedback from the community. Using MDTK, we have created the Altered and Corrupted MIDI Excerpts v1.0 (ACME v1.0) dataset [10] and include in MDTK a tool to create custom ACME-style datasets with different settings or data. We have proposed a set of four new tasks of increasing difficulty involving such datasets: Error Detection, Classification, Location, and Correction, and designed evaluation metrics and scripts for each of them. We also designed and presented simple models to be used as a baseline for each, which show that the proposed tasks are non-trivial, and may require innovative solutions.

The toolkit is ready to be used for improving Automatic Music Transcription (AMT). To do so, a user can:

1. use `measure_errors.py` to analyse the types of errors made by an AMT system or acoustic model.
2. instantiate a `Degrader` with the configuration produced by `measure_errors.py`—this can generate unlimited data matching the errors made by the system from step (1).
3. train a discriminative model using data generated by the `Degrader`.
4. apply that model to the output of the model from step (1) and evaluate the difference in performance.

As performance on the proposed tasks modelling ACME v1.0 improves, we intend to introduce ACME v2.0 with additional features such as multi-track excerpts, a track-based degradation, longer excerpts, multiple degradations per excerpt, and various parameter settings for the degradations. We also intend to analyze the effect of adding noise on MLM performance.

ABSTRACT

Tagging a musical excerpt with an emotion label may result in a vague and ambivalent exercise. This subjectivity entangles several high-level music description tasks when the computational models built to address them produce predictions on the basis of a "ground truth". In this study, we investigate the relationship between emotions perceived in pop and rock music (mainly in Euro-American styles) and personal characteristics from the listener, using language as a key feature. Our goal is to understand the influence of lyrics comprehension on music emotion perception and use this knowledge to improve Music Emotion Recognition (MER) models. We systematically analyze over 30K annotations of 22 musical fragments to assess the impact of individual differences on agreement, as defined by Krippendorff's α coefficient. We employ personal characteristics to form group-based annotations by assembling ratings with respect to listeners' familiarity, preference, lyrics comprehension, and music sophistication. Finally, we study our group-based annotations in a two-fold approach: (1) assessing the similarity within annotations using manifold learning algorithms and unsupervised clustering, and (2) analyzing their performance by training classification models with diverse "ground truths". Our results suggest that a) applying a broader categorization of taxonomies and b) using multi-label, group-based annotations based on language, can be beneficial for MER models.

1. INTRODUCTION

Several studies suggest that the main reason people engage with music is its emotional effect [1–3]. This makes the idea of computational algorithms that can "predict" the

emotions in music particularly intriguing and provocative. These algorithms evaluate emotionally relevant acoustic features from the audio signals, and correlate them with certain emotions that the music could convey, express or induce. Recently, deep learning approaches have been used to further improve emotion recognition [4–6]. However, the performance of these algorithms may have reached a "glass ceiling" possibly due to the subjective nature of the perception of emotions [7,8], the limited agreement in the annotations of datasets [9–11], the lack of an agreed methodology for annotation gathering [2], the generalized confusion between perceived and induced emotions [3, 12], amongst other reasons. In particular, the low agreement problem extends to other high-level description tasks in Music Information Retrieval (MIR) such as music auto-tagging [13], music genre recognition [14, 15], music similarity [9, 11], and even computationally well-defined tasks like automatic chord estimation [16] and beat tracking [17]. Given the importance of annotation collection and in an attempt to improve their quality, we address two research questions in this paper: *RQ1* - Do personal characteristics and mother tongue have an influence on the annotation of perceived emotions for listeners? *RQ2* - Can this information be used to improve MER algorithms? The rest of the paper is structured as follows: Section 2 reviews basic definitions and previous work, in Section 3 we detail the methodology of our study, including annotation gathering, clustering, and classification schemes. Section 4 provides results of our study which are later discussed in Section 5.

2. RELATED WORK

In this study, we focus on the *perception* of emotions as a key factor in the "musical communication" between music itself and a listener. *Perceived* emotions refer to those recognized by the listener through the interpretation of musical properties [3]. In contrast, *induced* emotions concern the arousal of psycho-physiological responses [18]. [1] The relation between musical properties and emotion perception has been widely researched in the literature [3, 12]:

---

[1] For a review of the emotivist-cognitivist argument, refer to [19,20].

happiness is linked to fast mean tempo, bright timbre, sharp duration contrasts; *sadness* is related to slow mean tempo, low sound level, dull timbre, slow vibrato; *fear* is linked with very low sound level, large sound level variability, large timing variations.

From music psychology, two dominant views or taxonomies for emotion representation prevail [21]:

- *Categorical approach*: emotions are represented as categories, distinct from each other - such as happiness, sadness, anger, and fear [22]. The major drawbacks of this approach are: (1) the amount of categories results too small compared to the richness of human emotion, and (2) the ambiguity of using language during self-reports [7].

- *Dimensional approach*: emotions are conceptualized based on their positions on a few dimensions, mainly arousal and valence (AV). Russell popularized the two-dimensional circumplex model, where the valence dimension describes the pleasantness or positiveness of the emotion, and the arousal dimension describes the activation or energy (i.e., *happiness* would have positive arousal and valence) [23]. However, the major flaw is that categories are not mutually exclusive and tend to overlap (i.e., rage-anger), making the mapping of categories on the dimensional space vague and unreliable [7].

In the particular case of instrumental classical music, Schedl et al. explored the relationship between listeners' characteristics and nine categories of emotion on segments from the 3rd Symphony *Eroica* by L.V. Beethoven [10]. Their results suggest that: (1) the perception of transcendence and power correlates significantly with affinity to classical music; (2) participants trained on classical music tend to disagree more on perceived emotions of peacefulness, tension, sadness, anger, disgust, and fear; (3) the agreement among perceived emotions decreases with increasing familiarity with the piece. Our work is based on this study, however we focus on music with lyrics of pop and rock style. Very few studies have explored different styles of music and researchers report that 50% of music and emotion studies focus on classical music [2,24]. When it comes to annotation reliability, researchers have studied ways of increasing inter- and intra-rater agreement for music similarity. Flexer and Lallai found evidence that upper bounds for inter-rater agreement (i.e., measured between different subjects) cannot be increased for this task, while the intra-rater case can be improved (i.e., measured on ratings from the same subject at different time) [11]. We base our research on increasing inter-rater agreement by analyzing listeners with similar characteristics and assembling group-based annotations based on listeners characteristics. Group-based MER has been attempted by Yang et al. by assembling annotations according to cultural factors, music experience, and personality traits [7, 25]. Their results suggest insignificant improvement for the regression task as compared to using general averaged annotations. However, and to the extent of our knowledge, this is the first work that uses language and self-reported lyrics comprehension to group annotations of perceived emotion.

3. METHODOLOGY

The main contribution of our work is to address open questions from previous studies by focusing on rock and pop music. We use these musical styles since they appear to be similar across different cultures and are musically homogeneous, even when sung in different languages. Contrary to most studies, we focus on a small set of songs with existing emotion annotations and gather large-scale, diverse annotations per song from participants of different mother tongues. The goal of our work is to study the relationship between listeners' demographics, preference, familiarity, musical knowledge, and native language with agreement of perceived emotions in music. In order to achieve this, we use these personal characteristics to form group-based annotations and analyze the agreement of participants belonging to these groups. We then perform manifold learning and K-means clustering to study if group-based annotations yield representations that are more similar amongst them. Finally, we compare the performance of well-known classifiers trained using these annotations, in order to analyze the impact of grouping variants on the MER task.

3.1 Emotion annotation gathering

Our pool of annotators were presented with surveys designed with PsyToolkit [26] in four languages: Spanish, English, German and Mandarin. The survey was structured as follows: (1) collection of general demographic information (age, gender, country of origin and formation, and language), (2) volume adjustment task, (3) explanation of the difference between *perceived* and *induced* emotions, (4) random presentation and annotation of excerpts with a 5-point Likert response format per emotion, and (5) the Music Sophistication Index self-report inventory [27]. In (2), each user was asked to set the volume w.r.t. a 1 KHz sinusoid making it barely audible. In (4), we used synonyms for each emotion for clarity, which were validated by native speakers from each language, following [10]. For each excerpt, we collected information about the listeners' preference, familiarity, and understanding of the lyrics. [2]

We selected a set of excerpts from the 4Q emotion dataset [28], which was previously annotated with categories in the four arousal-valence (AV) quadrants: Q1 (positive valence and arousal, A+V+), Q2 (positive arousal and negative valence, A+V-), Q3 (negative valence and arousal, A-V-), Q4 (negative arousal and positive valence, A-V+). In order to gather annotations on a larger scale, we asked participants to rate the excerpts with the following emotion categories: Q1 - *joyful activation*, *power*, *surprise*, Q2 - *anger*, *fear*, *tension*, Q3 - *bitterness*, *sadness*, Q4 - *peace*, *tenderness*, *transcendence*. These emotion adjectives were selected from the Geneva Emotion Music Scale (GEMS) [29] and a subset of basic emotions [30]. To select the target songs, we queried for these adjectives in

---

[2] Refer to Figure 1 - supp. mat. for the annotation interface.

English on the datasets' metadata. Since some words were not found, synonyms were used for certain emotions (e.g., fear - anguished). [3] From the resulting excerpts, we randomly selected two excerpts per emotion for a total of 22 fragments. All audio excerpts were normalized from -1 to 1 in amplitude, in order to balance the volume during playback. We collected additional audio features from Spotify API [31]: beats per minute, energy [0,1], and valence [0,1].

3.2 Emotion agreement analysis

Following [4, 10, 16], we used inter-rater reliability statistics to assess the agreement of the annotated data with respect to personal characteristics [32]. Researchers have found that Krippendorff's α is used increasingly to assess reliability in content analysis methodologies [33]. We employed Krippendorff's coefficient α defined as:

$$\alpha = 1 - \frac{D_o}{D_e} \qquad (1)$$

where D_o is the measure of observed disagreement:

$$D_o = \frac{1}{n} \sum_c \sum_k o_{ck} \cdot {}_{metric}\delta_{ck}^2 \qquad (2)$$

and D_e is a measure of the expected disagreement given chance:

$$D_e = \frac{1}{n(n-1)} \sum_c \sum_k n_c \cdot n_k \cdot {}_{metric}\delta_{ck}^2 \qquad (3)$$

The variables o_{ck}, n_c, n_k are the frequencies of values of observed coincidences of c and k values or ranks, and n is the total amount of paired $c - k$ values or ranks. Advantages of using α are: the suitability for any number of observers, handling of any type of metric (nominal, interval, ordinal), handling incomplete or missing data, and not requiring a minimum of sample size. When disagreement is absent ($D_o = 0$), there is perfect reliability ($\alpha = 1$). Conversely, when agreement and disagreement are a matter of chance ($D_e = D_o$), there is absence of reliability ($\alpha = 0$). Nevertheless, α could be smaller than zero if the sample size is too small or agreement below what would be expected by chance. According to [32], data with $\alpha \geq 0.8$ is considered to have good agreement and $0.4 \leq \alpha \leq 0.667$ shows fair agreement. Finally, ${}_{metric}\delta_{ck}$ represents the difference function: the squared difference between any two values or ranks c and k, depending on the data gathering approach (in our case, we use an ordinal metric).

To obtain annotation groupings, we defined positive and negative filters to classify ratings based on different user responses and characteristics. Considering the 5-point Likert response format, we define a positive filter by keeping ratings higher than 3 (neither agree or disagree) and a negative filter by keeping those less than 3. These filters were used to form groups using the users' response of preference, familiarity, and understanding for each excerpt. In the case of behavioral factors of music sophistication, we

specified positive and negative filters by grouping the annotations of participants with higher and lower scores than the population mean, respectively. We collected six behavioral factors, yet used the ones in **bold** to group ratings: Active Engagement, Perceptual Abilities, **Musical Training**, **Emotion Perception**, Singing Abilities, and **General sophistication**. [4]

In order to evaluate the collected annotations, we clustered group-based ratings in 2D and 3D spaces. Our intuition is that group-based annotations are more similar amongst them, and that clusters obtained with these annotations show less variance than those obtained with the original "ground truth". We generated a low-dimensional representation of all annotations with manifold learning, used one of the proposed filters to keep a group, clustered the resulting embeddings, and compared the resulting clusters with the original "ground truth" (i.e., four quadrants of emotion). We use Adjusted Rand Index (ARI) and Adjusted Mutual Information (AMI) for all filters as measures of quality of the clusters. We proceeded as follows: (1) standarization of the annotations, (2) categorical Principal Component Analysis (CATPCA), (3) manifold learning for dimensionality reduction, and (4) clustering of embeddings into the four quadrants of emotion using K-means (k-means++ initialization [34]). In (2), we use 10 components retaining 97.4% from variance. [5] In (3), we used the following algorithms: Multi-dimensional Scaling (MDS) [35], t-distributed Stochastic Neighbor Embedding (t-SNE) [36], and Uniform Manifold Approximation and Projection for Dimension Reduction (UMAP) [37]. [6]

3.3 Emotion classification approach

Despite the low number of data instances (22), we trained support vector machine (SVM) classifiers to study how group-based annotations compare to annotations from all participants. Following relevant literature [4, 38, 39], we extracted the IS13 ComParE feature set with the openS-MILE toolbox [40]: 260 low-level features (mean and standard deviation of 65 emotionally-relevant acoustic descriptors, and their first order derivatives) with a frame size of 60 ms and a 10 ms hop size. These features are widely used as a benchmark for speech and music emotion recognition tasks [4]. Each feature vector was aggregated in segments of 5 seconds with a 75% overlap, resulting in 24 feature vectors per excerpt and 528 samples in total. We performed standarization over each feature and PCA for dimensionality reduction. After a Scree test, we selected 8 components that retained 65.7% of the variance. We performed a grid search for parameter optimization with the following settings (final parameters in bold): regularization parameter C [0.001, 0.01, 0.1, 1, **10**] and radial ba-

---

[4] Refer to Table 2 - supp. mat. for music sophistication results.

[5] Refer to Figure 2 - supp. mat. for an example of CATPCA.

[6] We used different settings for each algorithm (final parameters in bold): (1) MDS - **metric** and non-metric, iterations [300, 1000, **3000**], epsilon [**1e-1**, 1e-3, 1e-9, 1e-12], (2) t-SNE - perplexity [**3**, 5, 10, 30, 50, 100], learning rate [**200**, 500, 1000], number of iterations [**1000**, 3000], (3) UMAP - minimum distance [0.1, 0.25, 0.5, **0.8**, 0.99], number of neighbors [**10**, 30, 100, 200], metric [**Euclidean**, Cosine and Chebyshev].

sis function kernel with coefficient gamma [**0.001**, 0.01, 0.1, 1]. We report precision, recall, and F1-score using 5-fold cross-validation to evaluate the models. We test three possible "ground truths" per excerpt: (1) single-label annotations from the original metadata (MD), (2) multi-label annotations from all participants (All), and (3) multi-label annotations from participants belonging to a group (Filtered). In cases (2) and (3), we summarized ratings by taking the statistical mode of each emotion rating across participants. We employ the mode as some ratings showed a bimodal distribution and our annotations were categorical. Since the mode may result in multiple maximum values, we created multi-label annotations (i.e., an excerpt can have a mode of 4 for both *anger* and *tension*). Anonymized data and evaluation code are available online. [7]

4. RESULTS

4.1 Emotion annotation and agreement analysis

The participation was unbalanced regarding languages: a total of 126 (65 Male, 61 Female, $M = 34.12$ years, $SD = 11.75$) participants completed all tasks in our experiment from English ($n = 26$), Spanish ($n = 56$), Mandarin ($n = 27$), and German ($n = 17$) surveys. Listeners that wanted to participate in the survey but were not native to any of the languages were asked to take the English

Table 2. Krippendorff's α for each emotion across different languages.

version ($n = 15$). Since the surveys were made available through different channels, listeners were asked to state the country in which they spent the formative years of childhood and youth [8]. We evaluated outliers for every musical fragment, finding that the participants that systematically annotated outside the interquartile range (Q1-Q3) did so at most 10.33% of the time. Hence, we decided to keep all ratings for analysis. Median and Kruskal-Wallis H tests showed that there was a statistically significant difference in the ratings of emotions between raters from the surveys of each language ($p < 0.01$). [9] Concretely, the ratings of *anger, bitterness, fear, sadness, surprise, tenderness, tension*, and *transcendence* have different distributions across the surveys. This suggests that emotion significance varies across cultures and languages as hypothesized in our study. Emotion adjectives might have varied meanings and associations across different languages and cultures as studied by [41], but results should be validated with a higher amount of participants and excerpts.

Results from the agreement analysis are presented in Tables 1 and 2, and appear **bold** when the agreement of the emotion is higher than 0.05 as to the agreement measured across all participants. Conversely, the text in *italic* indicates a difference less than -0.05, following [10]. Table 1 shows agreement over all participants that belong to a certain group (see Configuration column). Hence, it contains information about the number of ratings for the corresponding filters (groups). The music selection contained 20 songs with lyrics (17 in English and 3 in Spanish), thus agreement was analyzed only for this subset for lyrics comprehension to be meaningful. We find two tendencies for groups assembled with preference, familiarity, and lyrics comprehension: (1) positive filters will result in higher agreement with respect to all ratings for emotions such as *joy, surprise, power, sadness*, and *bitterness*; (2) positive filters will result in lower agreement for emotions such as *anger, fear, tension, peace, tenderness* and *transcendence*. Interestingly, emotions in (1) belong to

[8] Subjects participated from the following countries: (1) *Spanish* - Bolivia, Colombia, Ecuador, Perú, Spain, Uruguay, (2) *Mandarin* - Mainland China, Taiwan, (3) *German* - Austria, Germany, Switzerland, and (4) *English* - Australia, Bulgaria, Belgium, Brazil, France, Greece, India, Italy, Portugal, Romania, United Kingdom, United States.

[9] Refer to Table 3 - supp. mat. for multiple pairwise test results.

quadrants Q1 (A+V+) and Q3 (A-V-), while emotions in (2) belong to Q2 (A+V-) and Q4 (A-V+). Regarding musical sophistication, we find a consistent trend in groups assembled with musical training, emotion perception and general sophistication: positive filters will result in higher agreement in all filters with respect to all ratings. Table 2 shows agreement over all participants from each survey and exposes low agreement over certain emotions: *bitterness*, *fear*, *power*, *surprise*, and *transcendence*. On the other hand, a higher agreement is reached for emotions such as *anger*, *joy*, *peace*, *sadness*, and *tenderness*. The results confirm that participants of different surveys show significant differences in the emotions perceived from music. Additionally, we found positive linear correlations, as obtained by Pearson's coefficient, between *anger*, *bitterness*, *fear*, and *tension*; *peace* and *tenderness*; *joy*, *power*, and *surprise*; *sadness* and *bitterness*. [10]

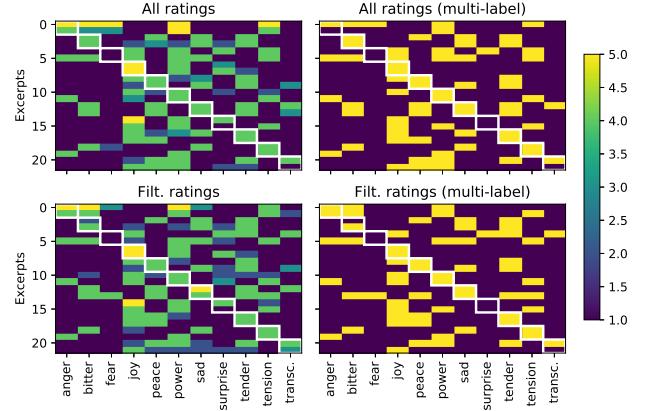
4.2 Implications for MER models


Table 3 shows the clustering evaluation when comparing clusters from manifold learning representations with the original "ground truth". Scores are reported in **bold** when they are higher than the scores obtained without filters (All). In every case, positive filters result in improved clusterability (particularly when selecting participants with high scores for music sophistication). MDS and UMAP appear to separate the data better than t-SNE before performing K-means. As a baseline, applying K-means on the raw data shows that manifold learning techniques can be useful to find similarities between group-based ratings. We argue that using manifold learning previous to clustering extracts possible similarities across annotations that belong to a given AV quadrant, yielding annotation embeddings that are easier to cluster. [11]

Table 3. Clustering metrics for all filters and manifold learning algorithms. MT refers to Musical Training, Emo. to Emotion Perception, GS to General Sophistication. The last column shows clustering results on the raw data.

An example of the group-based, multi-label annotations produced by using the positive understanding filter can be seen in Figure 1. This plot compares different "ground

truths" for the data according to the collected ratings and a given filter that we used to train our classifiers. For example, excerpt 0 (originally labeled as *anger*) is also labeled with *bitterness*, *fear*, *power*, and *tension* when considering our annotations (top-right plot). In contrast, excerpt 1 is labeled as *power* when considering all ratings, but labeled as *anger*, *bitter*, and *power* when considering the filter (comparison of top- and bottom-right plots).

Figure 1. Example of annotations using *All* ratings (top row) and the *positive understanding* filter (bottom row). White rectangles highlight the original annotation from the metadata (MD - single-label). For every plot, rows represent one of the 22 excerpts and columns represent an emotion. The plots on the left show the mode over the participants for each emotion. The plots on the right show selected multi-labels for each excerpt used for classification. The color bar represents the 5-point Likert scale.

Classification experiments are reported in Table 4, including precision (P), recall (R) and F1-Score (F) of classifiers trained on annotations with different filters and 5-fold cross-validation. We compare three settings: original labels from the metadata (MD - single-label), annotations collected from all raters (All - multi-label), and annotations from selected raters with respect to the defined groups (Filter - multi-label). Comparisons are presented by subtracting the mean performance scores of classifiers trained on two annotation scenarios. For example, All - MD refers to the comparison between a classifier trained on all annotations and one trained on the original metadata. Scores are reported in **bold** when the difference is greater than 0.05 and in *italic* when it is less than -0.05. We also report the Jaccard coefficient (JC), bounded from [0,1], to estimate the similarity of the compared ratings in each case [42]. JC shows that the similarity from the original "ground truth" and the collected annotations is low (i.e., All - MD and Filt. - MD), which is expected since we compare single- and multi-label annotations. Interestingly in these two cases, classification results from the collected annotations (multi-label) provide consistent mean improvements of 15.01 percent points in precision and 11.8 in F1-scores with respect to classifiers trained on the original "ground truth" (single-label). We argue that improvements are due to the correlations between tags that are exploited in the multi-label

case. In the case of comparing filtered and all collected annotations (i.e., Filt. - All), we find that a classifier trained on the group-based annotations generated from the positive understanding filter consistently results in better classification for this dataset. In this case, both classifiers were trained on multi-label annotations. In contrast, other filtered group-based annotations result in very similar performance as with all annotations, confirming previous findings from Yang [7].

Table 4. Performance comparison of models trained with different "ground truths". We report the difference of mean Precision (P), Recall (R), and F1-Score (F1). MD refers to metadata (single-label) and JC refers to Jaccard coefficient.

5. DISCUSSION AND CONCLUSION

In this paper, we systematically evaluated agreement of categorical annotations of emotions in 22 fragments of music. We characterized listeners by language, preference, familiarity, lyrics comprehension, and music sophistication.

With respect to *RQ1* - Do personal characteristics and mother tongue have an influence on the the annotation of perceived emotions for listeners? - our main finding is that there are substantial differences in the annotations of our surveys. In fact, the collected annotations show different distributions in the majority of emotions, and only the distributions of *joy* and *peace* appeared to be similar across languages. This relates to recent research on "colexification" of semantically related emotion concepts, where researchers found evidence that the relationship between emotion words varies significantly across languages [41]. Our results have also confirmed that certain basic emotions have higher agreement, while complex ones show the opposite. However, agreement in our experiment ap-

pears to be lower than values reported in [4] and similar to [10]. Our results advocate for taking into account diverse languages while gathering annotations and reducing the number of categories when dealing with cross-cultural MER models (i.e., four quadrants in AV space). Our findings suggest that preference, familiarity, and lyrics comprehension increase agreement for emotions corresponding to quadrants Q1 and Q3, and decreases it for quadrants Q2 and Q4. Regarding music sophistication, positive filters result in higher agreement for all emotions, conflicting with results from Schedl et al. [10]. We argue that in the case of classical music, music experts could tend to disagree more on subtle musical expression cues, while pop and rock music have stronger indicators for emotion (tempo, musical instruments, and meaning of lyrics). This has given us new understanding of the effect of language and lyrics comprehension: in the case of Q1 (A+V+) and Q3 (A-V-) higher agreement is found, contrasted to Q2 (A+V-) and Q4 (A-V+) where dimensions have opposite signs.

As to *RQ2* - Can this information be used to improve MER algorithms? - we find that models trained on multi-label annotations (all and filtered) will consistently show higher precision and F1-score than models trained with the original annotations from metadata (single-label) for this particular dataset. Our results show increments up to 18 percentage points in F1-Scores, when comparing single- and multi-labeled "ground truths". As to models trained with all collected annotations and our proposed filters (Filt. - All), we only find consistent gains for the case of positive lyrics comprehension. Nonetheless, further research is needed in order to confirm these findings. We propose four recommendations when creating datasets for MER algorithms with cross-cultural applications: (1) previous selection of listeners' population and music style have a deep impact on the agreement of annotations - good understanding of the population of annotators is required; (2) inter-rater reliability is crucial to define categories - agreement should be reported and analyzed; (3) group-based annotations can lead to improved agreement - models should be evaluated with both average ratings and group-based ratings; and (4) selecting annotators that are proficient in the language sung in the music may result advantageous - understanding the semantic content of lyrics could help increase the agreement in annotations and possibly lead to improving models. As future work, we consider balancing the styles with respect to different languages. It is also arguable that pop and rock are in fact musically homogeneous, since several variations across the world show different ways of conveying emotions (e.g., Hindi pop). Lastly, the experiment could have biased responses when asking for lyrics comprehension, forcing the participants' attention on lyrics and compromising ecological validity. Different studies regarding lyrics intelligibility should be taken into account in future research, such as [24, 43, 44]. Nevertheless, our study attempts to dispute Henry Wadsworth Longfellow's famous quote - is in fact music the universal language of mankind?

ABSTRACT

Psychology research has shown that song lyrics are a rich source of data, yet they are often overlooked in the field of MIR compared to audio. In this paper, we provide an initial assessment of the usefulness of features drawn from lyrics for various fields, such as MIR and Music Psychology. To do so, we assess the performance of lyric-based text features on 3 MIR tasks, in comparison to audio features. Specifically, we draw sets of text features from the field of Natural Language Processing and Psychology. Further, we estimate their effect on performance while statistically controlling for the effect of audio features, by using a hierarchical regression statistical model. Lyric-based features show a small but statistically significant effect, that anticipates further research. Implications and directions for future studies are discussed.

1. INTRODUCTION

Popular Western music very often contains lyrics. Social science research has shown informative relationships between popular songs and their lyrical content: e.g., country music lyrics rarely include political concepts [1], songs with more typical [2] and more negative [3] lyrics appear to be more successful, and the psychological content of song lyrics appears to correlate with cultural changes in psychological traits [4]. As for music consumption, lyrics have also been shown to be a salient component of music in the minds of listeners [5]. Furthermore, [6] showed that patients are more likely to choose music with lyrics

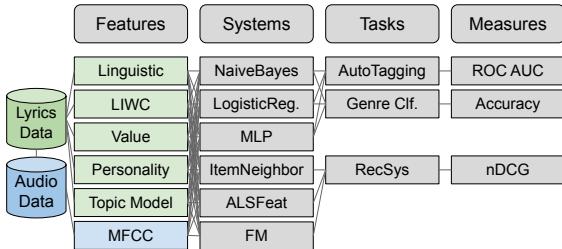
---

[*] Authors contributed equally to the work.

[†] Quoted words are lyrics written by Clifford Smith, from the song "The What", by the Notorious B.I.G. featuring Methodman, on the album "Ready to Die", released in 1994.

when participating in music-based pain reduction interventions; [7] showed that lyrics enhance self reported emotional responses to music, although melody had an overall larger effect, and [8] showed a number of additional brain regions were active during the listening of sad music with lyrics, vs. sad music without lyrics.

In the Music Information Retrieval (MIR) field, some interest for lyrics and how they can be used to improve MIR tasks has been shown. Popular uses of lyrics for MIR tasks consider mood classification [9–12], genre classification [13, 14] and topic detection for indexing and browsing [15, 16]. [17] also proposed a metric to assess the novelty of lyrics, and suggested that novelty can play a role in music preference.

From these findings, one can conclude that lyrics are a rich data source. Although MIR interests have historically focused more on audio, lyrics information may fruitfully be leveraged for various MIR tasks. Still, there are many possible ways to extract information from lyrics text, and it is an open question what information extraction procedure will turn out most fruitful. To gain more insight into this, we present a study investigating several textual feature sets. In shaping these sets—acknowledging potential value of the topic for social science research—we are inspired by the way text analysis has been performed in the Psychology domain, and draw several of our extractors from prior work in that field. We will assess the performance of these textual feature sets on 3 common MIR tasks, and will statistically control for the effect of each chosen feature set, including an audio feature set for comparison. Our analysis will be performed on a large dataset from the online Musixmatch lyrics catalogue.


In the remainder of the paper, in Section 2, we discuss relevant previous work on text information extraction in the Psychology literature. Section 3 will subsequently explain our research design, after which Section 4 discusses the feature sets we used. Section 5 describes the data collection and pre-processing procedures, after which Section 6 details the experimental design. Section 7 justifies our chosen analytical strategy, followed by a presentation of results in Section 8 and the conclusion in Section 10.

Figure 1. Overview of the experimental pipeline.

2. RELATED WORK

The field of Psychology has long pondered the importance of the words people choose to use, and how this reflects their individual differences [18]. The features we use in present work are primarily inspired by two prior lines of work in which Natural Language Processing (NLP) techniques were applied in psychology research: one employing closed-vocabulary lexicon approaches, the other employing open vocabulary approaches. Firstly, [19] used NLP techniques to derive estimates of personality for music genres. Specifically, they created a lexicon (a meaningful group of words) from psychology research that described personality dimensions, as well as a corpus of lyrics, separated into music genres. They then computed the similarity between the lyrics of music genres and the groups of personality dimension words, and considered this result to be an estimate of the personality dimension represented in the lyrics of each genre. Lexicon-based approaches have generally been popular, also thanks to the release of the Linguistic Inquiry Word Count (LIWC) lexicon-based software [20]; e.g., in the context of lyrics, [21] used it to examine psychological distress in the lyrics of musicians that committed suicide vs. those who had not.

Secondly, [22] demonstrated the usefulness of an open vocabulary approach vs. a lexicon approach while examining personality in the context of online social networks. Although lexicons are carefully curated and meaningful, they are also time-consuming to create and context-specific. In contrast, data-driven techniques can automatically estimate latent topics from groups of words that tend do appear together. [22] showed relationships between personality scores and automatically extracted latent topics. Further, they showed that the open vocabulary approach may have stronger correlations to self-reported personality scores than the closed-vocabulary lexicon approaches.

3. RESEARCH DESIGN

In this study, we seek to examine the relative importance of lyric-based text features—especially features drawn from psychology research— for various popular MIR tasks. We wish to compare this importance to that of conventional audio based features.

An overview of our experimental pipeline is given in Figure 1. Various feature sets will feed into various systems, that are appropriate for various MIR machine learn-

ing tasks. We employ a full-factorial experimental design for feature sets, tasks, and the systems attached to each task, which means we research all the possible combinations of those factors. For each combination, we will employ the traditional train-validation-test machine learning setup. Performance results on the test sets will feed into our statistical analysis, where we will explicitly control for the effect of each of the feature sets.

4. FEATURE SETS

In this work, we will consider 5 lyric-based text feature sets and an audio-based feature set. More details are given in the following subsections; a summary of the dimensionalities of all feature sets is given in Table 1.

4.1 Linguistic Features

As baseline textual features for this study, we first extract several simple *linguistic* features:

- *NumWords:* the number of words included in the lyrics text.
- *NumUniqueWords:* the number of unique words in the lyrics text.
- *NumStopWords:* the number of stop words in the lyrics text [1].
- *NumRareWords* the number of words that appeared in less than 5 lyrics.
- *NumCommonWords* the number of words extremely commonly used within a lyrics corpus. We set the threshold as the 30% percentile of the document frequency of words.

Along with the absolute number, we also compute the ratio over the total number of words for each lyrics text.

4.2 Topic Modeling

As a more advanced feature extraction technique, we employ probabilistic Latent Semantic Analysis (pLSA) [24] for *topic* modeling. We treat each of the lyric texts as a document, and will take the found topic distribution for a given document as the document feature. We chose the number of topics $K = 25$, which maximizes validation log-perplexity. Taking advantage of the unsupervised learning setup, we use the total pool of songs to setup the training-validation-test split.

4.3 LIWC

Linguistic Inquiry Word Count (LIWC) is a software package built on a lexicon that has been validated for text analysis in psychological studies [20]. It uses a curated lexicon, separated into 73 categories (e.g., the category 'Social Processes' includes references to family and friends). The software outputs the counts of words in a given text for each of the 73 categories. We employ the latest LIWC, released in 2015.

---

[1] As we will focus on English lyrics in this study, we used the English stop words corpus from the Natural Language Toolkit (NLTK) [23]

4.4 Psychology Inventory Scores

We will consider two more feature sets, inspired by psychology inventory scores: a feature set focusing on *personality* and a feature set focusing on *values*. In both cases, we will use lexicons from literature. However, rather than performing a word count as was done in LIWC, we will use more contemporary NLP techniques based on word embeddings.

Contemporary personality theory is derived from lexical studies: it has been suggested that meaningful individual psychological differences between people are captured in the adjectives that describe people [25]. Although the number of meaningful clusters of adjectives (called Personality Dimensions) is under debate, the OCEAN or Big-Five model is often used. It is composed of 5 traits : Openness to Experience, Conscientiousness, Extroversion, Agreeableness and Neuroticism [25]. Our *personality* feature set consists of 2 word clusters per dimension, comprised of words representing positive and negative aspects for each personality dimension, derived from prior research [26].

Personal *values* are another important component of identity, though less studied. They are stable over time and represent who people want to be, targeting the most important things for them in life at the most abstract level. The traditional way to obtain people's personal values is through questionnaires, but recent works focused on NLP techniques to extract them from text [27–29]. In our work, we used the value inventory and lexicon from [28].

Both for the *personality* and *values* feature sets, we will exploit the `word2vec` model [30] to approximate distances between lyrics and the various inventory categories in the feature sets. For this, we use the model pre-trained on the Google News dataset [2]. The average distance score $s_{d,c}$ for each lyric text d, and category c is computed by taking the average cosine distance between the words belonging to the lyrics and the categories, respectively:

$$s_{d,c} = \frac{1}{|\mathcal{W}_d||\mathcal{W}_c|} \sum_{n \in \mathcal{W}_d} \sum_{m \in \mathcal{W}_c} \frac{\langle \mathbf{v}_n, \mathbf{v}_m \rangle}{||\mathbf{v}_n|| \cdot ||\mathbf{v}_m||} \quad (1)$$

where $\mathcal{W}_d$ and $\mathcal{W}_c$ represent the set of words belonging to the lyrics text d and the category c. v_n and v_m denote the pre-trained word vectors corresponding to word n in the lyrics and word m in the category, respectively.

4.5 MFCC

Finally, we employ a set of audio features based on the Mel-Frequency Cepstral Coefficients (MFCC). We include these, such that the effect of the lyric-based text features can be compared to a commonly used feature set from the primary modality of interest in many MIR tasks. Specifically, we adopt the feature computation introduced in [31] with 40 mel bins.

Feature Set	Dimensions
Audio	240
LIWC	73
Values	49
Topics	25
Personality	10
Linguistic	9

Table 1. Number of dimensions per feature set

5. DATA COLLECTION

We analyzed the lyrics contained in the Musixmatch dataset [3], which is the official lyrics metadata selection integrated in the Million Song Dataset (MSD) [32], a collection of relevant data and metadata for one million popular contemporary songs. Musixmatch is a lyrics and music language platform. The Musixmatch community drives the content production by adding, correcting, syncing and translating lyrics of songs. The process of lyrics quality verification involves several steps, including spam detection, formatting, spelling and translation checking. These steps are accomplished by the use of both artificial intelligence and machine learning models. In addition, they are manually verified by more than 2000 Curators worldwide, and a local team of Musixmatch Editors, who are native speakers in different languages.

The data used for the purpose of this project consists of $182,808$ lyrics, plus relevant metadata such as the unique identifier, artist and title. The data encompasses $20,219$ unique artists over various genres of music.

5.1 Preprocessing

For the given lyrics dataset, we consider the following preprocessing steps: the sentence strings are 1) tokenized and 2) lemmatized, followed by 3) stop-words filtering and 4) filtering extremely rare and extremely common words (see Section 4.1). Finally, we filter out non-English lyrics by a filtering process using the topic modeling. More precisely, we fit the topic model to detect whether the topics contain non-English words above a certain threshold. Songs that mostly load on non-English topics are removed.

6. EXPERIMENT

6.1 Tasks & Systems

As shown in Figure 1, to assess the lyrics feature set, we consider 3 popular MIR machine learning tasks; for each of these, we use 3 different commonly used types of systems, and a task-specific performance measure is considered, as detailed below.

6.1.1 Music Genre Classification

Music Genre Classification (MGC) is a multi-class classification problem. Typically, a set of music genres is given as the classes, and music audio content or features are used as the observations. In this study, we examine 3 machine

---

[2] https://code.google.com/archive/p/word2vec/

[3] http://millionsongdataset.com/musixmatch/

learning based systems: *Gaussian Naive Bayes* (GNV), *Logistic Regression* (LR) and the *Multi-Layer Perceptron* (MLP). For performance quantification, we opt for *classification accuracy*.

For this task, we use the data in the intersection between our lyrics database and the part of the MSD for which the music genre mapping introduced in [33] can be made. By choosing the intersection with the MSD, our audio features can be extracted from the MSD preview audio excerpts. Due to genre label availability, this leads to $67,719$ songs being used in this task.

6.1.2 Music Auto-Tagging

Music Auto-Tagging (MAT) is often formulated as a multi-label classification problem in which multiple positive labels may exist for one input music observation. We used the same set of systems as in the MGC task [4]. Again, we cross-match to the MSD, now also considering MSD's LastFM social tags. Similarly to [31], we choose to focus on the 50 most frequent tags from the dataset. The *Area Under Curve - Receiver Operating Characteristic* (AUC-ROC) is used as the performance measure, which will be referred to as AUC^{song} for the rest of this paper [5]. Due to tagging label availability, $137,095$ songs are used under this task.

6.1.3 Music Recommendation

Finally, Music Recommendation (MR) is considered for a user-related retrieval task. In particular, we consider a cold-start scenario, in which a batch of songs is newly introduced to the market, and required to be recommended to users. Due to the lack of previous interaction history, in such a scenario, a model will be maximally dependent on item attributes. As this is a substantially different type of task than the previous classification tasks, a different set of the systems common to the recommender systems field is used. *Item Nearest Neighbor* (INN) is a memory-based collaborative filtering method, which recommends the items closest to those that the user had consumed. We employ the feature vector introduced in Section 4 to compute the distance between entities using the cosine distance. We also use the *Feature-augmented Matrix Factorization* (FMF) [34] method, as well as the *Factorization Machine* [35] (FM). These models are more sophisticated collaborative recommenders, which also are capable of exploiting item attributes. The systems are developed and evaluated using the MSD-Echonest dataset [32]. Due to limits on available computational resources, we exploit a densified subset with $96,551$ users and $66,850$ songs from the initial song pool with the lyrics [6]. Finally, the binarized *normalized Discounted Cumulative Gain* (nDCG) is

considered as performance measure, for the top-100 songs recommended.

6.2 Task Simulation Setup

All MIR tasks above are machine learning tasks, but the systems and data we choose to use for them did not yet exist in a real-life system. Therefore, we ran the machine learning procedures to initiate them. For this, for each task, we randomly split the available song data into *training/validation/test* subsets by a ratio of $8 : 1 : 1$. Each model is trained using the *training* set and evaluated on the *validation* set to tune the hyper-parameters. Once the optimal hyper-parameters are found, final performance is measured on the the the *test* set.

For MLP and FMF, which have more than one hyper-parameter, automatic hyper-parameter tuning is conducted through a Bayesian approach, using the Gaussian Process [7] [8]. Every search process iterates through 50 training-validation procedures to reach the optimal point. For the MGC and MAT tasks, the hyper-parameters are searched at every trial, while in the MR task, the search process runs only once and is used for all the other trials.

7. ANALYTIC STRATEGY

We wish to assess the usefulness of each of the feature sets for the 3 MIR tasks. Therefore, the resulting performance score from each trial run in our experimental setup (see Section 3) forms the measurement that is our outcome variable of interest. We seek to estimate the relative contribution of each feature set, while statistically controlling for the contribution of all other variables in the analysis. In addition, we assess whether feature sets perform better or worse, depending on the task.

Our data has a nested structure. Specifically, we might say that our systems are nested within the tasks: each task is likely to influence the score, as will the underlying systems that were used for each task. Further, not all systems were used in all tasks. To account for this structure, we employed hierarchical regression models which allow for the modeling of variances of nested data.

The typical example for this category of models is the task of modeling the standardized test scores of various students within various schools. Test scores may be due to the performance of the student, but the school itself may also influence the scores. In this case, the students are said to be nested within the school. If we wanted to accurately assess the effect of e.g. a specific teaching technique on the scores of the students, we would want to statistically control for the effect of the nested structure. A hierarchical regression allows for us to estimate the variance in both intercept and slope of the school, to more accurately assess the effect of the teaching technique on the score of the student. For example, the following equations allow us to model the varying intercepts and slopes of each school:

---

[4] We employ a one-vs-rest strategy for the LR and GNV, which transforms a multi-label classification problem to multiple binary classification problems.

[5] We employed song-wise aggregation for this study

[6] We initially matched the original Echonest dataset to our initial song pool and 30% of randomly sampled users. Consequentially, we apply a filter, such that users who interacted with more than 5 songs remain, and vice versa for songs.

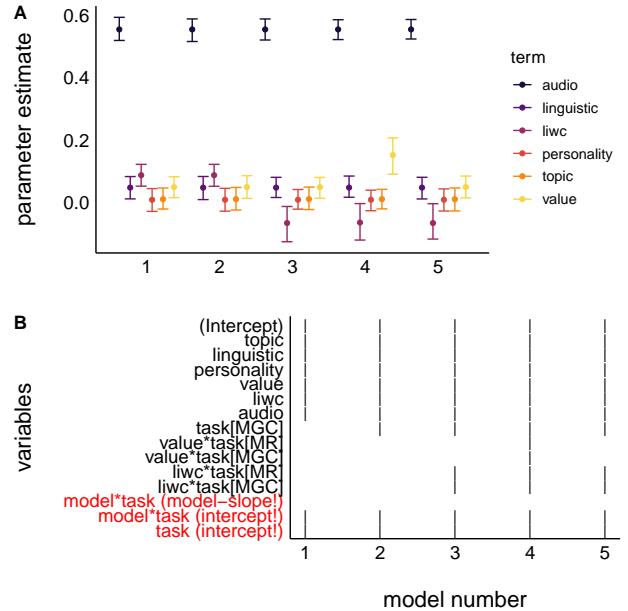
[7] We use the implementation from the *scikit-optimize* package.

[8] We do not search the hyper-parameters for FM and use a manually tuned setup, mostly due to the computational complexity required for this specific model.

$$y_i = a_{j[i]} + \beta x_i + \epsilon_i \qquad (2)$$

$$\alpha_j = a_0 + b_0 u_j + \eta_{j1} \qquad (3)$$

$$\beta_j = a_1 + b_1 u_j + \eta_{j2} \qquad (4)$$

where i refers to the individual students, and $j[i]$ refers to the school that student i attends. The first line is similar to a classic regression, where the x represents a predictor at the level of student, the teaching technique in our example, and the ϵ represents the error term of the main regression. However, equations (3) and (4) allow for the modeling of the intercept and slope respectively, where the u and η expressions are the predictors and error terms at the school levels.


By statistically controlling for these additional variances, hierarchical modeling allows for a more precise estimate of the variables of interest. A more complete discussion can be found in [36].

In our study, we treat the task similarly to the school in our example, and the systems similarly to the students. By controlling for these variances, we estimate the effect of each feature set. From the resulting parameter estimates, we extract 95 % confidence intervals, which we then interpret for our results.

This approach also allows for the comparison of models containing different specifications, where the specifications refer to which specific parameter estimates are computed. As some parameters may not meaningfully contribute to the variance, their effects will be estimated at very close to 0, and may be removed to improve model fit. Indices of fitness, i.e. Akaike and Bayesian Information Criteria (AIC and BIC respectively) give an estimate of model fit, which is penalized by the number of terms. We can therefore arrive at the best-fitting model with the fewest parameters estimated, by systematically removing poorly performing parameter estimates, comparing successive fit indices e.g. with a Likelihood Ratio Test.

Following from our strategy, we examined the usefulness of the inclusion of the various features sets on the 3 considered MIR tasks. Our variables of interest are 1) binary indicators for the inclusion of each of the feature sets: *linguistic*, *topic*, *LIWC*, *personality*, and *values*, as well as the set of audio features, where (0 = not included, 1 = included), 2) a categorical variable representing each of the MIR tasks, 3) a categorical variable representing the systems implemented within each task, and 4) the resulting Measurement scores which were standardized within each task for comparability. We further estimate whether feature sets perform better or worse for certain tasks, by examining interactions between each feature set, and our task variable. Feature sets had differing numbers of sub-dimensions which were not individually analyzed (see Table 1) [9].

We ran multiple models and compared the results of our feature sets across specifications (see Figure 2). Model specifications varied based on 1) how we accounted for the nested structure (i.e. task and systems), as we can estimate

---

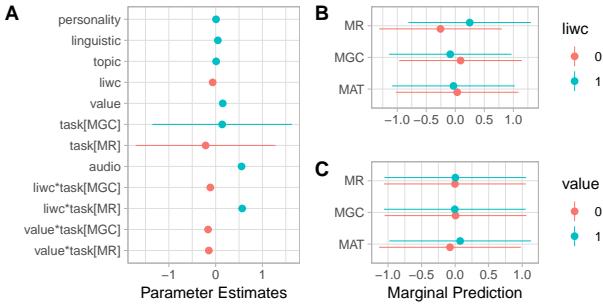
[9] Analyses were conducted on two servers running R 3.6.3. and 3.4.4.


Figure 2. A: Parameter estimates of 5 hierarchical regression models. Error bars are 95% confidence intervals, bootstrapped 500 times. B: Specific parameters that are estimated in the each of the models. Parameters that form the structure of the model are denoted both in red and with a "!" symbol, feature sets of primary interest are denoted in black, and variables for which two terms separated by a "*" are interaction terms.

intercepts for task, for system, for system within task, as well as as slopes for tasks, for systems, and for systems within task, etc., and 2) the interaction terms we specified, i.e. whether we estimated an interaction term for a given feature set and our task variable.

8. RESULTS

We assessed models with two nested structures specified, where the parameters estimated are referred to as "random effects". The first included intercepts for each task, and the system used within task. The second estimated the same intercepts, and additionally estimated a slope for each system. For each of these two random effects structures, we then determined which parameters to estimate, referred to as "fixed effects". Specifically, we estimated parameters for each feature set, and interactions between all feature sets and the tasks. We first specified a "maximal" model, with all features and the task variable, and all two-way interactions among these variables. To remove unnecessary parameters, we ran a protocol which iteratively removed parameter estimates, retaining only those that either 1) significantly decrease model fit if not included, or 2) do not significantly decrease model fit if excluded. The Step function in the *lmerTest* package, was used for this phase [37]. What remained were two interaction terms: the interaction between *values* and task, and between *LIWC* and task. As such, we estimated models with no interaction terms, as well as models with and without each of those inter-

Figure 3. A: Parameter estimates of model 4. Error bars are 95% confidence intervals. Interaction terms are denoted with the "*" symbol. B: Predicted scores for the inclusion of *LIWC* on each of three MIR tasks, where 1 indicates that it was included and 0 indicates that it was not. C: Predicted scores for the inclusion of *values* on each of three MIR tasks, where 1 indicates that it was included and 0 indicates that it was not.

action terms. When we assessed the interaction term, we also included the main effect of task. Thus, we also ran models with and without task included. The 5 models included for interpretation were those that converged without error. Parameter estimates are shown in Figure 2A, and Figure 2B shows which parameters were estimated in each model. For the full specification of our models, we refer the readers to the reproducibility package [10] accompanying this paper.

As is shown in Figure 2A, we observe a consistent, large, positive effect of *audio features* on the score, and no meaningful effects of *topic* and *personality* feature sets. Further, we observe a consistent, small, positive effect of *values* across our specifications. This effect size increases in model 4, where the interaction between values and task was included. Similarly, *LIWC* shows a small but positive effect, that appears to decrease when the interaction term of *LIWC* and task is included. This suggests that *LIWC* and *values* may perform differently, depending on the task.

To clarify if this is the case, we examined the parameter estimates of model 4, which included interaction terms for both *LIWC* and *values* (see Figure 3A). Although both interaction terms were statistically significant, we observe that the confidence intervals for the main effect of task are very wide. This was expected, as 1) we were assessing an interaction effect which might increase the width of a the confidence interval, and 2) we were largely accounting for this variance by standardizing the score within each task, and by including task in the random effect structure. Figures 3A and 3B show the predicted values for both *LIWC* and *values* across tasks. Although the score was higher when *LIWC* was included in the MR task and when *values* was included in the MAT task, the predicted estimates are imprecise, as evidenced by the wide confidence intervals. As such, a more sensitive study design is likely required to obtain estimates of these interaction effects, e.g. analyses

on individual dimensions of feature sets, to establish the most informative features, and/or more systems and more MIR tasks. Thus, we conclude that *linguistic* and *values* feature sets show the most consistent positive effects, and that *LIWC* and *values* may vary in performance based on task.

9. LIMITATIONS AND FUTURE WORKS

Several limitations are still present in our current study. Firstly, although our feature sets did show promising yet small effect sizes, we did not assess the performance of individual dimensions. Given that the feature sets vary greatly in both in terms of the number and content of sub-dimensions (see Table 1), reducing the overall set may result in a more sensitive set of features to examine.

Secondly, we did not consider subgroups of users, or of groups of songs. It may be possible that some users are more sensitive to the content of lyrics than others, and that lyric-sensitive users would benefit far more from lyric features than others. Further, it may be the case that lyrics are very important in some groups of songs vs. others (e.g Hip-Hop music vs. electronic dance music). Further research could examine the potential existence of a lyric-sensitive sub-group of users, lyric-sensitive songs, and how these two may interact.

Thirdly, aspects of our experimental design can be elaborated in future work: 1) Although we strategically sampled a limited number of MIR tasks and a limited number of systems, we did not fully address all possibilities. For instance, future work can include more contemporary systems such as deep learning, thereby increasing generalizability of our results. 2) Certain task metrics could be improved, although we strategically designed our experiment to prevent local noise from skewing our conclusions: e.g. a different performance measure for the genre classification (i.e. AUC-ROC) could deliver a more accurate experimental result, given its skewed class distribution.

Lastly, the reliability of all of our feature sets could be better assessed in the future. This is particularly true of our *personality* features: they contain words that have been shown to describe individuals that have or lack in personality traits, but it is not clear that individuals with those traits use the specific words that describe them.

10. CONCLUSION

Although the *audio* features in our analysis most positively affected performance on various MIR tasks, our lyric-based text features did show some promise. More specifically, *linguistic* and *values* feature sets showed consistent, small effect sizes. Given that the interactions between *LIWC* and task were significant, it may be the case that *LIWC* features are also useful. We can conclude that text-based features drawn from Psychology literature anticipate further research, and that further investigations addressing the current limitations will lead to better data-driven understanding of the role lyrics play in music consumption.

ABSTRACT

Many musics across the world are structured around multiple *modes*, which hold a middle ground between scales and melodies. We study whether we can classify mode in a corpus of 20,865 medieval plainchant melodies from the Cantus database. We revisit the traditional 'textbook' classification approach (using the final, the range and initial note) as well as the only prior computational study we are aware of, which uses pitch profiles. Both approaches work well, but largely reduce modes to scales and ignore their melodic character. Our main contribution is a model that reaches 93–95% F_1 score on mode classification, compared to 86–90% using traditional pitch-based musicological methods. Importantly, it reaches 81–83% even when we discard all absolute pitch information and reduce a melody to its contour. The model uses tf–idf vectors and strongly depends on the choice of units: i.e., how the melody is segmented. If we borrow the syllable or word structure from the lyrics, the model outperforms all of our baselines. This suggests that, like language, music is made up of 'natural' units, in our case between the level of notes and complete phrases, a finding that may well be useful in other musics.

1. INTRODUCTION

In his seminal Grove entry, Harold Powers [1] points out a remarkable cross-cultural generalisation: many musics are structured around multiple *modes*. Modes are often associated with the major–minor distinction in Western music, but there are much richer systems of modes: examples include Indian *raga*, Arabic *makam*, Persian *dastgah*, *pathet* in Javanese gamelan music and the *modes* of Gregorian chant. The specifics obviously vary, but all these phenomena share properties with both scales and melodies, and are perhaps best thought of as occupying the continuum in between [1]. On the one hand, a mode is more than a scale: it might imply a hierarchy of pitch relations or favour the use of characteristic motifs. On the other hand, it is not as specific as a particular tune: a mode rather describes a melody *type*. Modes are of central importance to their musical tradition, both as means to classify the repertoire, and

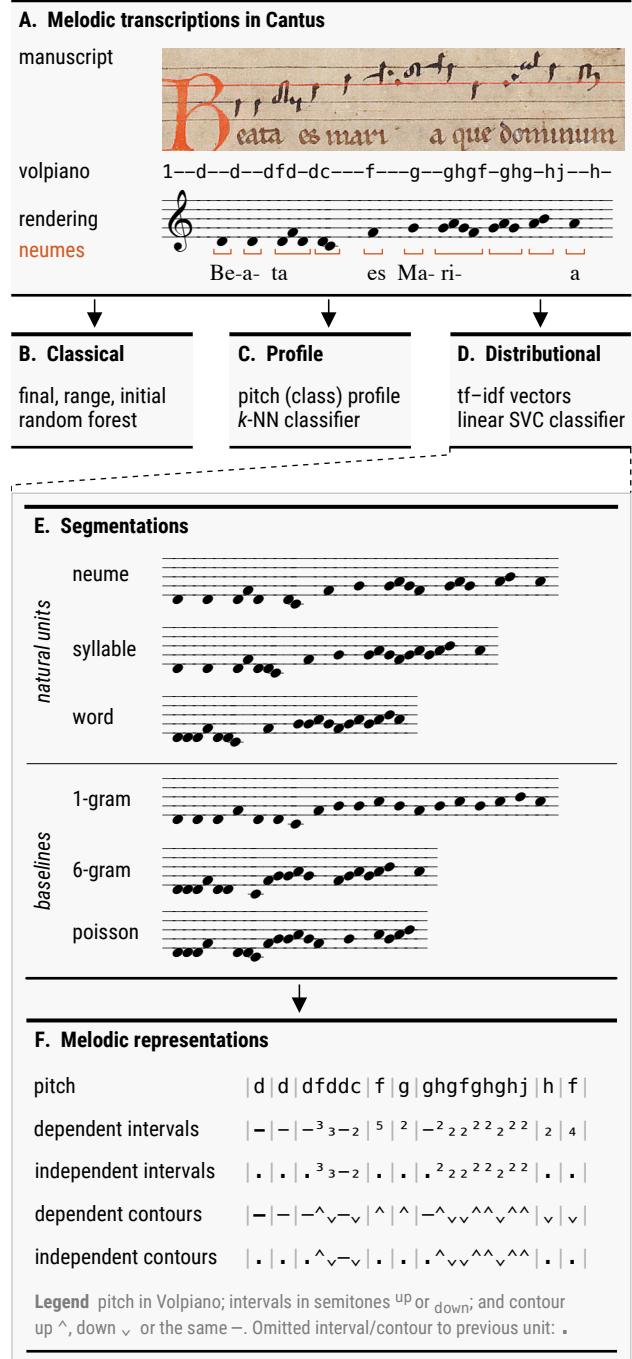
as practical guides for composition and improvisation [1]. Characterising modes computationally is therefore an important problem for *computational ethnomusicology*.

Several MIR studies have investigated automatic mode classification in Indian *raga* [2, 3], Turkish *makam* [4, 5] and Persian *dastgah* [6, 7]. These studies can roughly be divided in two groups. First, studies emphasising the scalar aspect of mode usually look at pitch distributions [2, 5, 7], similar to key detection in Western music. Second, studies emphasising the melodic aspect often use sequential models or melodic motifs [3, 4]. For example, [4] trains *n*-gram models for 13 Turkish makams, and then classifies melodies by their perplexity under these models. Going beyond *n*-grams, [3] uses motifs, characteristic phrases, extracted from raga recordings to represent every recording as a vector of motif-frequencies. They weigh counts amongst others by the *inverse document frequency* (see section 3.4), which balances highly frequent motifs, and favours specific ones.

In this paper, we focus on automatic mode classification in Medieval plainchant. This has only rarely been studied computationally, even though the term (if not the phenomenon) 'mode' originates there. At first glance, mode in plainchant is relatively clear, though certainly not entirely unambiguous. With a second glance, it has a musicological and historical depth that inspired a vast body of scholarship going back over one thousand years. The music is indeed sufficiently distant in time from most other musics, including Western classical and pop music, to provide an interesting cross-cultural comparison. And for once, data is abundant, thanks to the immense efforts of chant scholars.

Chant has mostly figured in MIR studies in optical music recognition of medieval manuscripts: the SIMSSA project, for example, has used such systems to transcribe plainchant from the Cantus database [8]. Recent ISMIR conferences have also included analyses of Byzantine plainchant [9] and Jewish Torah tropes [10], and a comparison of five Christian chant traditions using interval *n*-grams [11]. But, to the best of our knowledge, Huron and Veltman's study [12] is the only computational study addressing mode classification in chant. They took a scalar perspective on mode by using pitch class profiles, an approach which was later criticised, partly for ignoring mode's melodic character [13].

We aim to revisit this work on a larger dataset, and also to model the melodic aspect of mode. Concretely, we compare three approaches to mode classification:

1. **Classical approach:** based the range, final, and initial note of a chant.


2. **Profile approach:** uses pitch, pitch class and repetition profiles (cf. [12]).

3. **Distributional approach:** uses tf–idf vectors based on various segmentations and representation of the melody.

2. GREGORIAN CHANT

Gregorian chant is the monophonic, Latin chant sung during services in the Roman church. It started out as an oral tradition, coexisting with several others in late Antiquity. Although the specifics are debated [14, ch. 2], from the 9th century onwards it gradually turned into a (partly) written tradition, displacing other chant traditions. Initially, only the texts of the chants were written down, as singers would know the melodies by heart. Chant is rooted in recitation, and the music and text are intimately related: "the basic unit of music-writing [was] not the note, but the syllable" [15], the smallest singable unit of text. Accordingly, the earliest notation lived between the lines of text: signs, called *neumes*, reminding the singer of the contour of the melody: perhaps how many notes and their direction, but not *which* exact pitches. The earliest melodies are therefore unknown, but later manuscripts use a pitch-specific notation by placing neumes on staff lines, preserving those melodies to the present day (see Figure 1A).

There are different chant genres for different parts of the liturgy, each with own musical characteristics [16]. Some genres consist of recitations of a sacred text mostly on a fixed pitch, with common starting and ending formulae, while others use elaborate melodies and few repeated notes. Genres also differ in their *melismaticness*: the number of notes per syllable (see Figure S5). In *syllabic* genres like *antiphons*, every syllable of text aligns with roughly one note. More melismatic genres like *responsories* align single syllables to long melismas of ten notes or more. In this paper, we focus on antiphons and responsories, two melodic and common genres.

Gregorian chant uses a distinct tonal system of eight modes, usually numbered 1–8, but sometimes named like church scales. Modes come in pairs that share the same scale (*Dorian*, *Phrygian*, *Lydian* or *Mixolydian*), but have a different range or *ambitus*: *authentic* modes moves mostly above the tonal center or the *final*, *plagal* ones mostly around it. Mode 3 is for example also called *Phrygian authentic*, and melodies in this mode rarely go below the final note E. The standard way of determining the mode is to first determine the final, and then the range [16]. For the majority of the chants this will be sufficient, but one might further consider the initial note, characteristic phrases or circumstantial evidence (e.g. psalm tones). Nevertheless, the mode of some chants will remain ambiguous: the *theory* of eight modes was borrowed from Byzantine theory in the 8th century, and applied to an already existing chant repertoire (with its own modalities [13]). The fit between theory and practice was reasonable, but not perfect [1]. This also suggests that perfect classification accuracy is likely out of reach.

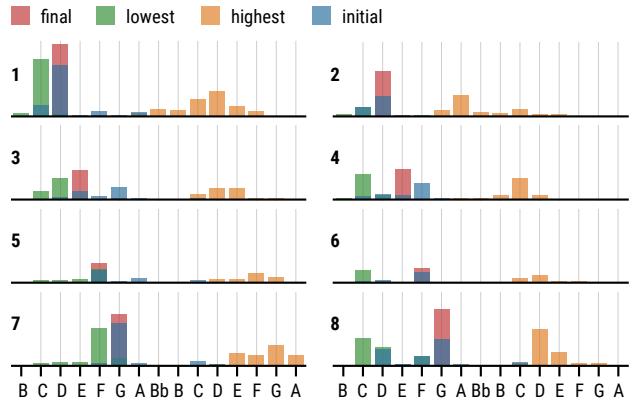
Figure 1. **Overview of this study** which compares three approaches to mode classification in a corpus of Gregorian chant. Cantus contributors have transcribed a vast number of melodies from medieval manuscripts (**A**). We classify mode based on the final, range and initial in the *classical approach* (**B**), and based on pitch (class) and repetition profiles in the *profile approach* (**C**). Finally in the *distributional approach* (**D**), we use tf–idf vectors where we tweak two parameters: the *segmentation*, or which melodic units we use (**E**), and the *representation* (**F**), where we gradually discard information about the scale when we move from pitches to contours. In this way we aim to capture the melodic, rather than scalar, aspect of mode.

3. METHODS

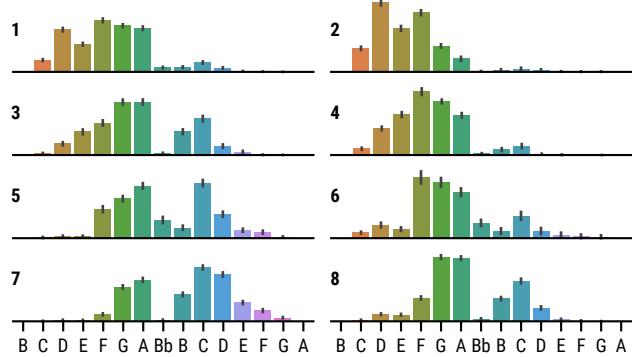
The design of this study is visualized in Figure 1.

3.1 Data: the Cantus Database

We use chant transcriptions from the Cantus database [17]. This is primarily a digital index of medieval chant manuscripts, recording the chant location in the manuscript, its full text, and properties like the mode, the liturgical feast, but also links to manuscript images. Cantus currently consists of almost 150 manuscripts, containing over 450,000 chants, contributed by chant scholars from all over the world. Over 60,000 chants also contain melodic transcriptions written in Volpiano.[1] It sets plain text as musical notes on a five-line staff, as illustrated in Figure 1a. Volpiano also supports some accidentals, clefs, liquescents, barlines and strokes. All submissions to Cantus are subject to strict guidelines and manually checked by the Cantus editors (see also [18]). This ensures the quality and consistency of database, making it a valuable resource for computational research.

We scraped the entire database of 497,071 chants via its REST API and we have released this as the CantusCorpus.[2] We here only consider chants that have a Volpiano transcription (63,628 chants) and further filter out chants with incomplete or non-standard transcriptions, without a complete melody, without 'simple' mode annotation, and exact duplicates (see section S1). This resulted in 7031 responsories (966,871 notes, avg. length 138 notes) and 13,865 antiphons (825,143 notes, avg. length 60 notes). We fixed a 70/30 train/test split for all datasets and only used training data in exploratory analyses. Cantus often contains multiple variants of any particular melody, transcribed from different manuscripts (see Figure S11). One may wonder whether the simple train/test split is sufficient, or whether even more care is needed to avoid overlap between such melodic variants in the train and test sets. This is a difficult issue that also applies to other musical corpora (e.g., the Essen folk-song corpus), and for which there is no perfect solution. We tried repeating our experiments on a subset without variants and return to this issue in section 4.4.


According to the transcription guidelines, flat symbols are transcribed only once, directly before the first flattened note. We replace the first and later flattened notes by the corresponding accidental, a Volpiano character that sits at a specific staff line. In this way, flat notes are also encoded by a single Volpiano character. We discard characters like clefs and pausas, and only retain the notes, accidentals and boundaries (hyphens). The resulting string is used in our three classification experiments, which we now discuss.

3.2 Classical Approach: Final, Range, Initial


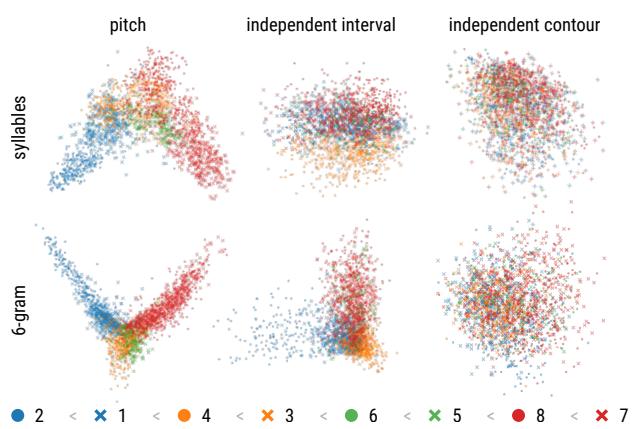
The first approach is motivated by the classical procedure for mode classification. We extract three features from every chant: the final pitch, the range (lowest and highest pitches)


Figure 2. Classical features. The classical approach uses the final, range and initial to determine the mode. The overall distribution for each of the modes (1–8) is clearly different, although not entirely without ambiguity.

Figure 3. Pitch profiles showing the relative frequency of every pitch in each of the 8 modes. Again, although the distribution of individual modes are clearly distinct, some residual ambiguity remains.

Figure 4. PCA of tf–idf vectors. Principal component projection of the tf–idf vectors of responsories in several conditions. The figure suggests that classification gets harder when moving from a pitch to a contour representation. The legend shows a theoretical ordering of the modes based on their range. See Figure S9 and Figure S10 for larger plots.

and the initial pitch. Theory suggests that the final alone should give an accuracy of roughly 50%, and adding the range should further increase that by roughly 50%, if there is no ambiguity. Figure 2 shows the feature distributions for all modes. It suggests that there is some ambiguity, and so numbers will be a little lower. For this task we use random forest classifiers [19], which aggregate multiple decision trees. Training details of all models are discussed below.

3.3 Profile Approach: Pitch (Class) Profiles

The second approach is inspired by Huron & Veltman [12]. Using 97 chants from the Liber Usualis, they compute average *pitch class profiles* (the relative frequency of each pitch class) for each of the modes and then classified chants to closest profile. We take a similar approach and use k-nearest neighbour classification, where k is tuned (see section 3.5). In a commentary, Wiering [13] argued for using actual pitches rather than pitch classes, as the pitches an octave above the final have a very different role than those an octave below it. We follow that suggestion by also computing *pitch profiles* (Figure 3). Finally, we propose a *repetition profile* aiming to describe which notes function like a recitation tone. For every Volpiano pitch q we compute a repetition score $r(q)$, which is the relative frequency of direct repetitions, and collect these to get a repetition profile. Formally, if a chant has pitches $p_1, \ldots, p_N$, then $r(q) = \#\{i : p_i = q \text{ and } p_{i+1} = q\}/(N-1)$ since there are $N-1$ possible repetitions.

3.4 Distributional Approach: tf–idf Vectors

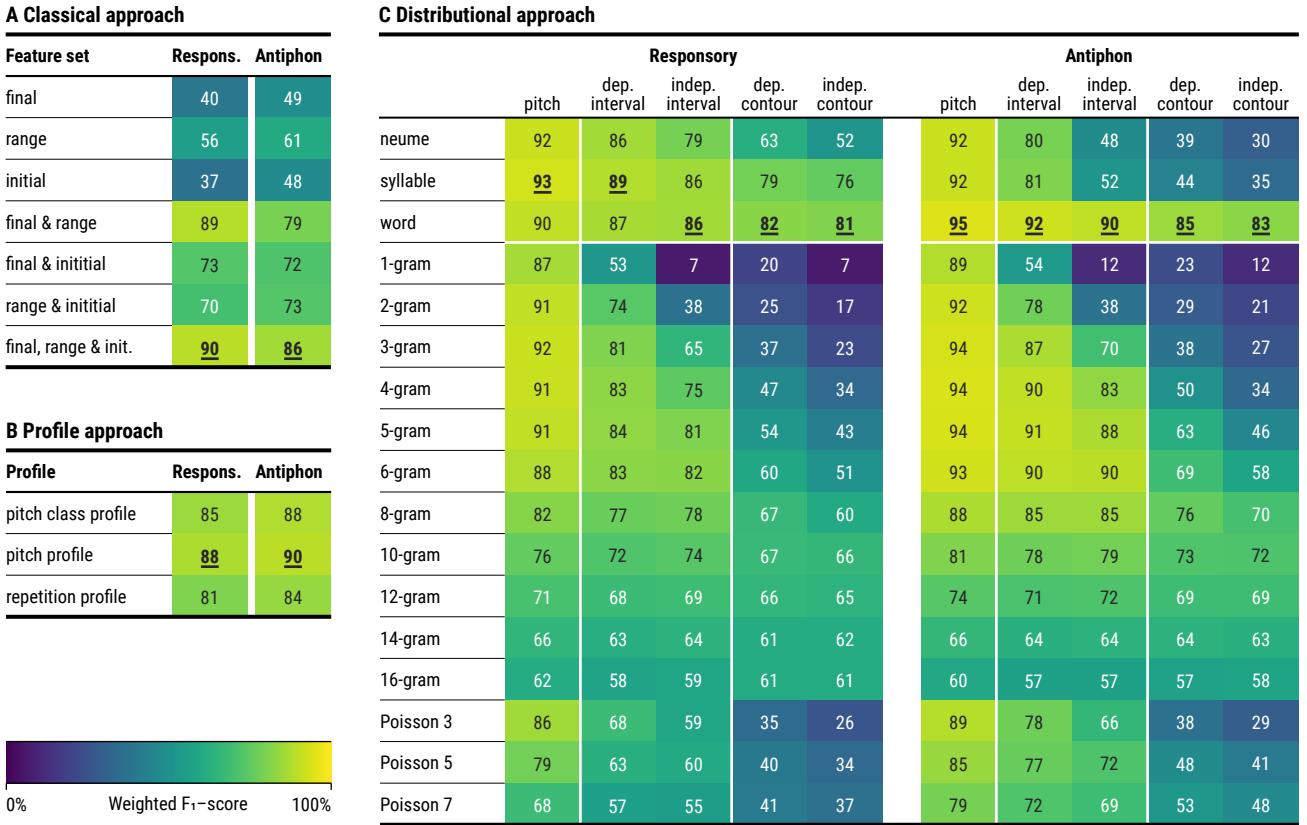
Our third approach aims to capture the melodic aspect of mode. In short, we use a bag of 'words' model (cf. [3]) and tweak two parameters: the segmentation (which melodic units to use as 'words') and the representation (pitches, intervals and contours). The idea is to discard more and more information about the scale, and see if we can nevertheless determine the mode.

First, the units. For chant, three natural segmentations suggest themselves: one can segment the melody (1) at neume boundaries, but also wherever we find (2) a syllable or (3) a word boundary in the lyrics. Given the close relation between text and music in chant, there is some reason to believe that these are meaningful units. Conveniently, all of these boundaries are explicitly encoded in Volpiano, by a single, double and triple dash respectively. Note that these natural units are nested: neumes never cross syllable boundaries. We compare the natural units to two types of baselines. The first is an *n*-gram baseline where we slice the melody after every *n* notes, for $n = 1, \ldots, 16$. The second is a random, variable-length baseline. Here the melody is segmented randomly, but in such a way that the segment length is approximately Poisson distributed with a mean length of 3, 5, or 7. We stress that all these units are proper segmentations: units do not overlap. In particular, we choose not to use a higher-order model (using *n*-grams of units), because we are only interested in comparing different segmentations.

Second, the representation. We represent melodies in three ways: as a sequence of *pitches*, *intervals* (the number of semitones between successive notes) and *contours* (the contour between successive notes: up, down or level). There is one complication when segmenting sequences of intervals or contours: we introduce dependencies between the units. All units would, for example, start with the interval from the previous unit. We call this a *dependent* segmentation. Alternatively, you could discard the intervals between units to obtain an *independent* version. This effectively makes every unit one interval shorter. We analyse both independent and dependent versions, but in the independent one we found it convenient to start all units (including the first) with a dot to keep the segmentation identical across representations. You can think of the dot as marking the omitted interval to the previous unit.

Third, the model. Given a segmentation, we represent every chant by a vector of unit frequencies, but weighted to favour frequent, yet *specific* units: units that do not occur in too many chants. A standard way of doing this in textual information retrieval is using *term-frequency inverse-document-frequency* (tf–idf) scores, which multiply the frequency of a term in a document (tf) by the inverse document frequency (idf): the inverse of the number of documents containing the term. We use +1 smoothing for the idf, at most 5000 features, and found it was important *not* to set a minimum or maximum document frequency. We train a linear support vector machine to classify mode using the resulting tf–idf vectors.

In sum, we analyse 22 segmentations (3 natural ones, 16 *n*-grams, 3 random) and 5 representations (pitch and dependent/independent interval/contour), giving a total of 110 conditions.

3.5 Training


We tune every model using a randomised hyperparameter search with 5-fold stratified cross-validation. That is to say that we randomly sample hyperparameters from a suitable grid (determined by extensive manual analyses) and determine their performance using 5-fold cross-validation on the training set, where we ensure the class frequencies are similar in all folds. We use the hyperparameters yielding the highest cross-validation test accuracy to train the final model. All models were implemented in Python using scikit-learn [20] and data and code are available online. [3]

4. RESULTS

Figure 5 gives support-weighted [4] averages of F_1-scores obtained on the full test sets for all three approaches. The scores are averages of five independent runs of the experiment, using different train/test-splits. Standard deviations were small and are included in figure S12. We now compare the three approaches and then discuss the effect of representation and segmentation on the distributional approach.

Figure 5. **Classification results.** Weighted F_1-score for three approaches to mode classification, using two chant genres: responsories and antiphons. Scores are averages of five independent runs of the experiment. The classical approach (**A**) using the final, range and initial reaches F_1-scores of 90% and 86%. The profile approach (**B**) works better for antiphons (90% vs. 86%) and somewhat worse for responsories (88% vs. 90%). As [13] suspected, pitch profiles outperform pitch *class* profiles by a small margin. The distributional approach (**C**) reaches the highest F_1 scores of 95% on both responsories and antiphons. The choice of segmentation (vertically) is crucial: classification is improved by using 'natural' units, word-based units in particular, rather than *n*-grams. As the representation (horizontally) becomes cruder, from pitches to intervals and finally to contours, the task becomes much harder. But, when using word-based segmentation, performance remains high.

4.1 Approaches: Distributional Approach Works Best

First of all, we report the highest classification scores with our distributional approach using pitch representations: an F_1-score of 93% for responsories and 95% for antiphons. This corresponds of an error reduction of 30–60% compared to the classical approach (90% and 86%). The classical approach confirms the rule of thumb: the range and final are very informative features. Using only these, we obtain F_1-scores of 89% and 79%, which are further increased by also adding the initial. The profile approach outperforms the classical approach for antiphons (90% vs. 86%), but is outperformed for responsories (88% vs. 90%). Our results support Wiering's [13] intuition that pitch profiles more accurately describe mode than pitch *class* profiles, but the effect is small: it increases F_1 scores by 2–3%. Repetition profiles appear to be less useful for both genres.

In broad strokes, our results validate the classical and profile approach, both of which peak around a 90% F_1-score, using simple features. The distributional approach improves this, up to 95% using complex features. Importantly, we now show that the distributional approach maintains high performance when using interval or contour representations.

4.2 Representations: Contours are Sufficient

We find that the classification task gets harder when the representation gets cruder, from those based on pitch, to intervals and finally to contours (figure 5C, horizontally). This was anticipated: cruder representations are obtained by discarding information from every unit. Shorter units are impacted more by this information loss. For example, the performance with 1-grams drops by over 75% when moving from pitch to independent contour representation. At that point it performs at majority baseline (a 7% F_1-score for responsories and 12% for antiphons). [5] For longer units such as 10-grams, the drop is not as dramatic (around 10%). However, this comes at the cost of a comparatively low performance using the pitch-representation, presumably because of increasing sparsity.

Natural units, however, escape this trade-off. Word-based segmentations perform consistently well, dropping

---

[5] For 1-grams in independent interval *and* contour representation, every unit is identical: a dot representing the omitted contour to the previous note. The majority class for both responsories and antiphons is mode 8, taking up 21% and 28% of the test data respectively (see table S3). This is precisely the accuracy of the model in those conditions.

only 3% below the classical baseline using the highly impoverished independent contour representation. In contrast to the other representations, the contours do not carry any information about the scale: the same contour can be reproduced in any scale. Apparently, we can discard the scalar aspect of mode, and still classify it: contours alone contain sufficient information for mode classification. The success of pitch-based methods might obscure the fact that mode is as much a melodic phenomenon as a scalar one.

It is interesting to note that the earliest chant notation used *unpitched* neumes that mainly described the contour of the melody—not the exact pitches. Our results reinforce the idea that contour is highly informative—so informative that given a mode, text and contour, an experienced singer could reconstruct the chant melody.

4.3 Segmentations: Natural Units Work Best.

Our most important result is that among all the representations we considered, natural units (neume, syllables, and words) yield the highest classification performance. The 4- and 6-gram baselines also reach top F_1-scores in antiphons, but only when we use representations that include information about pitch. Furthermore, the success of natural units cannot be explained solely by their length. In responsories, neumes, syllables and words are on average 2.3, 3.0 and 7.1 notes long, respectively (see table S6), and yet the performance of these natural units is consistently higher than n-grams of comparable length. The performance of the natural units is also consistently higher than that of the variable-length Poisson baselines, which are intended to mimic the overall distribution of natural lengths but ignore musical and textual semantics.

A few other observations merit discussion. Firstly, although neume and syllable segmentations behave differently for responsories, they behave similarly to each other for antiphons. The reason may be that in antiphons, neumes and syllables more often coincide. Antiphons are less *melismatic* than responsories (i.e., they use fewer notes per syllable, 1.5 to be precise). Secondly, both the n-grams and the Poisson baseline perform better on antiphons than on responsories, possibly because the n-grams are more likely to end up being coincidentally aligned with the natural units the less melismatic the genre.

4.4 Controlling for Melodic Variants

We repeated all experiments on a subset of the data from which we removed melody variants (see supplement S13 for details). In terms of the number of notes, this meant a 75% and 66% reduction in data size for responsories and antiphons respectively. The performance of all models decreased on this subset, and for responsories more than for antiphons. Our main findings that contours are sufficient and that natural units work best across representations stand. We do observe some reorderings: some already high-performing n-grams in antiphons now for example slightly overtake word segmentations, although only for pitch and dependent interval representations. The distributional approach works best for antiphons regardless of including or excluding chant variants, but for responsories, the distributional approach drops slightly below the classical approach on the subset (where the profile approach is worst). These findings might be explained by increased sparsity in the smaller dataset: natural units in responsories are, after all, longer. Exploring these issues further is left for future work.

5. DISCUSSION AND CONCLUSION

In this paper, we analyzed three approaches to mode classification in a large corpus of plainchant: (1) the classical approach using the final, range and initial; (2) the profile approach using pitch (class) profiles and (3) the distributional approach using a tf–idf vector model and various segmentations and representations. We found that the distributional approach performs best, and that it can maintain high performance on contour representations if using the right segmentation: at word boundaries, in this case. The main findings were largely upheld when we removed melody variants, but the handling of variants is an issue that deserves further investigation and that has implications beyond this study.

Although our results are specific to one corpus of medieval music and one classification task, we believe our conclusions are of wider relevance. We often fall back on n-grams because they are well understood and easy to use. A more natural segmentation may be harder to obtain, but if finding them can have such a large effect on a relatively simple task like mode classification, their advantages may be even stronger for more complex tasks.

A first next step could be to explore whether lyrics yield equally useful units in other vocal musics. As noted, the link between text and music in plainchant is particularly tight. This at least suggests that the text may be useful in other types of chant, like Byzantine chant or Torah trope. For folk melodies designed to standard poetic meters, it is not as obvious whether lyrics would help or hinder the identification of useful units. This is worth investigating, as characteristic motifs and repeated pattern are commonly used in computational folk-song studies, in particular for tune family identification [21, 22].

Our results raise another question: is chant indeed composed by stringing together certain melodic units, much like a sentence is composed of words? It has been suggested (and disputed) that Gregorian chant is composed in a process of *centonization*, and that a chant is a patchwork of existing melodic chunks called *centos*. A recent study used the tf–idf weighting to discover centos in Arab-Andalusian music [23]. This raises the possibility that classification using natural units may have been successful because they indeed are the building blocks, the centos.

Chant is not yet commonly studied in the MIR community, but we hope that this study shows that chant is an interesting repertoire that can yield insights of broader relevance. The immense efforts of chant scholars mean that data are abundant. In short, we think chant can aid the development of models that apply beyond Western classical and pop music, and embrace the true diversity of musics around the world.

ABSTRACT

We introduce CONLON, a pattern-based MIDI generation method that employs a new lossless pianoroll-like data description in which velocities and durations are stored in separate channels. CONLON uses Wasserstein autoencoders as the underlying generative model. Its generation strategy is similar to interpolation, where MIDI pseudo-songs are obtained by concatenating patterns decoded from smooth trajectories in the embedding space, but aims to produce a smooth result in the pattern space by computing optimal trajectories as the solution of a widest-path problem. A set of surveys enrolling 69 professional musicians shows that our system, when trained on datasets of carefully selected and coherent patterns, is able to produce pseudo-songs that are musically consistent and potentially useful for professional musicians. Additional materials can be found at `https://paolo-f.github.io/CONLON/`.

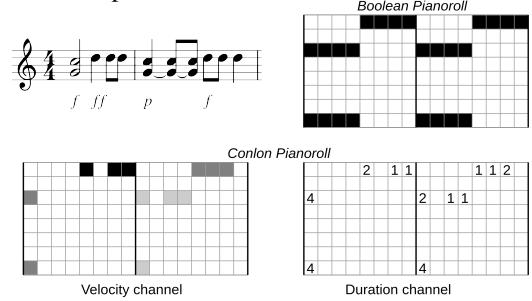
1. INTRODUCTION

Algorithmic music generation has attracted the interest of musicians and practictioners for long time, starting from early works by Guttman, Hiller and Isaacson [1] and Xenakis [2] in the 1950's. Significant progress has recently resulted from the widespread application of new and powerful methods based on deep generative models, letting this class of data-driven approaches gradually take over more traditional rule-based or probabilistic techniques [3, 4]. This thriving line of research spans several dimensions of the generation process, including different types of data: audio signal [5, 6] vs. symbolic MIDI data; musical textures: monophonic [7] vs. polyphonic [8, 9]; ensembles: single-instrument [9] vs. multi-instrument [7]; goals: e.g., continuation [10], accompaniment [11], style transfer [12–14], or interpolation [7, 14].

We are particularly interested in developing a tool for a context where the automatic generation and proliferation of new music material (not necessarily finished pieces) is useful to assist musicians in music and media production. Usefulness in this context may have different facets: supporting and accelerating personal explorations of unknown or semi-known music areas, collecting intra-genre or cross-genre ideas of various complexity and abstraction, augmenting the composer's ability to explore the combinatorial space of rhythmic, melodic, and harmonic variations. In other words, what Boden calls "exploring conceptual spaces" [15]. In spite of the impressive amount of recent advancements in music generation with machine learning approaches, the musical quality of the results is still not always sufficient to enable a widespread adoption in realistic professional scenarios such as studio production using standard Digital Audio Workstations (DAWs) or live performance of electronic music.

In this paper, we focus on the autonomous generation of polyphonic and multi-instrument MIDI partitures, aiming at producing relatively long *pseudo-songs* (i.e. tracks that have the duration of a song but whose temporal structure is not controlled by a compositional intent) in mainstream genres such as Acid Jazz, Soul or High Pop, that are effectively *usable* in a professional music production context. We argue that achieving this goal requires not only the effective exploitation of algorithmic ideas but also a careful selection of coherent musical materials to be used as training data. Unlike the case of image data, where there exist large scale high quality coherent datasets (for example CelebA [16] focusing on human faces), existing symbolic music datasets for mainstream music contain large variations in genre, style, and track/instrument role, that make it more difficult to learn to generate musically coherent pseudo-songs. In the attempt to verify the impact of dataset quality on the results, we introduce in this paper (perhaps for the first time in this research area) two new datasets that were not extracted from existing collections but that have been especially composed and edited by two musicians made aware of creating training sets for generative models. One dataset, ASF-4, is in Acid Jazz, Soul and Funk; the other one, HP-10, in High Pop. Compared to datasets used in other experiments (e.g. LPD-5 [17]) they are small, i.e. of a size that individual musicians would be able to compose or curate by themselves. This opens up the

possibility of personalized generators, assisting musicians in producing their own music.

From the algorithmic point of view, possible solutions to the music generation problem can be characterized across several separate dimensions (see [3] for a thorough taxonomy). The most important ones for the goals of this paper are (1) the type of data structures that are used to describe MIDI patterns (2) the nature of the generative learning models, and (3) the strategy used to produce a whole musical piece. The system presented in this paper introduces novelties across all these three dimensions, whose combination allows us to generate meaningful and professionally usable streams of music. In terms of data description, we introduce a novel pianoroll-like pattern description that stores velocities and durations in two separate channels. The description is lossless (i.e., it can be inverted to recover the original MIDI data exactly) and perceptually robust to reconstruction errors (i.e., it does not suffer the note shattering problem associated with binary pianorolls that store consecutive high bits to represent note durations). As a generative model, we experiment with Wasserstein autoencoders (WAE) [18], a type of autoencoder that is less subject to the "blurriness" problem typically associated with variational autoencoders (VAE) [19]. To the best of our knowledge, WAEs have not been applied to music generation before. Third, our generation strategy is based on interpolation as in previous works [7,14] but we formulate it as an optimization problem for exploring the autoencoder latent space in a way that prevents abrupt transitions between consecutively generated patterns, as well as regions with little variation.


We call our system CONLON, for Channeled Onset of Notes and Length Of Notes, and in honor of Conlon Nancarrow (1912–1997), a pioneer of piano roll compositions. A thorough evaluation with human experts suggest that CONLON is able to produce pseudo-songs that are truly exploitable by professional musicians in mainstream genres.

2. A NEW PIANOROLL WITH EXPLICIT DURATIONS

Each track in a MIDI stream consists of a sequence of time stamped events. We consider here only two types of note events: $\mathrm{ON}(t, n, v)$, and $\mathrm{OFF}(t, n)$. Here t denotes the time at which a note with pitch n begins or ends, measured in MIDI clock pulses. In general, n takes values between 0 (C-1) and 127 (G9). The MIDI velocity, v, takes values in the integer range $[0, 127]$. Roughly, velocity is associated with the note intensity (allowing to represent dynamic expression elements, such as *pianissimo*, *forte*, or accents in percussive instruments) but depending on the instrument attached to the track, it can also affect timbre (for example, a "clicked" Hammond organ sound could be selected in the sound bank when the velocity exceed a given threshold). Note that although n and v take values in the same range, v should be regarded as a continuous variable and n as a categorical one.

Before this data can be fed into a learning algorithm, it needs to be arranged in a proper description format.

Both variable-lenght and fixed-lenght descriptions have been studied in the literature. Variable-length descriptions are typically used in conjunction with various types of recurrent neural networks (RNNs) [20]. Fixed-length description include the pianorolls (PR) introduced in [21] for melodies and later extended to the multitrack polyphonic case [17, 22], and are suitable for modules based on convolutional neural networks (CNNs) [23]. Pianorolls, however, are a *lossy* description of MIDI data in at least two ways. First, they do not include note velocities, which are important for dynamic expression in many musical genres. Second, they make it impossible to distinguish between long notes and repeated occurrences of the same notes (see Fig. 1). The latter limitation can be mitigated by using a finer quantization step or fixed by adding a replay matrix [9]. Still, the PR description may suffer a fundamental problem when there are imperfections in the reconstructions generated by a trained model. In facts, false negatives in the reconstruction may shatter a long note into several shorter ones, which may produce a musically obsessive and unpleasant result.

Figure 1. A short phrase described as PR (top right) and as PR$^\mathrm{C}$ (bottom). To construct a simple example, here we set quantization at 1/8.

The solution proposed in this paper uses a second channel as in [9] but explictly represents note durations as continuous variables. More precisely, in our PR$^\mathrm{C}$ description, the tensor associated with a fixed-length music pattern is constructed as follows. First, we introduce a time quantization function q that maps fine-grained timestamps into coarse-grained temporal positions in the range $1, \ldots, T$. For example $T = 128$ if we quantize four $\frac{4}{4}$ bars at 1/32th. Assuming for simplicity a single instrument and denoting by N the number of pitches in the used range, we create a tensor x of shape $T \times N \times 2$. In the first channel, $x_{q(t),n,1} = v$ if there occurs an event $\mathrm{ON}(t, n, v)$ and $x_{q(t),n,1} = 0$ otherwise. In the second channel, $x_{q(t),n,2} = d$ if there occurs an event $\mathrm{ON}(t, n, v)$ whose duration (expressed in quantized steps) is d, and $x_{q(t),n,2} = 0$ otherwise. The construction is illustrated in Fig. 1. Polyphony is handled naturally in this description and multi-instrument patterns with K tracks can be easily described by allocating two channels for each track as above, resulting in a $T \times N \times 2K$ tensor. Our PR$^\mathrm{C}$ description does not suffer the ambiguity between long notes and repeated occurrences of the same note and, except for time quantization, is completely lossless (i.e., a quantized MIDI pattern transformed into the corresponding PR$^\mathrm{C}$ tensor can be recovered exactly). Ad-

ditionally, it can be perceptually more robust to reconstruction errors. A further advantage is that all the information about a note is local, whereas in the case of PR, a convolutional network requires a wide receptive field to infer the note duration.

3. GENERATING PATTERNS WITH WASSERSTEIN AUTOENCODERS

Generative models that have been applied to music include various types of encoder/decoder architectures, different variants of generative adversarial networks (GAN) [24], as well as transformer based architectures [25]. Variational autoencoders (VAE) [19] have been used in systems like VRAE [26], GLSR-VAE [27] and MusicVAE [7] while GANs have been used in systems like C-RNN-GAN [28] MidiNet [21] and MuseGAN [17, 22].

Both with autoencoders and GANs, a network $G(z)$ (called either decoder or generator) is trained to map a latent or noise vector $z \in \mathbb{R}^{d_z}$ into a pattern. Here we are interested in autoencoder based approaches (see also Section 4.1 for a motivation). Among these approaches, VAEs are theoretically elegant and applicable to music generation. They are regularized by penalizing the expected KL divergence between the posterior $q(z|x)$ and a zero-mean Gaussian prior p_z, with the expectation being taken over training points. However, as nothing prevents different patterns being mapped to close latent codes, the decoder is sometimes asked to reconstruct different patterns from similar codes, resulting into a well known blurriness phenomenon in the case of images [29]. In the case of music patterns described as tensors, we observed that a form of "blurriness" also occurs, resulting in large clusters of notes being played together and sometimes in swarms of short notes that are never present in the training data. WAEs [18] avoid this problem by pushing the expectation inside the divergence, i.e., penalizing a divergence $\mathcal{D}$ between the prior q_z and the *aggregated* posterior $q_z(z) = \mathbb{E}_p \, q(z|x)$, where p is the data distribution. WAEs thus minimize, with respect to the parameters of the decoder, the quantity

$$\min_{q(z|x)} \mathbb{E}_p \, \mathbb{E}_{q(z|x)} \, c(x, G(z)) + \lambda \mathcal{D}(q_z, p_z) \qquad (1)$$

where c is a reconstruction loss and λ a hyperparameter to be fixed. In all our experiments we employed the Maximum Mean Discrepancy (MMD) [30] for $\mathcal{D}$ and a Gaussian prior for p_q, and we structured the encoder and the decoder as in the DCGAN [31] architecture. Note that unlike MuseGAN, which stacks bars over an additional tensor axis and uses 3D convolutional layers, tensors in PR^C can be processed by 2D convolutional layers. The input tensors are normalized in the $(-1, 1)$ range. The final layer of all our decoders has hyperbolic tangent output units. The mean squared error between reconstructions and input patterns was used in the optimization criterion during training.

The latent vector size, d_z, was adjusted with a trial-and-error approach, trying to find the smallest possible value yielding good quality interpolations. If d_z is too small the validation error is large but if d_z is too large, interpolations tend to create many patterns that are too close to those in the training set, in spite of a small validation error (which is therefore not an useful metric). Additionally, nearly empty patterns tend to appear in the middle of interpolations. We found $d_z = 3$ for ASF-4 and $d_z = 5$ for HP-10 and LPD-5 to be a reasonable compromise. The remaining hyperparameters were tuned using random search [32] guided by the validation set reconstruction error. We focused in particular on the learning rate, η, and the number of epochs T used in conjunction with the Adam algorithm; the number of layers n_l; the number of filters n_f and the size of filters, k, used in the the DCGAN encoder and decoder (strides were fixed to 2). Interestingly, large filter sizes $k = 8$ were found to perform better than standard smaller sizes as compact filters are not able to capture musical patterns and distant relationships between notes.

3.1 Converting Generated Tensors to MIDI

In the case of PR^C descriptions, "decoding" a MIDI pattern from the output tensor is almost straightforward (unlike the case of PR, where specialized GAN architectures have been introduced to avoid post-processing based on either hard thresholding or Bernoulli sampling [22]). First, predicted velocities and durations for each time t, pitch n, and instrument i, are rescaled in the range 0–127. Events whose rescaled predicted velocity $v(t, n, i) < 1$ or duration $d(t, n, i) < 1$ (i.e., non-audible notes) are discarded. Finally, we apply the following transformation (similar to a gamma correction) to obtain corrected velocities $v_c(t, n, i)$ as follows:

$$v_c(t, n, i) = \left\lfloor 127 \left(\frac{v(t, n, i)}{127} \right)^{\frac{1}{\gamma_i}} \right\rfloor \qquad (2)$$

where γ_i is an instrument specific correction factor ranging from 2.9 for drums to 4.0 for Rhodes. Durations are directly retrieved from the (rescaled) duration channel.

4. PSEUDO-SONGS

The following approach assumes that a generative model $G : z \in \mathbb{R}^{d_z} \mapsto x \in \mathbb{R}^{m \times q \times 2}$ from embeddings to patterns is available. Function G can be either the decoder of an autoencoder or the generator of a GAN. A pseudo-song is then generated by creating a trajectory of length T, $z_1, \ldots, z_T$, and applying G to each latent vector to produce a corresponding sequence of patterns.

4.1 Interpolations

When using autoencoders, we have the choice of picking a start pattern x_s and a goal pattern x_g (both from the test set) and use the encoder E to obtain $z_1 = E(x_s)$, $z_T = E(x_g)$. This for example allows users to produce a pseudo-song that moves smoothly from one genre to another. Musicians could even create ex-novo start and goal patterns with a particular purpose in mind. When using GANs to generate, this option is not available but z_1 and z_T can be sampled from $p(z)$ (with a less intentional result) or, alternatively, users may be given a set of pre-generated patterns

from which to pick the endpoints from the pre-images of the generator.

Two options are common for creating trajectories, linear interpolation: $z_t = \frac{t-T}{1-T}z_1 + \frac{1-t}{1-T}z_T$, $t = 2, \ldots, T-1$, and spherical interpolation:

$$z_t = \frac{\sin\left(\frac{1-t}{\theta(1-T)}\right)z_1 + \sin\left(\theta\frac{t-T}{1-T}\right)z_T}{\sin(\theta)} \qquad (3)$$

where $\theta = \arccos(z_1/\|z_1\|, z_T/\|z_T\|)$. The latter is preferable when $p(z)$ is Gaussian and d_z is large [33].

4.2 Swirls

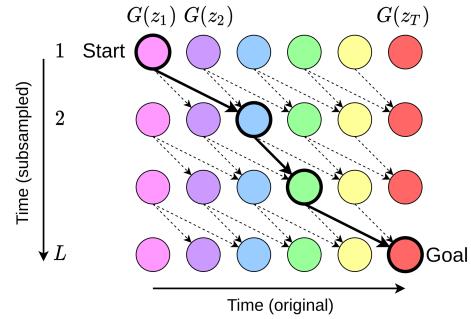
In this approach (also applicable to GANs), latent trajectories are produced by taking real and imaginary parts of periodic complex-valued parametric functions of the form

$$f(t; a_l, b_l, c_l, d_l) = e^{ja_l t} - e^{jb_l t}/2 + je^{jc_l t}/3 + e^{jd_l t}/4$$

for random choices of (a_l, b_l, c_l, d_l), i.e., using $z_{2l,t} = \Re(f(t; a_l, b_l, c_l, d_l))$ and $z_{2l+1,t} = \Im(f(t; a_l, b_l, c_l, d_l))$, for $l = 1, \ldots, \lfloor d_z/2 \rfloor$, $t = 1, \ldots, T$.

4.3 Trajectory Smoothing

Equally spaced points in the embedding space do not necessarily correspond to equally spaced reconstructions in the pattern space. This essentially depends on how generative models allocate points in the pattern space to points in the embedding space. When creating pseudo-songs with either interpolations or swirls, this fact may lead in some cases to abrupt transitions and in some other cases to repetitive regions that might be musically uninteresting. To address this issue, we suggest to increase T beyond the desired length and then subsample the trajectory. Smoothness can be achieved by maximizing the minimum distance between consecutive reconstructions and constraining the final length to a desired integer L:

$$\max_{t_1, \ldots, t_L} \min_{i=1, \ldots, L-1} \delta(G(z_{t_i}), G(z_{t_{i+1}})) \qquad (4)$$


$$\text{s.t.} \quad 1 \le t_i < t_{i+1} \le T \quad i = 1, \ldots L-1 \qquad (5)$$

$$t_{i+1} - t_i \le H \quad i = 1, \ldots L-1 \qquad (6)$$

where δ is a distance function on patterns (e.g., the Euclidean distance on PR^{C} tensors) and H a lookahead horizon, i.e., the maximum allowed number of positions that may be skipped. Problem (4) can be reduced to an instance of the bottleck shortest path problem [34] on the $T \times L$ trellis with vertex set $\{(t, \tau), t = 1, \ldots, T; \tau = 1, \ldots, L\}$, edge set $\{((t, \tau), (t+1, \tau+s)), t = 1, \ldots, T; \tau = 1, \ldots, L, s = 1, \ldots, H\}$, and edge weights $w((t, \tau), (t+1, \tau+s)) = \delta(G(z_t), G(z_{t+s}))$ (see Fig. 2). The problem is solvable by a slightly modified version of the Dijkstra algorithm (where nodes in the frontier are labeled by their maximum step cost rather than the sum of the step costs) or by a faster algorithm based on bucketing [34].

5. DATASETS

We tested CONLON on three dataset. ASF-4 is a set of 910 patterns of four bars in three genres: *acid jazz*, *soul*

Figure 2. Trellis for trajectory smoothing. The horizon H is 2 in this example. Among all paths from Start to Goal, the highlighted path is the one whose smallest edge weight is maximum.

and *funk*. Each pattern has $K = 4$ tracks associated with a simple electro-acoustic quartet: drums, bass, Rhodes piano, and Hammond organ. HP-10 is a set of 968 patterns of four bars in two genres: *high-pop* and *progressive trance*. Each pattern has $K = 10$ tracks associated with the following instrument set: drums, bass, Rhodes, brass-synth, choir, dark-pad, guitar, lead, pad, and strings. Both ASF-4 and HP-10 have been especially composed by two professional musicians for this study. In both cases, composers were instructed to create coherent 120bpm patterns of four bars. All patterns in these datasets were subsequently quantized at 1/32th resolution, manually curated for mistakes (including fixing errors due to quantization), and finally transposed to either Cmaj or Amin to prevent tonality variations. The resulting PR^{C} tensors have size $128 \times N \times 2K$, where $N = 55$ for ASF-4 and $N = 60$ for HP-10. LPD-5 (cleansed version) was derived from the Lakh MIDI dataset [35] by Dong *et al.* [17] by retaining only songs with high matching scores to the Million Song Dataset. It contains 21,425 multitrack MIDI songs with $K = 5$ tracks and $N = 108$ pitches, where original tracks/instruments were merged into instrument families and cut by the authors of [17] into patterns consisting of two 4/4 bars. Automatic quantization at 1/48 was applied yielding tensors of size $192 \times 108 \times 10$.

Being manually curated, ASF-4 and HP-10 are much more *coherent* than LPD-5 in at least three ways. First, music style and genre is highly constrained, whereas LPD-5 contains a wide assortment of different genres. Second, instrument-role is well defined, i.e., the instrument that plays in a certain track always maintains its role across the whole dataset. In LPD-5, some heuristics have been applied by the authors of [17] to map instruments to the five tracks but in some cases very different instruments may collide on the same track. Third, the endpoints that demarcate patterns always cover homogeneous phrases, i.e., the phrase always begins on the first bar. In LPD-5, patterns are extracted by an automatic segmentation technique that cannot be equally reliable.

6. LISTENING EXPERIMENTS

To validate the CONLON approach, we conducted three listening experiments with a group of 69 musicians, re-

cruited by the authors with the help of colleagues teaching in several music educational institutes. Subjects mainly identified themselves as composers and producers (often in combination with instrumentalist/performer), working mostly in three (non mutually exclusive) genres: Classical, Contemporary and Electronic Dance Music. Over half the participants had more than 10 years of professional experience in music, only one less than 3 years.

Participants were told that the survey was part of a research project on the generation of music with machine learning techniques, with the long-term aim of developing new tools for music production and performance. They participated through an online survey service [1] that allows for questions with audio materials. The experiments consisted of two types of tasks.

Comparison Subjects listen to a pair of short music tracks (64 bars, 130s), and indicate which of the two tracks is most usable in the context of mainstream music production (forced choice). The scenario they are asked to keep in mind is that they would receive the tracks as a midi file for inclusion and editing in the production of a mainstream song in their own DAW.

Analysis Subjects listen to a single track, an excerpt (64 bars) from a longer piece and assess the musical development of the composition over time, with regards to four aspects: Harmony, Rhythm, Melody, and Interplay of instruments, each judged on a 5-point Likert scale (from "very incoherent" to "very coherent"). To obtain further feedback, we asked the subjects to comment on good points of the composition and points for improvement.

Answers in the comparison task were converted to ranks for the tracks in a pair (i.e. rank is 1 for the preferred track and 2 for the other). We then computed the mean rank of the tracks across subjects. Following [36], we employed Kendall's Coefficient of Concordance (W) [37], to analyse the level of agreement among subjects, along with a commonly used significance test against the null hypothesis of no agreement [38].

In the following we describe three experiments aiming at testing specific hypotheses relating CONLON to MuseGAN, PR to PR^C, and the usability of pseudo-songs. For all models we set the interpolation length $T=64$, the desired length $L=16$, and the widest-path horizon $H=20$.

	Aspect			
	Harmony	Rhythm	Melody	Interplay
Coherent	49%	67%	42%	51%
Neutral	35%	20%	29%	20%
Incoherent	16%	13%	29%	29%
Significance	$p<.005$	$p<.0005$	$p<.005$	$p<.0005$

Table 3. Coherence of CONLON pseudo-songs as judged by subjects, with respect to harmony, rhythm, melody, interplay of instruments. $m = 69$ judgements were collected.

6.1 Comparing CONLON and MuseGAN

To substantiate that CONLON is more usable in music production than previous approaches, we tested *Hypothesis 1: Musicians find pseudo-songs generated with WAEs and PR^C descriptions more useable in music production than pseudo-songs generated with the MuseGAN model and PR (other factors being equal).* A WAE-model was trained on PR^C representations of the datasets HP-10 and LPD-5, and a MuseGAN model on PR representations of datasets HP-10 and LPD-5 to generate interpolations. On the same data, we trained a MuseGAN model with binary neurons [22] using the implementation at https://github.com/salu133445/musegan. Subjects were given pairs of matching interpolations to compare, differing in the approach used, but with the same start, goal and length. Six pairs (three for each dataset) were presented for comparison to 25 subjects, producing a total of 75 observations per dataset.

Subjects generally judged pseudo-songs generated by CONLON to be more usable than pseudo-songs generated with the MuseGAN approach (for 5 out of the 6 pairs). But whereas the difference in ranking is clear and concordance among participants is significant for the three pairs on the HP-10 dataset, differences were small and concordance not significant among subjects for pseudo-songs generated from LPD-5. Table 1 shows the aggregated mean ranking per dataset.

6.2 Comparing PR and PR^C

To investigate whether part of the improvement over previous approaches is due to the representation, we tested *Hypothesis 2: Musicians find pseudo-songs generated with PR^C descriptions more useable in music production than pseudo-songs generated with PR descriptions (other factors being equal).* A WAE-model was trained on PR

	ASF-4				HP-10				LPD-5			
	P	R	V	D	P	R	V	D	P	R	V	D
PR	6.1	51.1	32.2	2.5	4.1	58.9	28.8	3.1	1.4	89.7	41.0	5.5
PR^C	32.1	53.9	24.3	1.0	37.0	58.0	23.4	1.8	35.5	60.2	19.5	2.6

Table 4. Test set precision (P), recall (R), mean absolute errors on velocity (V) and duration (D) for PR and PR^C .

and PR^C representations of the datasets ASF-4, HP-10 and LPD-5 to generate interpolations. 26 subjects were given nine pairs of matching interpolations to compare (differing only in representation used), three for each dataset, resulting in 78 observations per dataset.

Subjects generally judged pseudo-songs generated with PR^C representations to be more usable than pseudo-songs generated with PR representations (for 8 out of the 9 pairs). The difference in ranking is clear and concordance among participants is significant for the 6 pairs on the ASF-4 and HP-10 datasets, but differences were small and concordance not significant for the 3 pairs generated on different representations of the LPD-5 dataset. Table 2 shows the aggregated mean ranking and cross-subject concordance per dataset.

6.3 Analyzing Development over Time

To validate the way patterns are chained together by CONLON, we tested *Hypothesis 3: Musicians find the development over time of pseudo-songs generated with WAEs and PR^C description coherent rather than incoherent (in terms of harmony, rhythm, melody and interplay between instruments).* A WAE-model was trained on a PR^C representation of datasets ASF-4 and HP-10 to generate swirls. All subjects were given the analysis task for a swirl, resulting in 69 observations per aspect.

Subjects generally judged the coherence of pseudo-songs on the positive side of the scale. For the three swirls presented in the experiment, each with four aspects, the median for all aspects lies at "somewhat coherent" (8 out of 12) or "neutral" (4 out of 12). The rating "very coherent" is reached for all aspects, the rating "very incoherent" in 10 out of 12. For all swirls, rhythm is the aspect with the highest coherence rating. Table 3 shows the aggregated answers for the three swirls, recoded to a 3-point scale.

7. QUANTITATIVE EVALUATIONS

When only a limited amount of human expert time is available for surveys, it becomes difficult to cover all different dimensions on which alternative methods can be compared. Rather that allowing non experts in our surveys, it may be preferable to complement human evaluation with a number of automatically computed metrics [39]. Here we consider reconstruction error and note shattering.

7.1 Reconstruction error

Here we complement human evaluations with some automatically computed metrics that are derived from test set reconstructions and are applicable to autoencoder-based methods. In particular, we aim to compare WAEs fed by

PR vs WAEs fed by PR^C . Precision and recall are defined on the binary classification problem where the ground truth consists of Bernoulli variables $y(t, n, i) = 1$ if there is a note-on event at time t for note n and instrument i. For these metrics we considered as predictions the binary quantities $\hat{y}(t, n, i) = 1$ if the reconstructed value of the velocity at position (t, n, i) is above the smallest velocity encountered in the training set. In the case of PR description, the predicted note-on event was the first element in the merged row of consecutive predictions. We further considered the mean absolute errors in predicting velocities (in the range $[0 - 127]$) and durations (in units of 1/32ths of bar). Test set results comparing PR and PR^C (everything else being equal) are reported in Table 4.

7.2 Note Shattering

Results in Table 4 indicate that PR yields good recall but very low precision, and has a higher error on both velocity and duration. This can be partially explained by the presence of a high number of shattered notes. To verify this hypothesis we computed the note number growth due to shattering as follows. For each note in the ground truth, identified by the triplet (n, i, T), being n the pitch, i the instrument, and $T = [t_{\text{ON}}, t_{\text{OFF}}]$ the temporal interval, we counted the number of notes in the reconstruction that have the same pitch n and instrument i, and whose note-ON time falls within T. We then summed these counts over all notes in the test set. In the absence of shattering, the total count equals the original number of notes. We found that WAE-PR increased the number of notes by 19%, 12%, 38% on ASF-4, HP-10, and LPD-5, respectively. By comparison, the increase factors were only 5%, 3%, and 10% in the case of WAE-PR^C .

8. CONCLUSIONS

CONLON combines the new PR^C data description with Wasserstein autoencoders and generation strategies based on optimized interpolation and swirling to produce pattern-based pseudo-songs. When trained on coherent datasets, the generated material is musically coherent and potentially useful in music production by professional musicians.

Pseudo-songs can sound like directed musical flows, but this is entirely due to the properties of the embedding space, longer-term structure is not considered. In that sense, interpolating and swirling are closer to improvisation than to composition. A natural next step is to label dataset patterns with structural categories (e.g. verse, chorus) and introduce form via mechanisms of conditioning.

ABSTRACT

Version identification systems aim to detect different renditions of the same underlying musical composition (loosely called cover songs). By learning to encode entire recordings into plain vector embeddings, recent systems have made significant progress in bridging the gap between accuracy and scalability, which has been a key challenge for nearly two decades. In this work, we propose to further narrow this gap by employing a set of data distillation techniques that reduce the embedding dimensionality of a pre-trained state-of-the-art model. We compare a wide range of techniques and propose new ones, from classical dimensionality reduction to more sophisticated distillation schemes. With those, we obtain 99% smaller embeddings that, moreover, yield up to a 3% accuracy increase. Such small embeddings can have an important impact in retrieval time, up to the point of making a real-world system practical on a standalone laptop.

1. INTRODUCTION

The concept of music versions is as old as the concept of music itself. Before the existence of recorded music, listening to a piece mostly meant listening to a version of it. Nowadays, with the advancements in recording technologies, most music we listen to comes in recorded form. Nevertheless, musicians keep creating their own versions of existing songs for various reasons, including commercial ones (for example, to attract new audiences), political ones (to connect people or make a stance), and artistic ones (to re-imagine a song with a personal touch).

Version identification (VI) is the task of automatically detecting different renditions of the same underlying musical composition. VI systems are mainly focused on retrieval, aiming to find all renditions of a query song in a reference database. Although creating new versions is common practice, defining the characteristics that enable us to perceive the links connecting different renditions of the same piece is not a straightforward task [1, 2]. Based on quantitative evidence, many successful systems exploit tonal and melodic descriptors that are invariant to the typical differences among versions, including the differences in timbre, tempo, structure, lyrics, and so on [3–5]. By further processing such descriptors, the ultimate goal is to obtain representations that allow inferring links among versions.

The accuracy-scalability trade-off stands as a key challenge in version retrieval. The early, alignment-based systems [6, 7] incorporated musical know-how to capture the similarities among versions, resulting in strong performances. However, due to the scarcity of data, and their dependence on complex representations and computationally-intensive algorithms, they ended up in limited evaluation environments and, ultimately, not being suitable for industrial-size databases. With the release of the Million Song Dataset [8], researchers were further encouraged to address the scalability issue by exploring embedding-based systems that encode songs into more compact vectors. Although offering significant improvements for the scalability aspect, the performance of such systems failed to match their predecessors [9]. Recent embedding-based systems that use deep learning techniques pave the way to encapsulate the similarities among versions in ways that are both efficient and accurate [5, 10–12].

The main use case of version retrieval in commercial settings is to detect copyright infringement cases in media streaming platforms and live performance venues or events. Such application scenarios require having fast and scalable solutions. For example, more than 500 h of video content are uploaded to YouTube every minute [1], and handling the music licensing aspect of that requires having accurate and scalable systems that can identify the cases where a video includes a copyrighted piece of music.

In this paper, we investigate a number of ways to improve the scalability of existing embedding-based VI systems that use neural networks as encoders. Specifically, our goal is to reduce the size of embedding vectors without compromising the accuracy of the systems. Since embeddings can be pre-computed, reducing their size is crucial to improve data storage and, more importantly, retrieval

---

time. For this purpose, we consider three core state-of-the-art strategies, namely unsupervised dimensionality reduction, neural network pruning, and knowledge distillation. Apart from introducing a number of techniques from other fields to VI research, we also consider a novel knowledge distillation loss for metric learning, which aims to optimize a clustering evaluation metric. Moreover, inspired by transfer learning applications, we propose a technique called latent space reconfiguration, to show that learning a compact and efficient latent space is facilitated by using a pre-trained feature extractor due to its stronger priors, compared with using a randomly-initialized one. Our experiments suggest that the performance of a pre-trained network can be preserved, or even improved, while shrinking the embedding vectors down to less than 1% of their original sizes. We evaluate our approach on a publicly-available test set, and share our code, instructions for using a newly-contributed training dataset and supplementary materials (SM) on Github [2].

2. RELATED WORK

2.1 Version identification

Like many other systems in music information retrieval (MIR), VI systems extract audio descriptors to obtain relevant information from signals, including mid-level ones, such as pitch class profiles (PCP) [7, 13–16] and predominant melody [4, 10, 17], or low-level ones, such as the constant-Q transform (CQT) [18–20]. To achieve invariance against the changes in musical characteristics, further processing steps have been proposed, including beat-synchronous features for handling tempo variations [13,15, 21], and the optimal transposition index for handling pitch transpositions [6, 7, 14, 15]. Many rule-based VI systems use alignment algorithms to then compare these representations, resulting in long retrieval times.

Embedding-based VI systems are designed to obtain compact representations that speed up the retrieval phase. Compact embeddings reduce the required storage and facilitate similarity estimation through the use of efficient nearest-neighbor libraries implementing common metrics like Euclidean or cosine distances. Early attempts of such systems use techniques like the 2D Fourier transform, principal component analysis, and linear discriminant analysis for encoding and dimensionality reduction operations [21, 22].

Current deep learning-based systems learn non-linear transformations that map the feature representations into embedding vectors of various sizes, ranging from 300 to 16,000. Xu et al. [23] and Yu et al. [11] train their convolutional networks with a classification loss, but obtain the embedding vectors to use in the retrieval phase from the penultimate layer of their networks. Doras and Peeters [10], and Yesiler et al. [5] formulate the network training as a metric learning setting, in which they use the triplet loss for optimizing distances among training samples.

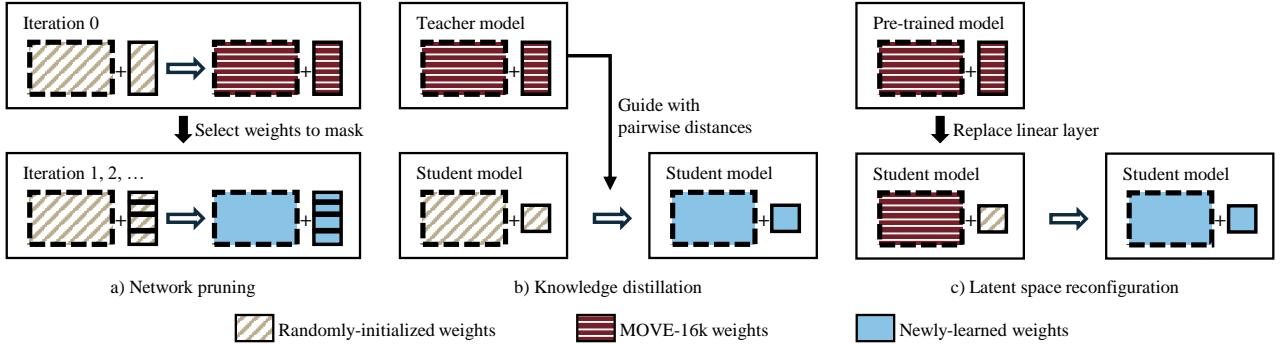
2.2 Metric learning

This line of research is concerned with learning functions that produce low distance values between semantically similar data points, and high values otherwise. The early approaches include learning Mahalanobis distances [24] with linear [25, 26] or non-linear [27] transformations. Parametrizing such transformations with neural networks was pioneered by Chopra et al. [28] and Salakhutdinov and Hinton [29], and the research domain combining these two concepts is often called deep metric learning.

Deep metric learning methods offer new solutions regarding how to exploit the semantic relations among data, often by formulating or revising loss functions. The triplet loss [30], similar to LMNN [26], manipulates the distances between genuine and impostor pairs with an energy-based approach. The ProxyNCA loss [31], similar to NCA [25], and NormalizedSoftmax loss [32], similar to cross entropy loss, maximize the likelihoods of samples being close to particular class proxies. The group loss [33] incorporates the idea that similar elements should belong in the same class by using replicator dynamics [34]. Although there is a variety of deep metric learning losses, each one with distinctive advantages, the triplet loss variants remain the popular (and almost unique) choice in MIR research.


2.3 Model reduction

2.3.1 Neural network pruning

Pruning a large neural network can preserve the original performance while eliminating more than 90% of its weights [35–38]. The main challenge is to identify the importance of connections and weights, and previous techniques explored the use of absolute weight magnitudes [36–38] and the Hessian of the loss function [35]. Pruning operations can be performed layer- or network-wise, in a one-shot or an iterative fashion, and combined with quantization or clustering. To the best of our knowledge, network pruning has not been considered for VI, nor further explored in MIR systems in general.

2.3.2 Knowledge distillation

Bucilă et al. [39], and later Hinton et al. [40], explored the idea where a small neural network (the student model) is trained with the guidance from a wide, deep, and better-performing network (the teacher model). In the metric learning context, some works explored this idea with a slightly changed formulation: Classical knowledge distillation methods use teacher networks to guide the students on individual examples, but metric learning methods exploit similarity relations among samples. For this, researchers proposed methods that match a number of properties between the embeddings obtained from the teacher and the student models, including the ranks of retrieved samples [41], distances between samples [42], class likelihood distributions [43], and absolute positions of embeddings in the latent space [44]. With few exceptions [45,46], distillation techniques are largely under-explored in MIR, and we believe that no attempt has been done within VI.

Figure 1: An overview of neural network-based embedding distillation methods. The hollow arrows denote training process, the boxes with dashed and with solid outlines denote feature extractors and fully-connected layers, respectively.

3. METHODOLOGY

3.1 Embedding distillation

Our study focuses on a set of techniques for improving the scalability of existing VI systems in the retrieval phase by reducing the size of the embeddings, rather than building a novel network architecture.[3] We hypothesize that a high-capacity encoder is still needed to extract the essential information from complex and noisy signals such as current tonal representations. However, once a reliable encoder is obtained, it can be used for training a second model that outputs embeddings with a lower dimensionality, ideally without compromising accuracy. Due to the goal of having smaller embeddings that yield a similar performance, we call this set of methods embedding distillation techniques.

3.2 Data

Our models are developed with the Da-TACOS training set that we make available under Creative Commons BY-NC-SA 4.0 license together with this publication. It features a training partition of 83,904 songs in 14,499 cliques (or unique works), and a validation partition of 14,000 songs in 3,500 cliques. The annotations for the songs are obtained using the API of `secondhandsongs.com`. We share the crema-PCP features [47] and the related metadata. Further detail on the contributed dataset is available in SM.

3.3 Model architecture and training details

Our methods require to start from a pre-trained and sufficiently reliable model. For this, we take advantage of the publicly-available MOVE model [5], together with its pre-trained weights. Nonetheless, we believe all methods introduced here can be applied to other embedding-based systems using neural networks (initial results are available in SM).

MOVE uses crema-PCP features $\mathbf{X} \in [0,1]^{12 \times T}$ as input, where T is the number of frames, pre-computed with non-overlapping windows of 93 ms. The model outputs embedding vectors $\mathbf{v} = f(\mathbf{X}) \in \mathbb{R}^d$, where d is the embedding size. The original work reports results for d between 128 and 32 k, and shows a clear accuracy drop for $d < 2048$ (the final model employs a rather high dimensionality $d = 16$ k). In contrast, the dimensionalities we consider in this work are $d = \{128, 256, 512, 2048\}$.

To find a suitable learning rate and an optimizer for each experiment setting, we perform a grid search over both stochastic gradient descent and Ranger[4] optimizers and initial learning rates in $\{0.0001, 0.001, 0.01, 0.1\}$, using our validation set. The full training lasts for 70 epochs, and we decrease the learning rate by a factor of 10 at epochs 50 and 60. We save the model weights that result in the best performance on the validation set. The remaining training details and design decisions follow the ones made by the MOVE authors [5]. All neural network models are trained using PyTorch [48], and the hyper-parameter values used for each experiment can be found at our repository.

3.4 Methods for embedding distillation

3.4.1 Classical unsupervised techniques

Before going into complex solutions, we investigate the benefits of using classical dimensionality reduction techniques for embedding distillation. For this, we use principal component analysis (PCA), independent component analysis (ICA), and Gaussian random projection (GRP) techniques. Each model is fit using the training set embeddings obtained with MOVE-16k, and applied to the evaluation set embeddings. We use the implementations from the scikit-learn library [49] and change only the number of target components.

3.4.2 Pruning

Based on the approach of Han et al. [37], we study whether we can prune the dimensions of the latent space constructed by MOVE-16k in an iterative way. Although pruning the weights of all layers throughout the network is the most common practice, the underlying idea can be applied

---

[3] To illustrate the benefits of using smaller embeddings, consider computing distances between a query and a reference database with 10 M embeddings. This takes us (with a simple brute-force, double-loop Euclidean distance function) 0.32 s using $d = 256$, but the elapsed time increases up to 4.75 s for $d = 4k$, and to 18.43 s for $d = 16k$ (the embedding size of MOVE [5]). Although the absolute values are subject to change based on computational resources, for real-world applications on portable devices, such differences in magnitude for the retrieval time (from 0.32 to 18.43 s) may drastically affect user experience and product appeal.

[4] https://github.com/lessw2020/Ranger-Deep-Learning-Optimizer

to only the final linear layer of the model in order to obtain embeddings with fewer dimensions. Denoting the weights of the linear layer of MOVE-16k as $\mathbf{W} \in \mathbb{R}^{d \times f}$, where d is the size of the embeddings and f is the number of input connections to the linear layer, we compute the mean of the absolute values per row for $\mathbf{W}$ and sort the rows based on these mean values. At the end of each iteration m ($m \in \{0, 1, ...\}$), the weights of the top 50% rows are restored to their initial values from Iteration 0 and retrained. The weights of the bottom 50% rows are zeroed-out and not considered for the next iterations (Figure 1(a)) .

3.4.3 Knowledge distillation

This set of experiments consider MOVE-16k as a teacher model, and our goal is to train from scratch a student model of the same size but with a lower embedding dimensionality. Our approach is formulated in a deep metric learning setting where the guidance of the teacher model is shaped by the distances among samples (Figure 1(b)). In the experiments described next, the weights of the teacher model are frozen, and the weights of the student model are initialized randomly.

Distance matching — Perhaps the most intuitive way of guiding the student model is to match the distances obtained from the student with the ones from the teacher, allowing the two models to have different embedding sizes. In our implementation, we pass the samples in each mini-batch to both models, compute in-batch pairwise distances, and use the mean absolute error between the pairwise distance matrices from the teacher model and the student model to train the latter:

$$L_i^{\mathrm{DM}} = \sum_j \left| D(\mathbf{v}_i^{\mathrm{s}}, \mathbf{v}_j^{\mathrm{s}}) - D(\mathbf{v}_i^{\mathrm{t}}, \mathbf{v}_j^{\mathrm{t}}) \right|, \qquad (1)$$

using

$$D(\mathbf{v}_i, \mathbf{v}_j) = \frac{1}{d} \left\| \mathbf{v}_i - \mathbf{v}_j \right\|^2, \qquad (2)$$

where $\| \ \|$ represents the Euclidean norm, and $\mathbf{v}_i^{\mathrm{s}}$ and $\mathbf{v}_i^{\mathrm{t}}$ the embeddings of song i obtained with the student and teacher models, respectively.

Cluster matching — Our second knowledge distillation scheme aims to obtain a student model that constructs clusters with both low intra-class and high inter-class distances. Assuming the teacher model holds this desired property, we take advantage of this information to guide the student model. To the best of our knowledge, this distillation criterion has not been explored in previous deep metric learning research.

Our criterion exploits internal cluster evaluation metrics [50]. In the experiments reported here, we use the Davies-Bouldin (DB) index [51], but other cluster evaluation metrics can be used:

$$L_i^{\mathrm{DB}} = \max_{j \neq i} \left(\frac{\sigma_i + \sigma_j}{D(c_i, c_j)} \right), \qquad (3)$$

where σ_i denotes the average intra-class distance, computed with a suitable distance measure D, and c_i denotes the centroid for class i. The DB index yields low values for configurations that have low intra-class and high inter-class distances.

In our implementation, we pre-compute the class centroids using the MOVE-16k embeddings from the entire training set. To match the dimensions of the centroids with the student model embeddings, we train a linear projection simultaneously with the student model. The intra-class and inter-centroid distances are computed using only the samples present in the mini-batch and their respective centroids. After computing DB scores for each class in the mini-batch, we average them to obtain the final loss value.

3.4.4 Latent space reconfiguration

Transfer learning applications take advantage of the strong priors learned by the feature extractor part of successful, high-capacity models that are trained on large datasets. Inspired by this idea, we hypothesize that, by using the feature extractor of a pre-trained model, we can obtain a better-structured and lower-dimensional latent space that cannot be obtained by training a randomly-initialized model from scratch.

To test this idea, we use the pre-trained convolutional layers of MOVE-16k as the feature extractor, remove the final linear layer, and learn a new latent space with a randomly-initialized linear layer using a metric learning loss function (Figure 1(c)). Note that the original MOVE-16k model is trained with a triplet loss, meaning that it learned a distance metric parametrized by a neural network. Our approach uses the non-linear part of that metric, and 'reconfigures' the latent space and the distance metric by optimizing a second loss function (hence the name latent space reconfiguration). Our motivation is based on two assumptions: (1) training losses play an important role in shaping the latent space where the embeddings lie, and (2) embeddings with lower dimensionalities may be sufficient to successfully represent semantically meaningful information, as long as the dimensions are effectively utilized. Note that although this technique follows the same procedure as transfer learning, the latter requires, by definition, distinct source and target tasks (or datasets), which is not the case for the proposed technique. Focusing on metric learning schemes, the term latent space reconfiguration denotes the process of starting with an already learned distance metric and modifying it to represent the semantic relations in a more compact embedding space.

In our experiments, we consider 4 loss functions which are explained below. The weights of the feature extractor are frozen during the first epoch and updated with a lower learning rate during the rest of the training. Batch normalization is applied after the linear layer as in MOVE-16k. Apart from using the loss functions below for latent space reconfiguration, we also use them individually and train models from scratch with the same settings to set baseline models.

Triplet loss — We follow the triplet loss formulation used by Yesiler et al. [5]. Distances among vectors are computed using D as specified in Eqn (2):

$$L_i^{\mathrm{T}} = \max \left(D \left(\mathbf{v}_i, \mathbf{v}_+ \right) - D \left(\mathbf{v}_i, \mathbf{v}_- \right) + m, 0 \right), \quad (4)$$

where $\mathbf{v}_i$ corresponds to the anchor, $\mathbf{v}_+$ to the positive sample, $\mathbf{v}_-$ to the negative sample, and $m = 1$ is a margin hyper-parameter. For selecting which triplets to use, we follow the hard-positive, hard-negative mining strategy used by the authors.

ProxyNCA loss — Our implementation of ProxyNCA loss [31] also uses the normalized squared Euclidean distance metric from Eqn (2). Every class in our training set is represented with one proxy vector that is initialized randomly and trained simultaneously with the model parameters. In mathematical notation, the ProxyNCA loss can be expressed as:

$$L_i^{\mathrm{P}} = -\log\left(\frac{\exp(-D(\mathbf{v}_i, y))}{\sum_{z \in Z} \exp(-D(\mathbf{v}_i, z))}\right), \qquad (5)$$

where $y \in \mathbb{R}^d$ denotes the proxy vector for the class of $\mathbf{v}_i$ and Z denotes the set of proxies for all classes different than the one of $\mathbf{v}_i$.

NormalizedSoftmax loss — As proposed in [32], we implement this function using the cosine distance. We randomly initialize one proxy per class and update their parameters at each training step. We use

$$L_i^{\mathrm{N}} = -\log\left(\frac{\exp(\langle \mathbf{v}_i, y \rangle / \tau)}{\sum_{z \in Z} \exp(\langle \mathbf{v}_i, z \rangle / \tau)}\right), \qquad (6)$$

where $\langle\ \rangle$ denotes cosine similarity, $y \in \mathbb{R}^d$ the proxy for the positive class, Z the set of proxies for all classes, and $\tau = 0.05$ the temperature parameter.

Group loss — Following the approach of [33], we use Pearson's correlation coefficient as the similarity metric and replace the negative values with 0. We perform three iterations for refining the class probabilities and, unlike the original implementation, we select one anchor per class in the mini-batch. The main loss is regular cross-entropy:

$$L_i^{\mathrm{G}} = -\log\left(\frac{\exp(l_i^c)}{\sum_{t \in C} \exp(l_i^t)}\right), \qquad (7)$$

where l_i^c denotes the logit of sample i with respect to its positive class c, and C denotes the set of all classes in the training set. However, in group loss, logits are updated with replicator dynamics using pairwise similarities [33].

4. RESULTS

4.1 Evaluation methodology

For development, we use the newly available dataset mentioned in Section 3.2 and detailed in SM. Results are then evaluated on Da-TACOS benchmark subset [9], which contains a non-intersecting set of cliques with respect to our training and validation data. Da-TACOS contains 1,000 cliques with 13 songs each and 2,000 noise songs that do not belong to any other clique and are not queried. Following common practice, we report the performance of our models using mean average precision (MAP) and mean rank of the first relevant item (MR1) metrics.

Method	d			
	128	256	512	2048
Baselines (no reduction, training from scratch)				
Triplet	0.459	0.469	0.478	0.487
ProxyNCA	0.168	0.185	0.212	0.206
NormalizedSoftmax	0.445	0.470	0.475	0.422
Group	0.265	0.271	0.269	0.271
Unsupervised

Group	0.465	0.483	**0.495**	**0.511**

Table 1: MAP for different embedding sizes d when training from scratch (top) and when using pre-trained models and embedding distillation (middle-bottom). MAPs for the original MOVE-4k and MOVE-16k baselines are 0.495 and 0.507, respectively (values equal to or above MOVE-4k are highlighted in bold).

4.2 Embedding distillation experiments

Table 1 presents the exhaustive list of results for the methods described in Section 3. The baseline results (top block) show that, when training from scratch, changing the loss function of a network causes significant accuracy differences. It should be noted that all alternative losses we consider achieve state-of-the-art performances in computer vision datasets. Nevertheless, our results suggest that they may not generalize across other types of data or tasks, or that they may be oversensitive to hyper-parameters or specific architectural decisions.

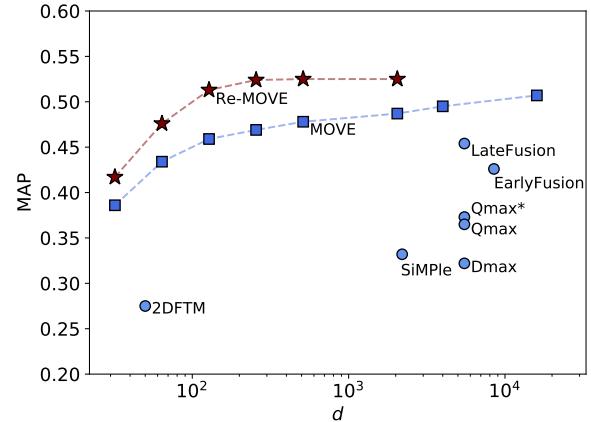
For unsupervised dimensionality reduction (second block of Table 1), we find that PCA successfully projects the information contained in MOVE-16k embeddings, even when using 256 dimensions. This suggests that, although achieving state-of-the-art performance, MOVE-16k embeddings contain redundant information that can be drastically compressed. GRP reaches a similar performance as PCA with $d = 2048$, but the resulting performance decreases when using lower-dimensional embeddings.

The initial experiments on pruning reached the same performance as MOVE-16k after one iteration, that is, after reducing the dimensionality by 50%. However, further pruning iterations drastically decreased MAP, up to the point of yielding non-useful embeddings. Therefore, we decided to stop iterating and not to report the corresponding results.

Among the considered knowledge distillation techniques (third block, Table 1), the additional distance matching loss clearly increases the model performance

	d	MAP	MR1
2DFTM [21]	50	0.275	155
Dmax [16]	5.5 k	0.322	132
SiMPle [14]	2.2 k	0.332	142
Qmax [7]	5.5 k	0.365	113
Qmax* [52]	5.5 k	0.373	104
EarlyFusion [15]	8.5 k	0.426	116
LateFusion [16]	5.5 k	0.454	177
MOVE [5]	4 k	0.495	42
MOVE [5]	16 k	0.507	40
Re-MOVE	**256**	**0.524**	**38**

Table 2: Comparison with existing VI systems using Da-TACOS (taken from [9]). When not explicit, embedding sizes d are estimated for a song duration of 3.5 min (see text). Results for the proposed methodology are highlighted in bold.

Figure 2: MAP with respect to embedding dimensionality d for Re-MOVE (red stars), MOVE (blue squares), and other existing approaches (blue circles). Notice the logarithmic axis.


compared with the case where only the triplet loss is optimized. However, the same advantage is not observed with cluster matching using DB loss. We hypothesize that this may be related to training an extra linear projection for compressing the centroid embeddings to match the size of the embeddings obtained with the student model.

Latent space reconfiguration results seem to justify our hypothesis regarding the use of strong priors of a pre-trained feature extractor (last block, Table 1). All considered alternatives outperform their baseline counterparts. Moreover, we find that using probabilistic losses such as NormalizedSoftmax and Group for latent space reconfiguration even outperforms the original model while reducing the embedding size by a large margin ($128/16000 = 0.8\%$). Notice that, in addition to these advantages, latent space reconfiguration does not suffer from the setbacks of network pruning and knowledge distillation methods, namely training a model for multiple iterations and using two models simultaneously during training, respectively.

4.3 Comparison with the state of the art

Lastly, Table 2 compares our best result with state-of-the-art methods. The second column, d, shows the size of the smallest representation (per song) required for each method to estimate pairwise similarities (equivalent to the embedding dimensionality). As the results for the first 7 methods are computed with the publicly-available acoss library [9], we use those implementations for estimating the embedding sizes [5]. As the sizes of some representations depend on the song duration (SiMPle, Qmax, Dmax, LateFusion) or tempo (EarlyFusion), we use 3.5 min and 102 bpm estimates, which correspond to average song duration and bpm of the songs in Da-TACOS, respectively.

Re-MOVE, which stands for 'reduced MOVE', denotes the model trained with latent space reconfiguration using NormalizedSoftmax. With $d = 256$, it demonstrates rel-

ative performance increases of 3%, 6%, and 15% when compared with MOVE-16k, MOVE-4k, and LateFusion systems, respectively (Table 2). We also find that Re-MOVE improves over MOVE for a wide range of dimensionalities $d \in [32, 2048]$ (Figure 2). Along with its state-of-the-art performance, Re-MOVE provides a crucial advantage in terms of scalability, which positions it as the most viable system from a practical point of view.

5. CONCLUSION

In this work, we have studied a set of techniques for reducing the embedding sizes of existing VI systems, which we consider under the name embedding distillation. We have claimed that by using a pre-trained and high-capacity network, we can train a second network that yields smaller embedding vectors without a decrease in performance. To investigate this idea, we have studied a wide range of techniques, including classical dimensionality reduction, neural network pruning, and knowledge distillation methods. Moreover, we have introduced latent space reconfiguration, which is a technique that builds upon the non-linear part of a distance metric learned by a pre-trained network to construct a compact latent space with fewer dimensions. Our results show that it is possible to reduce the embedding dimensionality of a model while maintaining, or even surpassing, its performance.

As future work, we plan to investigate further techniques for compressing entire networks rather than just embedding vectors. We emphasized the importance of having smaller embeddings for real-world applications, and we plan to demonstrate it further in carefully-designed version retrieval scenarios that mimic real-world use cases. Lastly, we believe that optimizing the existing methods to make them applicable in industrial scenarios is a valuable research direction, and we hope to facilitate bridging the gap between academy and industry in MIR research.

---

[5] For 2DFTM, the acoss library uses a 450-dimensional embedding while the authors apply PCA to reduce the dimensionality to 50.

ABSTRACT

We describe a novel approach for generating music using a self-correcting, non-chronological, autoregressive model. We represent music as a sequence of edit events, each of which denotes either the addition or removal of a note— even a note previously generated by the model. During inference, we generate one edit event at a time using direct ancestral sampling. Our approach allows the model to fix previous mistakes such as incorrectly sampled notes and prevent accumulation of errors which autoregressive models are prone to have. Another benefit is a finer, note-by-note control during human and AI collaborative composition. We show through quantitative metrics and human survey evaluation that our approach generates better results than orderless NADE and Gibbs sampling approaches.

1. INTRODUCTION

There have been two primary approaches to generating music with deep neural network-based generative models. In the first class, music generation is essentially treated as an image generation problem [1, 2]. In the second class, music generation is treated as a musical time series generation problem, analogous to autoregressive language modeling [3–7]. The human process of music composition, however, is often non-chronological. Notes can be filled in anytime throughout the music piece to create new chords and melodies, add harmony, or embellish existing motifs.

In this work, we propose ES-Net [1], a method that uses elements from both the image-based and time series generation techniques. Our method operates on piano roll images with a 2D convolutional neural network, but autoregressively adds or removes notes one at a time in an arbitrary, non-chronological order. We model the condi-

---

[1] Code: https://git.io/esnet
Samples: https://git.io/esnet-samples

tional distribution of note add or remove events given pre-existing notes. After sampling from the distribution, we re-input the resulting piano roll into the model to get the distribution of the next add and remove events. From a probabilistic point of view, this corresponds to considering each piano roll as obtained from a randomly ordered sequence of add and remove events and autoregressively modeling the distribution of such sequences of events.

Poor samples due to accumulation of errors is a well-documented problem with autoregressive models [8–11], especially when directly sampling from the conditional distribution (i.e. direct ancestral sampling). While other sampling techniques such as Gibbs sampling [12] can be used to bypass this problem, we show that direct ancestral sampling is sufficient if the data representation includes removal of past samples. This allows the model to detect previous mistakes and fix them.

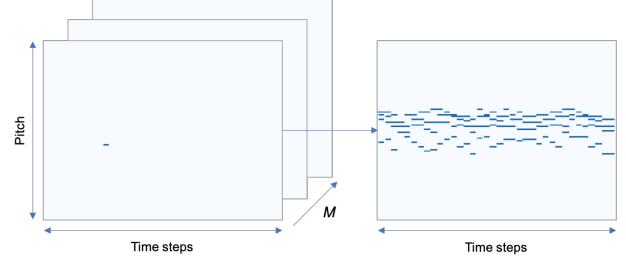
Our primary use case is melody assistance for users generating musical compositions. Users can feed in a melody as a conditional input and have the model generate musical accompaniments as well as fix any off-beat or out of tune inputs. One distinct advantage of our approach is that it allows note-by-note control for users. A user can undo and redo the generation of individual notes or explicitly add and remove individual notes to collaborate with the model and guide the music composition process. Thus, this approach allows users to have a finer degree of control during sampling and better promotes human and AI collaboration.

The remainder of the paper is organized as follows. In Section 2 we discuss related works. In Section 3 we show how to model a distribution of musical pieces using a new representation of music. In Section 4 we discuss our training procedure. In Section 5 we discuss our sampling procedure. In Section 6 we provide empirical results in the form of quantitative metrics and human evaluation compared against other approaches. Finally, in Section 7 and 8 we describe future work and conclusions.

2. RELATED WORK

Following the introduction of NADE [13, 14] and orderless NADE [15] there have been several works built upon the concept of ordered and unordered autoregressive models. Coconet—the algorithm behind Google's Bach Doo-

dle [2] —is a machine learning model that also uses a convolutional model to generate music by adding counterpoints to existing user input [12]. The difference with this work is that Coconet's inference uses Gibbs sampling rather than direct ancestral sampling. DeepBach [16] generates Bach style chorales using pseudo-Gibbs sampling. PixelCNN [17] models an image autoregressively and generates pixels one by one in a pre-specified order while our generation is unordered. In a NLP setting, recent works also explore non left-to-right ordering [18, 19] and deletion [20].

In general, there is a rich history of using deep learning to generate music [21]. Many of them use autoregressive based approaches. RNN-RBM models temporal dependencies to generate polyphonic music in a single track [22]. Hierararchical RNNs have been used to encode different features of pop music [23]. LSTMs were able to successfully model and generate music as well [24]. Music Transformer is able to capture and generate music with long term structure and motifs [3]. So far, these approaches have been mostly chronological while ours is non-chronological. While GAN-based approaches clearly differ from ours, these methods have shown the ability to generate high quality music. MuseGAN is a GAN-based approach for multi-track piano roll generation [1]. MidiNet uses a CNN-based GAN to generate music [2]. C-RNN-GAN generates music using a RNN based architecture with adversarial training [25]. SeqGAN use GANs for sequence generation and apply it to music generation [26]
.


3. PROBLEM DEFINITION

We consider a musical piece $x \in X$ as a point in $\{0,1\}^{T \times P}$ where T is the number of time steps and P is the number of note pitches. This represents a simplified piano roll (PR)—a discrete representation of music as an image matrix across pitch and time. There exists a probability density function $p^{\mathrm{PR}}(x)$ on $\{0,1\}^{T \times P}$ of musical pieces. Note in particular that this does not model velocity and that notes adjacent in time are treated as one continuous held note; we discuss ways to represent velocity and repeated notes in Section 7. Instead of modeling $p^{\mathrm{PR}}(x)$ on $\{0,1\}^{T \times P}$ directly, we model the distributions as $p^{\mathrm{ES}}(s)$ on the set of **edit sequences** (ES). An **edit sequence** of length M is a tuple of M-many **edit events** where an **edit event** is a matrix $e^{(t,p)} \in \{0,1\}^{T \times P}$ that has one entry equal to one, and all other entries equal to zero (i.e. a one-hot matrix). We denote the set of all edit events by $\mathcal{E}$ and of edit sequences of length M by $\mathcal{E}^M$. The following maps edit sequences to piano rolls:

$$\pi : \bigcup_{M=1}^{\infty} \mathcal{E}^M \to \{0,1\}^{T \times P} \qquad (1)$$

$$\pi(e_1, \ldots, e_M) = \sum_{i=1}^{M} e_i \pmod{2}. \qquad (2)$$

---

where (2) allows edit events to handle either note addition or removal depending on if a previous edit event exists at the same time and pitch.

Figure 1. Mapping from an edit sequence (left) of length M to a piano roll (right). Each slice in an edit sequence is the addition or removal of a note.

The mapping between the two joint probability distributions is as follows:

$$\begin{aligned} p^{\mathrm{PR}}(x) &= p^{\mathrm{PR}}(\{(t_1, p_1), \ldots, (t_N, p_N)\}) \\ &= \sum_{s \in \pi^{-1}(x)}^{\infty} p^{\mathrm{ES}}(s) \end{aligned} \qquad (3)$$

where N is the number of notes in the piano roll, (t_i, p_i) is the time and pitch of a note or edit event, $\pi^{-1}(x)$ is the inverse image set of $\pi(x)$, and s is a sequence of edit events $(t_1, p_1) \ldots (t_M, p_M)$ where $M \geq N$. We can further factorize $p^{\mathrm{ES}}(s)$ as:

$$\begin{aligned} p^{\mathrm{ES}}(s) &= p^{\mathrm{ES}}\big((t_1, p_1), \ldots, (t_M, p_M)\big) \\ &= \prod_{i=1}^{M} p^{\mathrm{ES}}\big((t_i, p_i)|(t_1, p_1), \ldots, (t_{i-1}, p_{i-1})\big) \end{aligned} \qquad (4)$$

We assume that $p^{\mathrm{ES}}((t_i, p_i)|(t_1, p_1), \ldots, (t_{i-1}, p_{i-1}))$ is ordering invariant (i.e. the ordering of edit events in an edit sequence does not affect the resulting piano roll).

Our goal is to train a model to map the distribution of edit sequences $p^{\mathrm{ES}}(s)$. By sampling autoregressively from $p^{\mathrm{ES}}(s)$, we will generate a sequence of edit events that can be mapped back into a piano roll representation and then converted to MIDI.

3.1 Orderless NADE

We compare our approach to orderless NADE which generates music by randomly choosing an ordering and sampling notes one by one until termination. We can represent the iterative notewise addition of orderless NADE as a special case of edit sequences where edit events can only represent note addition. Let us call this distribution $p^{\mathrm{O\text{-}NADE}}(x)$. Since notes are only added, $M = N$ for unconditioned generation; thus, there is a finite set of orderings and we can factorize $p^{\mathrm{O\text{-}NADE}}(x)$ as:

$$\sum_{\sigma \in S_N} \prod_{i=1}^{N} p^{\mathrm{O\text{-}NADE}}\big((t_{\sigma(i)}, p_{\sigma(i)})| $$

$$(t_{\sigma(1)}, p_{\sigma(1)}), \ldots, (t_{\sigma(i-1)}, p_{\sigma(i-1)})\big)$$

where S_N is the set of all permutations $\{1, 2, ..., N\} \rightarrow \{1, 2, ..., N\}$. This factorization is equivalent to orderless NADE [15]. In practice, the orderless NADE approach leads to poorer musical samples due to accumulation of errors which we confirm in Section 6.

4. TRAINING

Given an input piano roll, $\mathcal{I}$, and target piano roll, $\mathcal{T}$, we train our model to output the conditional probabilities $p^{\text{ES}}((t_i, p_i)|(t_1, p_1), \ldots, (t_{i-1}, p_{i-1}))$ of the next edit event in edit sequences that can recreate the target from the input piano roll. For each piano roll in the training set, we generate the input piano roll by (a) masking existing random notes and (b) adding extraneous random notes to the target piano roll. We train the model to recreate $\mathcal{T}$ from $\mathcal{I}$; augmentation (a) trains the model to add notes and (b) trains the model to remove notes. For each target piano roll, we generate multiple augmented inputs with varying number of notes masked and added, in order to train the model to handle varying number of differences between the input and target. We find that masking between 0 to 100 percent of all existing notes and adding 0 to 1.5 percent of all possible extraneous notes gives us the best results.

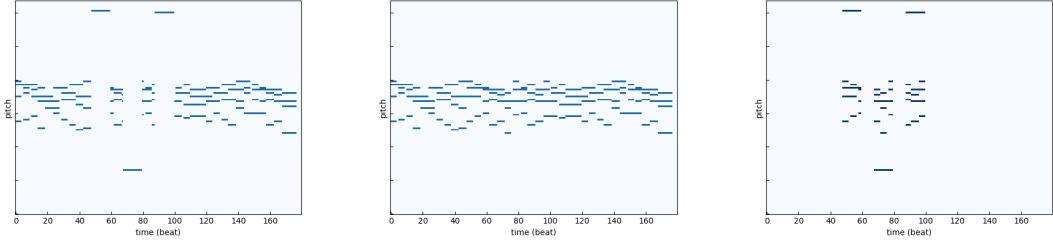
Our goal is to have the model output the conditional probabilities for the next edit event. Since we assume ordering invariance in (4), we can also assume that every note difference between $\mathcal{I}$ and $\mathcal{T}$—whether it requires the addition or removal of a note—is equally likely to be the next edit event. Thus, we model the distribution of edit events for the next step as the uniform distribution U supported on the symmetric difference $\mathcal{I}\Delta\mathcal{T}$ between $\mathcal{I}$ and $\mathcal{T}$ (i.e the exclusive or of each note between $\mathcal{I}$ and $\mathcal{T}$).

We use the Kullback-Liebler divergence between U and the model's output distribution as the loss function:

$$\mathcal{L}(\mathcal{I}, \mathcal{T}, P) = D_{KL}(P \parallel U), \tag{5}$$

where P is the softmax over the model's logits at each time and pitch. Normally, binary cross-entropy loss—where the label is the next note—would be used, but since we assume ordering invariance in (4), the next note is equally likely to be any of the future notes. Therefore, training with (5) is equivalent to training many times where the label is randomly chosen from future notes.

4.1 Model

We train a model based on the U-Net architecture [27]. This choice is not critical as our approach should generalize to other CNN architectures. We describe our approach for reproducibility. Our U-Net contains five downsampling blocks and five upsampling blocks. In each block there contains a batch normalization layer, two 2D convolutional layers each with a 3x3 kernel, a max pooling layer, and a drop out layer with a 0.5 dropout rate. We begin with 32 filters. We double the number of filters after each downsampling block and halve the number of filters after each upsampling block. We use the Adam optimizer [28] with a learning rate of 0.001. We use RELU for our activation


function, except for the final layer where we output a linear activation at each time and pitch. Finally, we apply softmax over the logits when calculating the loss and during sampling.

5. INFERENCE

We sample from the model's output probabilities through direct ancestral sampling. We feed the input melody to the model, sample from the softmax over all times and pitches to determine the next edit event, modify the input melody based on that edit event, and then feed that melody back into the model. We repeat this over multiple iterations and condition each time on our previous predictions. Since we do not differentiate between adding and removing notes during training, the sampling process is the same for any type of edit event. We allow users to restrict the number of notes to remove; this prevents the model from completely overwriting the original input. We also allow users to control how many sampling iterations are performed. Lastly, we allow the user to change the temperature during sampling. By changing the shape of the distribution, users can make compositions more or less "creative" at the risk of lowering quality. We surface these hyperparameters to allow users to more freedom and customizability when generating music compositions.

6. EMPIRICAL EVALUATION

We compare our approach against orderless NADE and Gibbs sampling using quantitative metrics and human survey evaluation. We also describe a notewise approximate log likelihood calculation for our approach and explain why log likelihood is not a good metric for comparing our approach to orderless NADE. We build an orderless NADE model using the approach described in Section 3.1 and training with only masked notes. We use Coconet [12] to represent Gibbs sampling. While our main focus is to only use Coconet for sampling technique comparisons, there are a few notable differences between Coconet and our approach. First, Coconet does not explicitly train the model to remove notes, but notes—including the input—may be removed during the Gibbs sampling masking process; our approach explicitly models note removal. Second, Coconet assumes that there are four instruments and that "each instrument plays exactly one pitch a time" [12]; our approach has no such constraint and can generate music across all times and pitches. Third, Coconet trains a CNN that preserves the same size for each layer; we train a model based on the U-Net architecture. Since Coconet is trained on the JSB Chorales dataset, we evaluate our results and Orderless NADE's results using the same dataset and the same train-val-test split in order to provide a fair comparison. For all other parameters (e.g. temperature), we maintain identical settings for each approach in order to benchmark fairly.

Figure 2. Input piano roll (left), target piano roll (middle), and symmetric difference between the input and target piano rolls (right)

6.1 Data

We use the Infinite Bach dataset[3] and the JSB Chorales dataset[4]. The JSB Chorales and Infinite Bach datasets contain MIDI files—382 for JSB Chorales and 498 for Infinite Bach—of chorales harmonized by J.S. Bach. The MIDI files in Infinite Bach dataset are generally longer in duration allowing for approximately three times more samples overall compared to the JSB Chorales dataset. Since the Gibbs sampling model is trained on JSB Chorales, we use the JSB Chorales dataset for benchmarking.

For both datasets, we preprocess the data by: 1) mapping MIDI to its piano roll representation using a sixteenth-note quantization, 2) converting multi-track inputs into a single track by merging all tracks, and 3) splitting each MIDI into multiple 2 or 8 bar samples.

6.2 Log Likelihood

We calculate log likelihood using equation (3). Since for each piano roll x the inverse image $\pi^{-1}(x)$ is infinite, the sum cannot be calculated exactly; thus, we calculate an approximate log likelihood for a subset of all possible edit sequences in $\pi^{-1}(x)$. This value lower bounds the true log likelihood value. We compare this lower bound to the log likelihood for orderless NADE. Since our method removes notes as well, the proposed model is modeling a distribution with larger support so we do not expect the likelihood value of our method to be better than orderless NADE's. Our likelihood values show that—in the toy case when the sum can be sufficiently expanded—the likelihood lower bound value approaches that of orderless NADE.

Consider a graph where each vertex corresponds to a piano roll state and each edge corresponds to an edit event. A path in the graph corresponds to an edit sequence described in equation (2). As we traverse over a path, we calculate the log likelihood of the edit sequence corresponding to that path.

For each input $\mathcal{I}$ and target $\mathcal{T}$ pairing, we calculate our log likelihood over multiple levels, traversing over edit sequences of length $K + 2d$ at level d. K is the minimum number of edit events needed to reach the target from the input. All K edit events are unique along time and pitch. For level $d = 0$, there exist $K!$ different edit sequences.

We calculate the average log likelihood over a randomly chosen subset of these edit sequences and approximate it over all $K!$ edit sequences. During the traversal we keep track of the most probable (time, pitch) predictions that do not occur in the edit sequences, and add them to a pool Q. We keep these predictions as they will appear in the most probable edit sequence paths at level $d = 1$. For level $d = 1$, we traverse down the same paths, but we add two edit events with the same time and pitch chosen from Q to the path. This increases the path length to $K + 2$ and results in the same target pianoroll since the two new edit events cancel out. We approximate the log likelihood sum over all possible edit sequences. We repeat this for each (time, pitch) pair in Q. This process can be repeated until level $d = D$ expanding our coverage of the edit sequence graph along the most probable paths.

We calculate the approximate log likelihood as:

$$\frac{1}{K} \log \sum_{d=0}^{D} \sum_{Q} \frac{(K+2d)!}{2^d} \frac{1}{|S|} \sum_{s \in S} p^{\text{ES}}(s)$$

where S is a random subset of $K + 2d$ length edit sequences that can transform $\mathcal{I}$ to $\mathcal{T}$.[5] As we increase the levels of our approximation, our log likelihood will converge towards orderless NADE which we see in Table 1 at $d = 1$.

Since music completion is a task with high uncertainty, the large number of low probability predictions leads to underflow issues, which we avoid by using the log-sum-exp trick. Also, since log likelihood in this case is highly dependent on the number of notes in a piece, we compute an approximate *notewise* log likelihood by dividing the approximate log likelihood by the minimum number of note additions and removals needed to reconstruct the target pianoroll. We do not use log likelihood to compare our approach with Gibbs sampling used in Coconet as they use framewise log likelihood, which is different than our calculation [12].

6.3 Quantitative Metrics

We calculate several quantitative metrics to compare the quality of generated music using our approach, orderless NADE, and Gibbs sampling. For each approach, we generate 3405 bars of music—the same number of bars in the

---

3 https://github.com/jamesrobertlloyd/infinite-bach
4 https://github.com/czhuang/JSB-Chorales-dataset

5 We divide the $K + 2d$ factorial by 2^d as we cannot "remove" before we "add" a note.

Approach	Notewise Approximate Log Likelihood
ES-Net	-0.635
Orderless NADE	-0.558

Table 1. Notewise approximate log likelihood for reconstructing 10 missing notes from each test sample.

training data—and compare them to the training data. We generate the music by conditioning on 150 8-bar monophonic inputs. We evaluate on the following metrics designed in [1, 29]:

- PC - Number of unique pitch classes used. Notes whole octaves apart from each other (e.g. C4 and C5) belong to the same pitch class.

- P - Number of unique pitches used.

- ISR - In-scale rate which is the proportion of all notes that lie in C Major [6].

- PR - Polyphonic rate which is the proportion of timesteps where the number of pitches being played is greater than or equal to 4.

We use pypianoroll [29] to calculate these values.

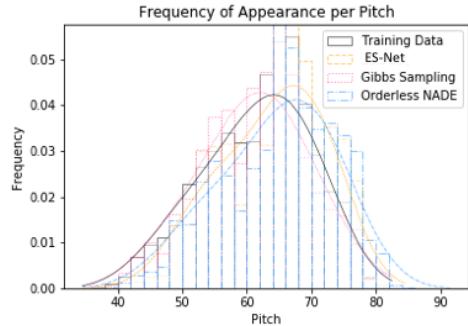
	PC	P	ISR	PR
Training Data	6	46	0.541	0.917
ES-Net	**6**	**46**	**0.540**	**0.930**
Gibbs Sampling	6	46	0.535	0.898
Orderless NADE	8	55	0.559	0.759


Table 2. Quantitative metrics for each approach. Closer to training data is better. Bold values are best between the three approaches.

We observe that our approach and the Gibbs sampling approach both produce music that have similar characteristics to the dataset, while orderless NADE shows less similarity to the dataset. As seen in Table 2, our approach is the closest for all four metrics, with Gibbs sampling tying for number of unique pitches and pitch classes used.

	Bhattacharyya	Kolmogorov-Smirnov		
		df	D	p
ES-Net	0.028	46	0.17	0.49
Gibbs Sampling	**0.021**	46	0.13	0.83
Orderless NADE	0.049	46	0.17	0.49

Table 3. Various metrics for how far pitch appearance frequency is from the training data. Lower is better and bolded is best for Bhattacharyya distance. The Kolmogorov-Smirnov test is unable to show significant difference between any of the approaches and the training data.

---

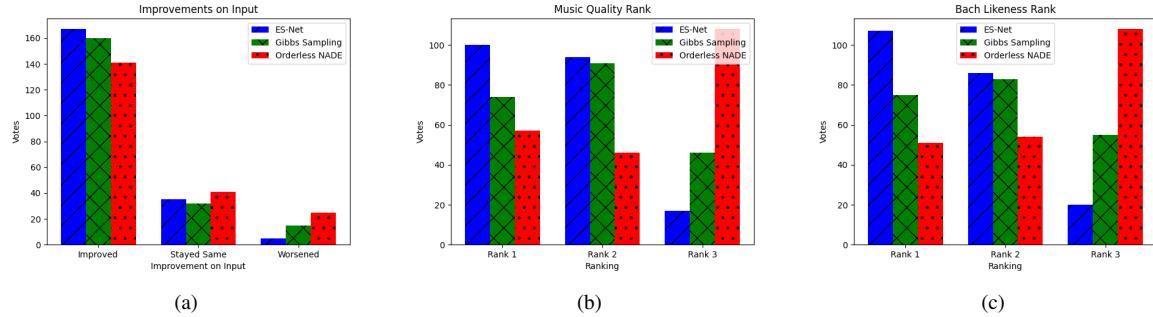
[6] The C-Major scale was chosen arbitrarily.


Figure 3. Frequency of occurrence for each pitch bin. Each bin is two pitches (i.e. one bin contains both pitch 31 and 32).

In Figure 3, we plot the frequency of pitch values for each approach and compare with the distribution of pitches in the training data. We observe that the distribution of pitches for all three approaches is very similar to that of the training data. In Table 3, we evaluate the similarity of each approach's pitch appearance frequency to the training data using various metrics. We calculate the Bhattacharyya distance [30] showing Gibbs sampling as the closest to the training data and orderless NADE as the furthest from the training data. We perform Kolmogorov-Smirnov tests and are unable to show significant differences between each approach and the training data.

6.4 Human Evaluation

We conducted a human opinion test in order to compare our approach against orderless NADE and Gibbs sampling. We generated 8 bar samples with a pitch range from 36 to 81. We assume 4/4 time (i.e. 4 beats per bar) and quantize to 16 time steps per bar (i.e. 1/16th note). We assume two notes continuous in time as one note. For orderless NADE, we sample 400 times to generate samples that approximate to 4 pitches per time step. Coconet optimizes the number of iterations it requires. Since our approach allows for the model to both add and remove notes, there is no fixed number of iterations to run the model; instead, the model eventually stabilizes and adds or removes the same set of notes repeatedly. We sample for 10,000 iterations for our approach. When conducting the surveys, we chose a large number of iterations to ensure stabilization; through later experiments, however, we found that the output almost always stabilizes before 2000 iterations.

Each survey contained fifteen randomly chosen sets of comparisons where each set of comparisons contained a random sample from each of the three approaches. Each of the samples in each set were randomly ordered. All three samples in a set were conditioned on the same input track which was also given to the participant. In order to simulate real user input, we created input tracks by taking two bar user inputs from the Bach Doodle Dataset [31]—a dataset of real user inputs to Coconet and its resulting composition—and repeated them four times to form eight

Figure 4. Human Survey Evaluation Ratings: (a) describes whether users thought a sample improved on the input. (b) describes user rankings for music quality. (c) describes user rankings for how similar a sample is to real Bach data. Bars are ordered from left-to-right as ES-Net, Gibbs Sampling, and Orderless NADE.

bars. Bach Doodle ranks their inputs based off of user feedback from the resulting Coconet composition; we chose an equal number of samples randomly from each feedback level. Each survey contained the same fifteen sets of comparisons. These inputs are monophonic (i.e. only one pitch per time step). For each set of comparisons, users were asked (a) if each sample improved on the input, (b) to rank the samples based on music quality, and (c) to rank the samples based on similarity to music composed by Bach.

We receive a total of 207 ratings for question (a), 211 ratings for question (b), and 213 ratings for question (c). [7] For question (a), we see that all approaches are comparable and each approach almost always improved the input as seen in Figure 4(a). For questions (b) and (c), we see in Figures 4(b) and 4(c) that our edit sequence approach is the best approach while the orderless NADE approach is the worst. We perform a Kruskal-Wallis H-test across all ratings for questions (b) and (c). We show that there is a statistically significant difference ($\mathcal{X}^2(2) = 64.47$, $p < 0.001$ for question (a) and $\mathcal{X}^2(2) = 73.07, p < 0.001$ for question (b)) between the three models. We use the Wilcoxon signed-rank test to conduct a pairwise post-hoc analysis. We show that there is a statistically significant difference ($p < 0.001$ for questions (b) and (c)) between our approach and both the Gibbs sampling and orderless NADE approaches.

7. FUTURE WORK

We currently trained on a limited number of datasets, both of which are based on Bach chorales. There is no reason, however, that our approach should be limited to any feature of Bach. By training on other datasets, we will be able to evaluate how well our approach generalizes.

We show that allowing the model to remove notes increases music quality which we believe is due to the model correcting its past mistakes. During our training process, we generate random notes in order to mimic those mistakes. Rather than merely mimicking those mistakes, however, we can generate real mistakes by feeding outputs

from the model back into itself. We believe that this self-adversarial training paradigm will allow the model to capture more realistic sampling mistakes and further improve performance.

Our current data representation does not convey features such as note velocity, repeated notes, or explicit note duration. These features, however, can add to the technical and emotive quality of music. We can map these new features as additional channels and concatenate this information with our existing piano roll. This new data representation will allow our model to learn from these new feature dimensions and produce more expressive and technically challenging music.

An advantage of our algorithm is the ease with which we can extend our approach to other use cases. For instance, currently our model generates fixed length outputs depending on the length of the training samples. In this way, we can extend user melodies up to a fixed length; however, we never explicitly train our model to extend inputs. By augmenting our dataset so that the latter portion of each sample is masked out, we can explicitly train our model to extend melodies. Then, during sampling, we can generate a fixed length output, feed the latter portion of that output back into the model to generate a new output, concatenate those two outputs together, and repeat. This would allow us to extend melody repeatedly rather than up to a fixed length output.

8. CONCLUSION

We show that by modeling removal of notes, we can train a model to produce better music by fixing past mistakes and preventing accumulation of errors. We discuss how our note-by-note approach allows for a finer degree of control and better human and AI collaboration. We demonstrate how to map an edit sequence representation into a piano roll representation and how we can use that to model a distribution of musical pieces. We discuss how we train our model by masking and adding erroneous notes and how we sample from our model during inference. Finally, we show through quantitative metrics and human evaluation that our approach is able to generate musical compositions that are of better quality than orderless NADE and Gibbs sampling.

---

[7] Some users did not answer all three questions per set of samples. Partial or incomplete rankings were discarded.

ABSTRACT

Human annotation is still an essential part of modern transcription workflows for digitizing music scores, either as a standalone approach where a single expert annotator transcribes a complete score, or for supporting an automated Optical Music Recognition (OMR) system. Research on human computation has shown the effectiveness of crowdsourcing for scaling out human work by defining a large number of microtasks which can easily be distributed and executed. However, microtask design for music transcription is a research area that remains unaddressed. This paper focuses on the design of a crowdsourcing task to detect errors in a score transcription which can be deployed in either automated or human-driven transcription workflows. We conduct an experiment where we study two design parameters: 1) the size of the score to be annotated and 2) the modality in which it is presented in the user interface. We analyze the performance and reliability of non-specialised crowdworkers on Amazon Mechanical Turk with respect to these design parameters, differentiated by worker experience and types of transcription errors. Results are encouraging, and pave the way for scalable and efficient crowd-assisted music transcription systems.

1. INTRODUCTION

Written musical resources, such as tablature or musical scores, are increasingly being digitized. The physical form of such resources would typically be a book, hence, the most obvious digitized form is a scan of the book, encoded in the form of images. In fact, numerous PDF files of scanned sheet music are commonly found on popular music websites such as the Petrucci Music Library (IMSLP [1]). One of the main disadvantages of scans though, is that the musical content contained in them cannot be computationally accessed. Having easily machine-readable

formats allows for computational analyses, easier enrichment of the digitized musical resources, and, most importantly, to ease the preservation of and the access to our written musical culture.

The majority of transcriptions for professional use involve experts using specialised interfaces, such as Finale [2] and Sibelius [3], to fully transcribe new editions of existing music manuscripts. Optical Music Recognition (OMR) aims at performing the transcription work automatically; state-of-the-art methods show acceptable performance in the case of clean music scores, but their quality quickly degrades in case of hand written notes [1]. In general, they still require substantial human intervention to provide results with consistent quality [1, 2], while interactive systems that could utilize human evaluation in an efficient and scalable way are still an open issue [3].

Microtask crowdsourcing is a popular approach for scaling up digital content annotation tasks. On online microtask crowdsourcing platforms, such as Amazon Mechanical Turk, large groups of individuals - called workers - perform *microtasks* such as image categorization, and audio or text transcription. By splitting a complex and cognitively intensive task into simpler steps, *microtasks* crowdsourcing allows people with little to no expertise, to contribute to knowledge-intensive activities [4].

Explicit control over a crowd's product, is in the heart of microtask crowdsourcing [5, 6]. To that end, microtasks design should allow the measurement of their outcomes in an algorithmic fashion. Few studies addressed the use of microtask crowdsourcing for music scores transcription, and they typically focus on guiding the workers in the transcription of whole scores [7] or by providing support to the experts [8, 9]. However, music scores are complex artefacts that need specific domain knowledge to read and understand, making the task of transcribing a score complex and cognitively demanding. To the best of our knowledge, how to address the task of score transcription through microtask crowdsourcing remains an open research question [10].

This paper contributes towards a better understanding of how music transcription could be supported, and potentially scaled up, through microtask crowdsourcing. We focus on a simple yet fundamental problem: the identification of differences (errors) between two music scores segments. Spotting errors is, in itself, a very useful operation

---

[2] `https://www.finalemusic.com/`
[3] `https://www.avid.com/sibelius`

in music transcription workflows, as it could be of assistance for experts transcribing a score, with the creation of labeled data to train automated OMR systems, or with the identification of errors made by such a system. Workers operating in online microtask crowdsourcing platforms are already accustomed to such type of tasks, but the understanding of music scores is not a common skill.

The main research question addressed in this work is: *To what extent are workers from microtask crowdsourcing platforms able to detect errors in transcribed music scores?*. To answer the question, we setup an experiment where two microtask design factors were adjusted respectively, the score transcription's *modality* (spotting errors on visual vs. audio), and the *size* (in terms of measures) to be analysed. We recruited 144 workers from Mechanical Turk, asked them to check 144 segments for several types of errors, and measured their performance in terms of completion time, accuracy, and sustained cognitive load.

Results show that crowd workers were able to achieve maximum precision of 94% and accuracy of 85% using an interface that combines visual and audio modalities, thus showing that microtask crowdsourcing is useful for error detection, and that workers benefit from the audio extract of the transcribed score, both alone and as a support for the visual comparison.

2. RELATED WORK

The topic of microtask crowdsourcing for music transcription is scarcely addressed in literature, with many relevant research questions left unanswered. In Burghardt et al. [7] the *Allegro* system was developed, a tool to allow the transcription of entire scores by a (single) human worker. However, *Allegro* has only been tested on a limited number of users, and it was not deployed on an online microtask crowdsourcing platform. The same limitation holds for the work in [8], one of the first attempts to study human input and how the task design can affect human input. This study focused on analysing segments which are one measure long, which is the smallest unit of analysis in our study as well. We expand this, by studying also how the size of the segment shown to the crowd affect its performance. An important work to mention is OpenScore [11], up to now the largest scale project to incorporate humans in music score transcription. In terms of user participation though, it was mainly carried out by seven community members with extensive musical background. Moreover they report different issues related to the management of data (done manually by the administrators of the platform) and user engagement (without any control they would focus on their preferred music score) admitting in the end that in their project "OMR (involving humans) is not currently a scalable solution".

So far, there is not any literature that has targeted unknown crowds with varying skills for music transcription tasks, thus research questions on [10] about what type of tasks users can perform and how to evaluate them still remain open. In this work we address this research gap by looking into similar crowdsourcing works in other domains. More specifically, in [12] it was found that for knowledge-intensive tasks involving artworks, a crowd with varying and unknown domain-specific knowledge found on online platforms can produce useful annotations when aided by good task design. Research has shown that UI design is an important part of a microtask design [13]. Research so far has experimented with various designs such as showing spectogram visualisations for audio annotation [14] or the use of chat-bots to assist common types of microtasks [15], all of which have yielded positive results on the performance of the crowdworkers. Inspired by this we make the design of the work interface a central point of our study.

3. EXPERIMENTAL DESIGN

The main focus of this work is to study to what extent a general crowd can identify *errors* in a music score transcription. We therefore designed an experiment aimed at testing the ability of crowd workers to spot errors using interfaces having a combination of visual and audio components.

3.1 Task Design

Our aim is to study how different task design factors can influence the crowdworkers performance, focusing on two aspects:

1. The *modality* (*visual* versus *audio*) used to spot errors: as music scores are complex artefacts, and music is primarily an auditory experience. Therefore, we investigate how the score comparison *modality* affect the error detection performance in workers that are potentially not familiar with musical notation. Intuitively, we want to investigate if "hearing" errors is easier that "seeing" errors.

2. The score *size* offered to crowdworkers for annotation. The goal is to assess how the size (in terms of measures) of the score offered to worker affects their performance.

To develop a better understanding on the characteristics of the crowd, we open the tasks with questions about their demographic information (occupational status, level of education and age) and their music sophistication. For the latter, we compiled a list of 6 questions from The Goldsmiths Musical Sophistication Index (Gold-MSI) [16].

Crowd workers' performance with error identification is measured using accuracy, precision and recall and time to execute a microtask. In addition, we measure user confidence with their judgements with a seven-value Likert scale.

Finally, we measure the sustained cognitive load when executing the microtask, measured through the NASA Task Load Index (TLX)[4], which ranges from 0 to 100 (higher the TLX is, the heavier cognitive load the worker perceives).

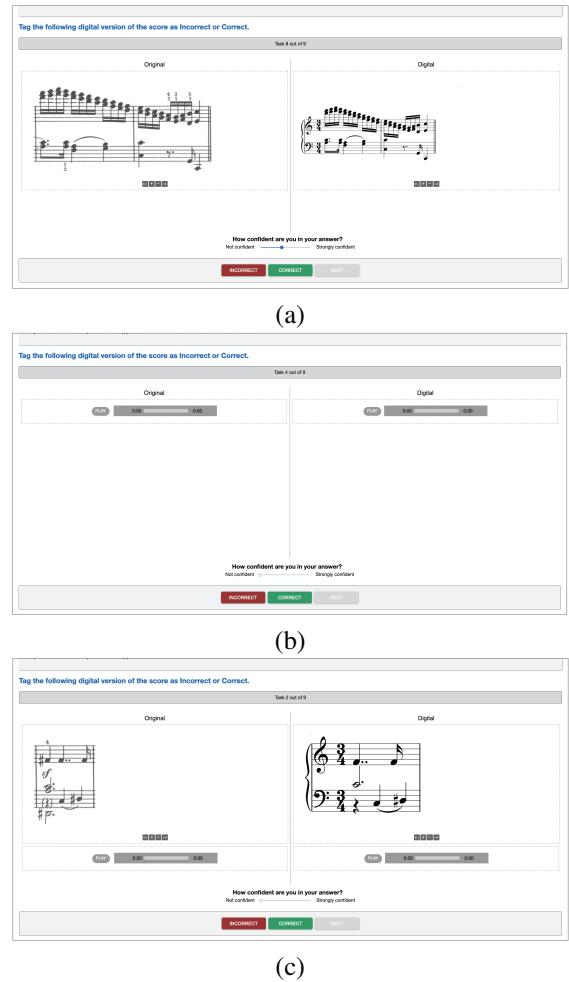
---

[4] https://humansystems.arc.nasa.gov/groups/TLX/

3.2 Evaluation Dataset

Selecting a suitable music score was our first step preparing our experiments. We use a single classical music score to avoid introducing additional variable in workers' performance. Specifically we use the Urtext of "*32 Variations in C minor*" by Ludwig van Beethoven. It is a piano piece and the music artifacts are all printed typeset forms. This is a slightly easier use case than hand-written scores. The score was retrieved from IMSLP as a PDF [5] .

As a Gold standard transcription of that PDF we used an MEI [6] file that had been transcribed by an expert. This file was accepted as error free, and it allowed us introduce errors in a controlled way for our experiments.

We segmented the music score in varying sizes to investigate how workers cope with shorter or longer tasks. We distinguish 1) *one measure* segments, 2) segments of *two measures* and 3) segments of *three measures*. Both of the two digital versions of the score, the PDF file of the original score and the transcribed MEI file, were segmented using the aforementioned segment sizes. The segmentation of the PDF was performed manually, while for the MEI we used the appropriate identifiers of each measure that was included in the corresponding image segment, to isolate the correct headers in the MEI. Since it's a piano score, each measure contains two staves.


We then introduced errors in the MEI segments derived from common errors that can occur in automatic OMR systems. The type of errors could impact the crowdworkers' ability to spot them and correctly identify them as errors. Some of them can be challenging to notice even to experts of the field. Therefore, we study different types of errors, all focusing on the music notes themselves and their accidentals. Errors on performance annotations, clefs, finger numbers etc, are out of scope in this study. We introduced the following types of error per MEI segment: 1) *Missing notes*; 2) *Wrong vertical position of a note*; 3) *Wrong duration of a note*; 4) *Wrong accidental*.

Each segment that was shown to the user contained only one type of error. The amount of errors per segment was kept constant at 40% of the notes present in the segment. Thus, if a crowdworker is presented with two measures with notes missing, then notes are missing on both measures at a 40% rate of the total notes on both measures combined. No more types of error are present in the segment.

To make the performance comparisons meaningful, we ensured that our dataset is balanced across all error types. In total we used 144 segments derived from the entirety of the selected piano score, with 48 segments per size category, from which 24 were equally distributed to each type of error, while the remaining 24 were kept correct.

3.3 User Interface Design

To test the modalities' effects separately and accurately, we designed three different interfaces: one that would have

Figure 1. Microtask User Interfaces: (a) Visual, (b) Audio and (c) Combination

image to image comparison to test the traditional form of the task, one with only audio to audio comparison, and one with both audio and image comparison. The interfaces are designed to include the following data. 1) **Original Score**: the segment's image from the scanned score. 2) **Correct MEI Render**: a render of the transcribed version of the *Original Score*'s segment; 3) **Incorrect MEI Render**: a render of the MEI transcription containing errors. 4) **Correct MIDI**: the MIDI extract of the correct version of *MEI Transcript*'s segment. 5) **Incorrect MIDI**: the MIDI extract of *MEI Transcript*'s segment containing errors.

We refrained from using audio from a recorded performance against a MIDI extract containing errors to avoid confusing the crowd on what constitutes as "different" or an "error" in the audio comparison task. A recorded performance would introduce performance-related artefacts to the audio, which do not exist in a MIDI extract, thus increasing the chance of false negatives in identifying an audio snippet as "incorrect". Finally, for the combined comparison, we used the same elements as with the individual comparisons. For the renders of the MEI transcripts and MIDI extracts we used Verovio [7] on our interfaces.

From a design perspective, the interfaces needed to be

simple and closely resembling each other to minimize their effect on the workers' judgements. They should also be able to facilitate the different segment sizes without changing the layout. Eventually, we also wanted to accommodate error detection in the same manner for both image and audio comparisons, to avoid differences on the annotation tools being another factor to the crowd's performance. Therefore, we designed the error detection task to ask from the users to annotate a given MEI transcript or MIDI extract as "*Incorrect*" if it exhibit errors and as "*Correct*" if they did not.

In all interfaces, the segments to the left are associated to the the original scanned score and the correct MEI transcription of it, while to the right we always place the segments that need to be annotated. The MEI render or the MIDI extract to the right can be either "*Correct*" or "*Incorrect*" and we calculate the performance of the workers based on identifying this correctly. In addition to the two buttons for the labels, we included a slider to indicate the worker's confidence in their label. Later in the analysis of the results, we used this indicator to study how each interface and segment size affected the confidence of the workers' to their judgements. These design considerations resulted in the following three interface designs:

- **Original Score** against **Correct/Incorrect MEI Render (Visual)**: This user interface, depicted in Figure 1(a), shows the segment of the original scanned score to the left, with the corresponding MEI render to the right. The user needs to compare the two images and spot differences related to the types of errors.
- **Correct MIDI** against **Correct/Incorrect MIDI (Audio)**: In this interface, as shown in Figure 1(b), we let the user listen to the correct MIDI extract on the left and the one generated from the MEI transcription to the right.
- **Original Score and Correct MIDI** against **Correct/Incorrect MEI and Correct/Incorrect MIDI (Combination)**: This final user interface, as shown in Figure 1(c), combines elements of the previous two. The user here has the option to either use the visual comparison, the audio comparison or both to realise if there are errors to the segment to the right. The MEI render and MIDI extraction to the right always originate from the same MEI transcription, therefore both will be correct or both will contain errors.

Each combination of interface with a segment size consists of a microtask. To efficiently and effectively gather performance data, we wanted the same worker to be "exposed" to all nine possible combinations. Therefore, in its final form, a worker would have to execute a task that would begin with a set of demographic and music sophistication questions, followed by the nine microtasks and end with the cognitive load questionnaire. To minimise the impact of issues related to the familiarity of workers with the interface, the task also includes an introductory explana-

tion of the work interface, with examples of errors and expected responses. The results of our experiment are analysed based on the overall, but also on error type, performance of workers.

4. RESULTS

As discussed in previous sections, we published our tasks on Amazon Mechanical Turk (MTurk). The platform offers several configurations for each batch of tasks submitted. We published them as public so they can be accessed by all the users of the platform and we did not require any Mechanical Turk Master (expert workers). Only to avoid malicious workers, we filter them by their previous HIT Approval Rate, and we set it to 95%.

In total, 144 workers executed our tasks on MTurk and we paid them per task execution according to the average US minimal hourly wage [8] . In order to minimize the effect of any biases or learning effect we randomized the order of the presentation of the different task designs (UI-segment size combination). One worker eluded the quality verification on task interface, which results in 143 unique workers.

4.1 Worker Demographics

From a demographic aspect, most of the workers (84.6%) reported that they had a full time occupation. Also, 67.8% of total workers reported their education level was Bachelor's degree, while 14.9% of them had Master's degree. Only 8.3% of the workers were above 45 years old.

Answers to the Gold-MSI questions indicate that the majority of workers seem to be familiar with listening to music, as 56% of them listen to music for at least 1 hour a day and 65% say they can hit the proper notes while listening to a record. Also, the majority of them (75%) state they can properly compare and discuss different performances of the same music piece. On the other hand, 52.4% of the workers reported having up to one year formal training in music theory, where the 26.6% has no prior education on the subject. Also, 41.95% of the workers have trained for maximum one year on a music instrument, while 22.4% of never had. Their answers here suggest that the majority of the crowd has little to no music theory background, and a considerable amount of them also no formal studies on an instrument. The results also suggest that the crowd executing our tasks was mainly composed of workers with little expertise with music theory.

4.2 Accuracy

The results per target segment were aggregated from three different individual workers. Table 1 shows that tasks performed with the *Audio* interface consistently achieved higher accuracy than the *Visual* one. The *Combined* interface achieved good accuracy figures with all segments sizes, but best accuracy with the 3-measure-long segments. The *Visual* interface yielded consistently the lowest recall and accuracy results, for all segment sizes. Interestingly,

---

[8] We estimated an average task completion time of 15'; each crowd-worker was awarded 2.5$

Interface	segment size		
	1	2	3
Visual	**P=66.22** R=59.76 A=60.27	**P=65.28** R=61.84 A=62.24	P=59.72 R=74.14 A=69.23

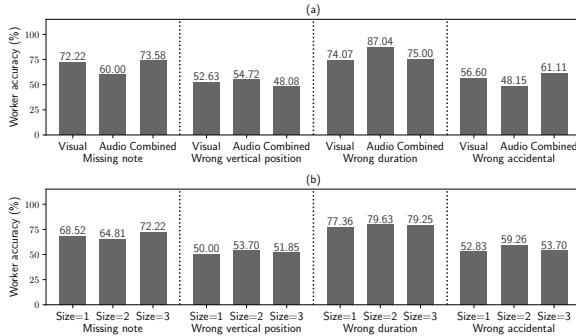
Table 2. Overall Precision, Recall and Accuracy of *aggregated* answers by segment sizes and interfaces. In bold you find the highest precision, recall and accuracy by segment size, while underlined you find the highest overall performance

the precision for this interface on segment size one, was the highest compared to *Audio* and *Combined* for the same size.


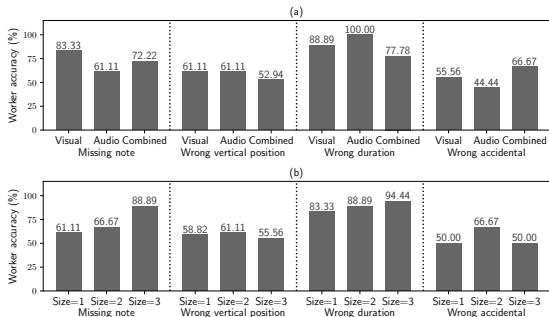


Figure 2. Workers error detection accuracy (unit:%) (a) per user interface and (b) per segment size.

Figure 3. Aggregated error detection accuracy (unit:%) (a) per user interface and (b) per segment size.

Figure 2 shows the accuracy of the workers in detecting specific type of errors. *Wrong duration* error seems to be accurately spotted in any user interface and segment size, with the *Audio* interface resulting in the highest accuracy (87.04%). Workers perform better detecting the *Missing Note* error using the *Combined* interface and the 3-measure

segments. The accuracy obtained with the *Visual* interface though, suggests that workers might rely more on the image of the score rather than the audio for this type of error. The *Wrong Vertical position* error was more difficult to detect in general; the highest accuracy was obtained with the *Audio* interface (54.72%) and with the segment size of 2 measures (53.70%). Finally, the *Wrong accidental* type was the second most demanding error to be detected with the highest accuracy achieved using *Combined* interface (61.11%), with a slight improvement in segments containing 2 measures.

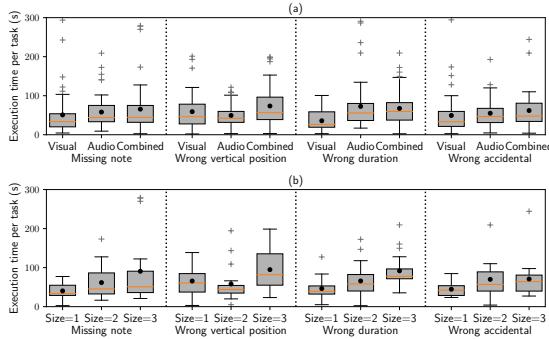
In microtask crowdsourcing it is common to aggregate individual results to improve overall quality. Table 2 shows the performance achieved using a simple *majority voting* aggregation scheme. The *Combined* interface with 3-measure-long segments still achieves best performance with a remarkable 94% in precision, and 85% in accuracy. The *Audio* interface achieves best precision performance for both 1-measure-long and 2-measure-long segments, while the *Visual* interface achieves best recall.


Figure 3 shows the aggregated accuracy in detecting specific type of errors. In terms of *Wrong Duration* error, the accuracy remains the highest after the aggregation. The *Audio* interface and the 3-measure-long segments achieve 100% and 94% in accuracy respectively. *Visual* interface and the 3-measure-long segments obtain the highest accuracy (82% and 88% respectively) in detecting *Missing note* error. The *Wrong Vertical position* error and the *Wrong accidental* error still have relatively low accuracy.

4.3 Execution Time

Figure 4 shows that, as expected, execution time generally increases as the segment size increase. We performed statistical tests (independent t-tests, $\alpha = 0.05$) to find significant differences between interfaces and segment sizes. In the case of *Wrong vertical position* error though, the *Audio* interface allowed the worker to spot the errors significantly faster compared to *Combined* interface ($p = 3.5\text{e-}3$). For the *Wrong duration* error the addition of audio and the

increased segment size can lead to a significantly longer average execution time (for both *Audio* and *Combined* interfaces compared to *Visual*, $p = 1.3e\text{-}4$ and $p = 1.9e\text{-}5$ respectively; and for 3-measure-long segment vs 1-measure-long segment, $p = 2.5e\text{-}3$).

For the *Wrong accidental* case, we see that worker spent less execution time on the *Visual* interface (no significance). However, comparing it with the results, the worker most probably dismissed the segment as "Correct", rather spend more time in case they had missed the error.

Figure 4. Worker execution time (unit: seconds) of each microtask by (a) user interface and (b) segment size.

4.4 Music Sophistication and Cognitive Load

The average score of cognitive task load (NASA-TLX) is 47.7%, a typical value for classification and similar cognitive tasks [17]. To investigate how music sophistication relates to worker performance and cognitive load on spotting music errors, we select and analyze a corresponding question from Gold-MSI questionnaire – "I find it difficult to spot mistakes in a performance of a song even if I know the tune.", where workers need to select an option from `Completely Disagree` to `Completely Agree`, before they execute the music transcription tasks.

Results show that 47% workers agreed with the statement that it was difficult to spot mistakes in a performance of a song; 33% of them disagreed with the statement, and the rest of them (20%) were unsure. We calculated the worker accuracy and the cognitive task load score, and performed significant testings (independent t-test, $\alpha = 0.05$). Workers who reported lower difficulty with spotting music errors (accuracy = $81 \pm 15\%$, TLX score = 44.36 ± 13.05) outperformed workers who had higher difficulty (accuracy = $63 \pm 16\%$, TLX score = 50.86 ± 13.61) in terms of both worker accuracy and perceived cognitive load ($p = 3.3e\text{-}8$ and 0.013 respectively). The workers who reported lower difficulty also had significantly higher accuracy ($p = 0.011$) compared to unsure workers (accuracy = $0.70 \pm 0.20\%$, TLX score = 46.01 ± 14.27). Results suggest that the self-reported music sophistication in some specific aspects strongly relates to actual worker performance in error identification and cognitive load. Nonetheless, workers with lower sophistication still achieved good performance, with a small additional cost in terms of cognitive load.

5. DISCUSSION

As expected, people with some formal knowledge in music, which could be useful to comprehend music scores, are very rare "in the wild". To enable the use of microtask crowdsourcing for music score transcription, good task design is therefore of essence. Results show that error detection is a task that could be successfully performed in a microtask crowdsourcing setting. Offering audio extracts of a target music score can positively affect the performance of the crowdworkers, especially for short segments of one or two measures. With larger segments, even though audio extracts are still yielding better results against to the textual measures of the score, a combination of the two modalities is more preferable. This result gives important indications for task splitting and scheduling purposes, as it suggests that it is possible to evaluate larger portions of scores without incurring accuracy penalties. This has obvious implications in terms of overall transcription costs.

In terms of types of detected errors, results suggest that the *Missing Note* and *Wrong Duration* errors are the easiest to be found, while the crowd had relatively more difficulty detecting *Wrong Accidentals* and *Wrong vertical position* ones. Furthermore, we see the clear effect of user interface and segment sizes in identifying correctly specific errors. Specifically, the *Audio* interface helps in finding *Wrong duration* errors, while the *Combined* one increases the accuracy in finding *Wrong accidental* mistakes. Showing segments longer than two measures seems to slightly hinder the ability of the crowd to detect any errors besides *Missing notes*.

Limitations. Correct MEI render and correct MIDI files of scores to be transcribed are typically not available in the real world. The distribution of errors in the evaluation dataset might not reflect the actual distribution of errors produced, for instance, by OMR systems. Given these limitations, the results of our experiment are probably to be interpreted as an "upper bound" in terms of achievable performance; nonetheless, they clearly indicate that the detection of errors in transcribed music score is an activity that can be successfully performed by crowdworkers.

6. CONCLUSION

Music score transcription is an important activity for written music preservation. Through this work, we show that microtask crowdsourcing can be used to scale up specific transcription activities. Worker interfaces that combine visual and audio modalities allow the evaluation of longer score segments. Focusing on the error detection task, results show that crowd workers can achieve high precision and recall, especially with *Missing Note* and *Wrong Duration errors*. In future work, we plan to expand the evaluation dataset, perform experiments where workers are asked to compare recorded performance, and address a broader set of transcription errors. Finally, we will investigate other types of microtasks, and study to what extent crowd workers could also be employed to *transcribe* scores.

ABSTRACT

The assessment of music performances in most cases takes into account the underlying musical score being performed. While there have been several automatic approaches for objective music performance assessment (MPA) based on extracted features from both the performance audio and the score, deep neural network-based methods incorporating score information into MPA models have not yet been investigated. In this paper, we introduce three different models capable of score-informed performance assessment. These are (i) a convolutional neural network that utilizes a simple time-series input comprising of aligned pitch contours and score, (ii) a joint embedding model which learns a joint latent space for pitch contours and scores, and (iii) a distance matrix-based convolutional neural network which utilizes patterns in the distance matrix between pitch contours and musical score to predict assessment ratings. Our results provide insights into the suitability of different architectures and input representations and demonstrate the benefits of score-informed models as compared to score-independent models.

1. INTRODUCTION

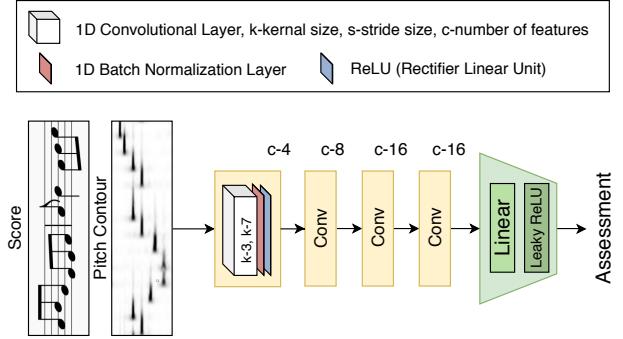
A performance is a sonic rendition of a written musical score (in the case of Western classical music). The characteristics of a music performance play a major role in how listeners perceive music, even if performances are based on the same underlying score [14]. To perform a musical piece, the performer must first parse the score, interpret or modify the musical information, and utilize complex motor skills to render the piece on their instrument [21].

From the perspective of the performer, mastery over the art of music performance is often a journey spanning several years of instruction and practice. A major factor in learning and improving one's skill as a performer is to analyze and obtain feedback regarding the performance. Due to the complex nature of music performance, students require regular feedback from trained professionals. Teachers are expected to grade or rate students based on various performance criteria such as note accuracy or musicality. These criteria are often ill-defined and subject to interpretation, thus making objective and consistent music performance assessment (MPA) rather difficult [26, 29]. Regardless, this subjective manner of MPA is still used, e.g., in school systems where ensemble members are selected based on instructors' assessments of student auditions.

Wu et al. discussed the notion of objective descriptors (features) which are potentially useful for automatic MPA [30]. Such features are computed by applying signal processing methods to recorded performances and are used to model teachers' assessments of the performances using machine learning. With the rise of deep learning, neural networks were found to outperform the classical pipeline of feature extraction followed by regression [22]. However, one issue with these approaches is that they ignore the score that the students are meant to play. We will refer to such approaches as *score-independent*. The idea of incorporating score-based features utilizing audio to score alignment was explored, e.g., by Vidwans et al. [27]. Further analysis of hand-crafted features for MPA showed the relative importance of score-based features over score-independent ones [8]. Therefore, the design of deep architectures that incorporate score information is an obvious and overdue extension of previous approaches.

The goal of this paper is to explore different methods to incorporate this score information. Our hypothesis is that including score information will lead to improved performance of deep networks in the objective MPA task. To this end, we present three architectures which combine score and audio features to make a *score-informed* assessment of a music performance. First, we concatenate aligned pitch contours and scores into a 2-dimensional time-series feature representation that is fed to a convolutional neural network (CNN). Second, we propose a joint embedding model for aligned score and pitch contours. The assessment ratings are predicted using the cosine similarity between the score and performance embeddings. Third, we utilize the distance matrix, a mid-level representation combining both the score and pitch contour, as the input to a deep CNN trained to predict the teachers' assessments. Finally, using a fairly large scale dataset of middle school and high school student auditions, we perform an in-depth evaluation comparing these proposed architectures against each other and with a

score-independent baseline approach for MPA .

2. RELATED WORK


MPA deals with the task of assessing music performances based on audio recordings. Progress in MPA is roughly categorized into feature design-based approaches [8, 13, 20, 24, 30] and feature learning-based approaches [9, 22, 31]. Feature design-based methods rely on signal processing techniques to either extract standard spectral and temporal features [13], or use expert knowledge to extract perceptually motivated features capable of characterizing music performances [20, 24]. The extracted features are then fed into simple machine learning classifiers to train models which predict different performance assessment ratings. Feature learning-based approaches, on the other hand, stem from the argument that important features for modeling performance assessments are not trivial and cannot be easily described. Hence, they rely on using mid-level representations (such as pitch contours or mel-spectrograms) as input to sophisticated machine learning models such as sparse coding [9, 31] and neural networks [22].

Most performances of Western music, however, are based on written musical scores. Hence, performances are also assessed based on their perceived deviations from the underlying score. There has been some prior research on incorporating the score information into the assessment modeling process. Most of the these approaches rely on computing descriptive features using some notion of *distance* between the score representation and the performance representation [3, 6, 11, 17, 19]. The most common approach has been to first use an alignment algorithm, e.g., Dynamic Time Warping (DTW) [25], to temporally align the performance recording with the score and then compute descriptive features which characterize the deviations of the performance from the score [1, 27]. However, to the best of our knowledge, incorporating score information directly into neural network-based models for MPA has not been investigated before.

Score-informed approaches have helped improve results for both related performance analysis tasks and other music information retrieval tasks. Most of these methods have also relied on an alignment between the audio recording and the score as the primary tool for incorporating score information. Aligning audio recordings with scores has been useful for several tasks such as detecting expressive features in music performances [15], identifying missing notes and errors in piano performances [5], and segmenting syllables in vocal performances [23]. Scores have also been used to generate soft labels and/or artificial training data for tasks such as source separation [4, 18].

3. METHODS

We propose and compare three different approaches to incorporate the score information with audio features for MPA. [1] The score information is represented as the MIDI pitch sequence (in ticks) obtained from the sheet music of the score

---

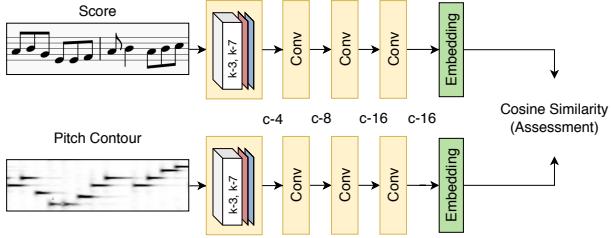
[1] The code is available at: https://github.com/biboamy/FBA-Fall19

Figure 1. Schematic for the SIConvNet. The aligned *score* and *pitch contour* are stacked together and fed into a 4-layer CNN to directly predict the assessment ratings.

to be performed. Henceforth, the MIDI pitch sequence will be referred to as the *score*. The student's *performance* is represented by the pitch contour of the audio. We use pitch contour since it captures both pitch and rhythmic information. Musical dynamics and timbre are ignored in this study; while dynamics are an important expressive tool for the performer [14], the score usually lacks specificity in dynamics instructions and cannot serve as the same absolute reference as for pitch and rhythm.

3.1 Score-Informed Network (SIConvNet)

The first approach that we use is probably the most straightforward way of incorporating score information into the assessment model. A simple CNN is used that relies on both the score and performance as the input and directly predicts the assessment ratings.

3.1.1 Input Representation


The input representation for this approach is constructed by simply stacking an aligned pitch contour and score pair to create a $N \times 2$ matrix, where N is the sequence length of the pitch contour. The two channels correspond to the pitch contour and score, respectively.

In order to obtain this representation, we first consider a pitch contour snippet of length N (sequence of logarithmic frequencies). Then, we find the corresponding part of the score using a DTW-based alignment process. The obtained score snippet (sequence of MIDI note numbers) is then resampled to have the same length N as the pitch contour.

3.1.2 Model Architecture

A schematic of the model architecture is shown in Figure 1. We use a simple 4-layer CNN based on the architecture proposed by Pati et al. [22] and append a single linear layer which predicts the assessment. Each convolutional stack consists of a 1-D convolution followed by a 1-D batch normalization layer [12] and ReLU non-linearity. The linear layer at the end comprises of a dense layer followed by Leaky ReLU non-linearity.

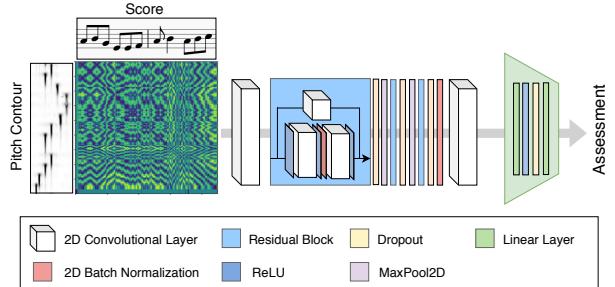
Figure 2. Schematic of the JointEmbedNet architecture.

3.2 Joint Embedding Network (JointEmbedNet)

The second approach is based on the assumption that performances are rated based on some sort of perceived distance between the performance and the underlying score being performed. Consequently, we use two separate encoder networks to project the score and the pitch contour to a joint latent space and then use the similarity between the embeddings to predict the assessment ratings.

3.2.1 Input Representation

This approach uses the same input representation as SIConvNet (see Section 3.1.1). However, instead of stacking the aligned pitch contour and the score, the individual $N \times 1$ sequences are fed separately to the two encoders.

3.2.2 Model Architecture


This network (see Figure 2) uses two 1-D convolutional encoders having the same architecture as SIConvNet. Each encoder has 4 convolutional blocks to extract high level feature embeddings. The performance encoder is expected to extract relevant features pertaining to the performance from the pitch contour. On the other hand, the score encoder is expected to extract the important features from the score. Assuming that the assessment rating for the performance is high if these two embeddings are similar, we use the cosine similarity $\cos(E_{\mathrm{score}}, E_{\mathrm{performance}})$ between the two embeddings to obtain the predicted assessment rating. E_{score} and $E_{\mathrm{performance}}$ are the embeddings obtained from the score and performance encoders, respectively. If the two embeddings are similar, the cosine similarity is close to one, and the model will predict a higher rating.

3.3 Distance Matrix Network (DistMatNet)

The final approach uses a distance matrix between the pitch contour and the score as the input to the network. Given the information from both the pitch contour and the score, the task of performance assessment might be interpreted as finding a *performance distance* between them. Thus, the choice of the distance matrix as the input representation allows the model to learn from the pitch differences. A Residual CNN [10] architecture is chosen for the network.

3.3.1 Input Representation

The distance matrix elements are the pair-wise wrapped distances between the pitch contour and the MIDI pitch sequence. The octave-independent wrapped-distance is

Figure 3. Schematic of the DistMatNet architecture.

used to compensate for possible octave errors made by the pitch tracker. To ensure a uniform input size to the network, the matrix is resampled to a square shape of a fixed size. Thus, a performance with constant tempo would result in an aligned path located on the diagonal. Unlike the previous two methods where the input pitch contour and the score are aligned using DTW, the distance matrix input avoids any error propagation caused by alignment errors. The choice of this input representation stems from the success of distance matrices (or self-similarity matrices) in other areas of MIR such as structural segmentation [2, 7] and music generation [28].

3.3.2 Model Architecture

The model architecture is shown in Figure 3. It is composed of 3 residual blocks. Each residual block has 2 convolutional layers. Dropout and max-pooling are added between each residual block. A classifier with two linear layers (128 features) with one ReLU and dropout layer in between is used after the residual network to perform regression prediction. We use (3,3) kernal size and 4 feature maps for all convolutional layers, 0.2 dropout rate, and a (3,3) kernal size for all max-pooling layers.

4. EXPERIMENTS

4.1 Dataset

The dataset we use to evaluate our methods is a subset of a large dataset of middle school and high school student performances. These are recorded for the Florida All State Auditions, which are separated into three bands: (i) middle school band, (ii) concert band, and (iii) symphonic band. The recordings contain auditions spanning 6 years (from 2013 to 2018), and feature several monophonic pitched and percussion instruments. Each student performs rehearsed scores, scales and a sight reading exercise. For the purpose of this study we limit our experiments to the *technical etude* for middle school and symphonic band auditions. We choose *Alto Saxophone*, *Bb Clarinet* and *Flute* performances due to these being the most popular across all pitched instruments. Table 1 shows the distribution of data across different instruments. The average duration of each performance is 30 s for middle school and 50 s for symphonic band students. The dataset also includes the musical scores that the students are supposed to perform for each exercise. The average length (in notes) of the musical

	Middle School	Symphonic Band
Alto Saxophone	696	641
Bb Clarinet	925	1156
Flute	989	1196

Table 1. Number of performances for the different instruments per band.

scores are 136 for middle school and 292 for symphonic band. Note that these scores are the same across all students performing the same instrument in the same year but vary across years and instruments.

The dataset also contains expert assessments for each exercise of a student performance. Each performance is rated by one expert along 4 criteria defined by the Florida Bandmasters' Association (FBA): (i) musicality, (ii) note accuracy, (iii) rhythmic accuracy, and (iv) tone quality. All ratings are on a point-based scale and are normalized to range between 0 to 1 by dividing by the maximum. Since we focus on pitch contours as the primary audio feature, tone quality is excluded from this study.

4.1.1 Data pre-processing

The pitch contours are extracted using the pYIN algorithm [16] with a block size and hop size of 1024 and 256 samples, respectively. The audio sampling rate is 44100 Hz. The extracted frequencies are converted from Hz to MIDI pitch (unlike the MIDI pitches from the musical score, these can be floating point numbers). Both the resulting pitch contour and musical score are normalized by dividing by 127. Finally, for the purpose of model training and evaluation, we divide our dataset into three randomly sampled subsets: training, validation, and testing. We use a ratio of $8 : 1 : 1$ for splitting the dataset.

We use *random-chunking* as a data augmentation tool when training SIConvNet and JointEmbedNet since it has shown to be useful in improving model performance [22]. First, the pitch contour is chunked into snippets of length N by randomly selecting the starting position. The corresponding aligned and length-adjusted score snippet is obtained using the method described in Section 3.1.1. We assume the chunked segment has the same assessment score as the whole recording. We do not perform chunking on our distance matrix since the matrix has already been resampled into a smaller resolution. Instead, we discuss how varying the resampling size could effect the performance in one of the experiments.

4.2 Experimental Setup

We present three experiments to evaluate our proposed methods. First, we compare the overall performance of the proposed architectures against a score-independent baseline system PCConvNet [22] which uses only the randomly-chunked pitch contour as input. This experiment also gives us an indication of the effectiveness of each of the proposed methods. Second, we look at the sensitivity of the SIConvNet and JointEmbedNet to the chunk size N. Finally, we investigate the effect of varying the resolution of the input

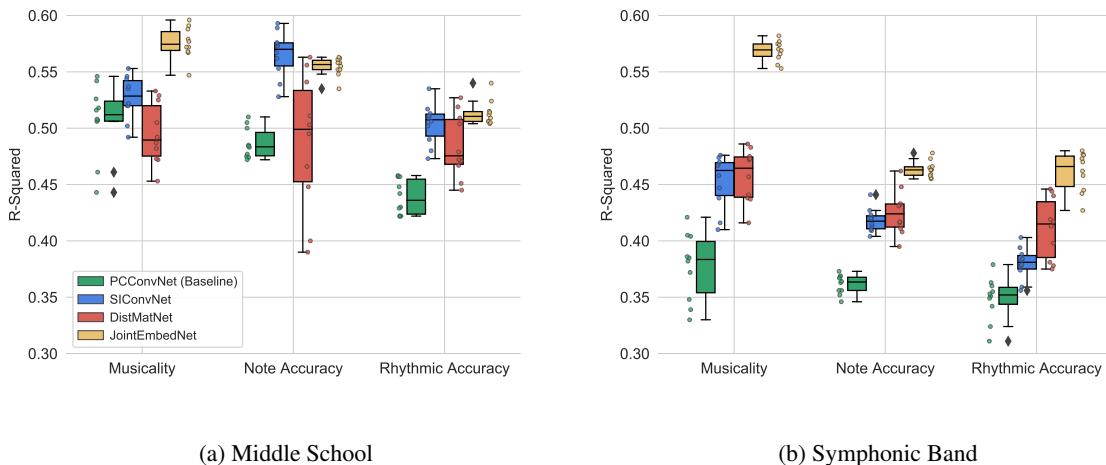
SIConvNet	JointEmbedNet	DistMatNet
3,089	6,144	63,417

Table 2. Number of parameters for each model.

distance matrix for the DistMatNet model. The latter two experiments were aimed at understanding the effects of the different hyper-parameters used while constructing the input data for each model. These helped us arrive at the best parameters for each approach.

The number of trainable parameters for each method is shown in Table 2. DistMatNet has a higher number of parameters because it uses a higher-dimensional input with a deeper architecture to capture high level information [10].

For each method, we trained separate models to predict each assessment criterion. Moreover, to measure the variation of each model, we trained each model on 10 different random seeds. We used M_i to represent the model training on different random seed where $i = 0 \dots 9$. A boxplot with median and variation of each M_i is shown to demonstrate the results. All the models are trained based on the mean squared error between estimated and ground truth ratings. All the models are trained with a stochastic gradient descent optimizer with a 0.05 learning rate. We apply early stopping if the validation loss does not improve for 100 epochs. The performance of all models is measured using the coefficient of determination (R^2 score):

$$R^2 = 1 - \frac{\sum_i (y_i - \hat{y}_i)^2}{\sum_i (y_i - \bar{y}_i)^2}, \tag{1}$$


where y_i is the ground truth rating, $\hat{y}_i$ is the estimated rating, and $\bar{y}_i$ is the average of the ground truth rating. R^2 is a common metric to evaluate the fit of a regression prediction to the ground truth value.

5. RESULTS & DISCUSSION

5.1 Overall Performance

Figure 4 shows the comparative performance for all models for middle school and symphonic band. We can make the following observations (with independent t-test results reported):

(i) We compare the performance of various models trained on different band performances. All systems perform better (higher R^2 value) on the middle school recordings than on the symphonic band recordings ($p < 0.01$ except JointEmbedNet for musicality). One possible explanation for this is that symphonic band scores are usually more complicated and longer. For example, symphonic band scores tend to be performed at high tempo with high note density. The chunking into smaller lengths (and the downsampling of the distance matrix) compared to the score length might lead to a less accurate mapping to the assessment rating. An additional factor is that most performers in the symphonic band auditions exhibit greater skill level than middle school performers thus making it

(a) Middle School

(b) Symphonic Band

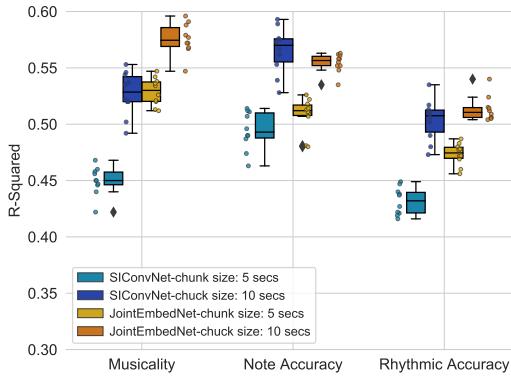
Figure 4. Box plots showing comparative performance (higher is better) across different models and assessment criteria.

potentially more difficult to model the differences in proficiency levels.

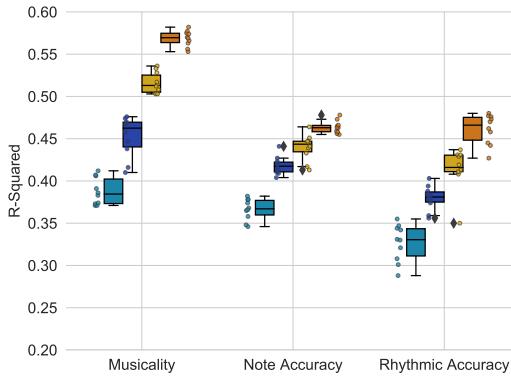
(ii) All score-informed models generally outperform the baseline, implying that score information is indeed helpful for MPA ($p < 0.01$ except SIConvNet for musicality, DistMatNet for musicality and note accuracy on middle school). We notice, however, that the difference between the score-independent baseline and the score-informed models is smaller for the middle school than for symphonic band. Given the significant improvement over the baseline for symphonic band performances (which have complicated scores), we speculate that the score-informed models benefit more from access to score information. In other words, a score reference becomes more impactful with increasing proficiency level while the pitch contour alone contains most relevant information for medium proficiency levels.

(iii) While the two models SIConvNet and JointEmbedNet both use the same input features, JointEmbedNet either outperforms or matches SIConvNet in all experiments. The main difference between these two architectures is that SIConvNet simply performs a regression to estimate the assessments while JointEmbedNet learns a similarity in the embedding space to model the assessments. Therefore, we can assume that JointEmbedNet is able to explicitly model the differences between the input pitch contour and score especially in the case of symphonic band where the scores are more complicated.

(iv) We observe that while DistMatNet and JointEmbedNet both utilize the similarity between the score and pitch contour, albeit at different stages of the network, JointEmbedNet typically performs better across categories and bands, and the gap is larger for musicality than for the other two categories. It is possible that the absolute pitch at the input may be important for the final assessment (octave jumps, for example, would not be properly modeled in the distance matrix). More likely, however, is that the significantly larger input

dimensionality of the matrix (compared to the aligned sequences for JointEmbedNet) negatively impacts performance. Most of the relevant information for MPA centers around the diagonal of the distance matrix with relatively small deviations depending on the students' tempo variation. Most of the distance matrix elements far from the diagonal contain redundant or irrelevant information, thus complicating the task. Another advantage that JointEmbedNet might have over DistMatNet in terms of overall assessment is that the distance is computed on the whole performance while DistMatNet computes a frame-level pitch distance, potentially complicating the task for overall quality measures like musicality.


5.2 Chunk Size

In this experiment, we look at the impact of two different chunk sizes for the first two methods. Figure 5 shows the results on middle school (a) and symphonic band (b). For both SIConvNet and JointEmbedNet, a chunk size of 10 s outperforms that of 5 s across all the bands.


Chunking with random sampling is a form of data augmentation. By using the ground truth rating of the whole performance, the chunks are assumed to reflect the quality of the whole performance. The results show that 5 s chunks might be too short to evaluate the whole performance while 10 s chunks are much better suited regardless of category and score complexity. Chunk lengths greater than 10 s were not tested because we restricted ourselves to the length of the shortest performance in the dataset. Consequently, we used a 10 s chunk size for the experiment in Figure 4.

5.3 Distance Matrix Resolution

In this experiment, we study the impact of the different input matrix resolutions 400×400, 600×600, and 900×900, for the DistMatNet model. The results for both middle school and symphonic band are shown in Figure 6. First, the performance of rhythmic accuracy criterion tends to decrease with increasing distance matrix resolution. It might

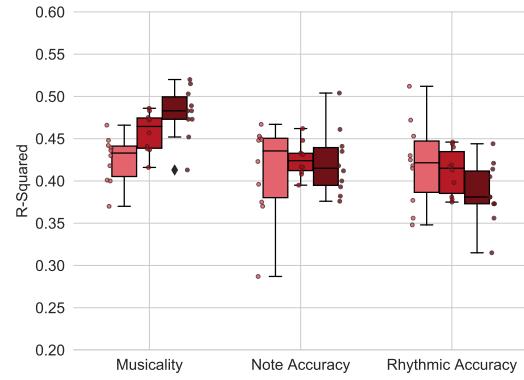
Figure 6. Box plots showing comparative performance (higher is better) across different matrix sizes for the distance matrix network (DistMatNet).


be more difficult for the same model structure to capture the complexity inside a larger matrix. This can also explain the result for middle school: although increasing the input resolution from 400×400 to 600×600 will capture more details, the performance decreases when the matrix resolution is further increased. Second, an input matrix size of 600×600 leads to a slightly higher average score (0.46) on both symphonic and middle school than the other two resolutions (0.45 for 400×400 and 0.43 for 900×900). We ended up using the 600×600 resolution for the experiment in Figure 4.

6. CONCLUSION

This paper presents three novel neural network-based methods that combine score information with a pitch representation of an audio recording to assess a music performance. The methods include: (i) a CNN with aligned pitch contour and score as the input, (ii) a joint embedding model that learns the assessment as the cosine similarity of the embeddings of both the aligned pitch contour and the score, and (iii) a distance-matrix based CNN, using a differential repre-

sentation of pitch contour and score at the input. The results show that all the methods outperform the score-independent baseline model. The joint embedding model achieves the highest average performance.

Beyond the obvious applications in software-based music tutoring systems, score-informed performance assessment models (and objective MPA in general) can benefit the broader area of music performance analysis. Models capable of rating performances along different criteria could serve as useful tools for objective evaluation of generative systems of music performance. In addition, such models could also be explored for objective analysis of inter-annotator differences in rating music performances.

In the future, we plan to incorporate timbre and dynamics information into the models as it has been shown to improve accuracy [22]. This will also enable the model to assess performances in terms of tone quality, the criterion ignored in this study. We also plan to investigate other instruments and to examine cross-instrument relationships by training instrument-specific models. Furthermore, the musical score reference could be replaced with other representations such as the pitch contour of a highly-rated performance.

HIERARCHICAL TIMBRE-PAINTING AND ARTICULATION GENERATION

Michael Michelashvili

ABSTRACT

We present a fast and high-fidelity method for music generation, based on specified f0 and loudness, such that the synthesized audio mimics the timbre and articulation of a target instrument. The generation process consists of learned source-filtering networks, which reconstruct the signal at increasing resolutions. The model optimizes a multi-resolution spectral loss as the reconstruction loss, an adversarial loss to make the audio sound more realistic, and a perceptual f0 loss to align the output to the desired input pitch contour. The proposed architecture enables high-quality fitting of an instrument, given a sample that can be as short as a few minutes, and the method demonstrates state-of-the-art timbre transfer capabilities. Code and audio samples are shared at https://github.com/mosheman5/timbre_painting.

1. INTRODUCTION

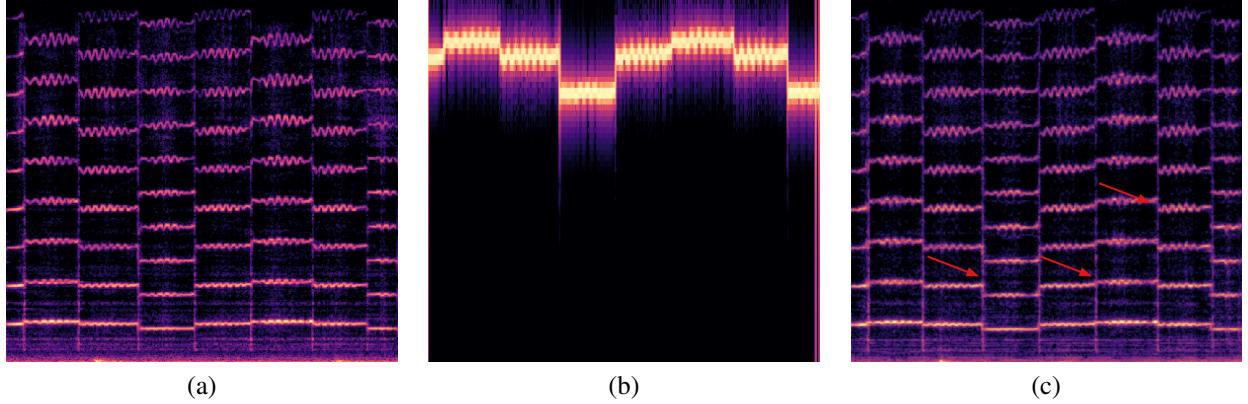
The melody, as depicted by a sequence of notes, or alternatively by a sequence of frequencies, is one generic aspect of the musical experience. The dynamic loudness signal is another prominent aspect that is also almost instrument-invariant. Due to the invariance property of these two aspects, it is natural to employ them as specifications to the instrument-independent essence of a musical piece.

A prominent aspect that does depend on the instrument is the timbre. The music-AI task of timbre-transfer considers methods that receive, as input, an audio segment and a target instrument, and output the analog (melody preserving) audio in the target domain, by replacing the timbre of the original audio clip with that of the specified instrument.

Another aspect that defines a musical instrument is articulation, or the joining-up of notes. Timbre transfer methods address this implicitly with varying degrees of success. The physical properties of the instrument lead to constraints and subsequently different characteristic ways to move from one note to the next in a smooth manner. This aspect, therefore, varies considerably, e.g., between violin, guitar, and trumpet.

While this interpolation process is second nature for trained musicians, it can be sophisticated and involves the introduction of new frequencies that are not part of the original notes. See Fig. 1.

In this work, we build a hierarchical music generator network. Given a fundamental frequency (f0) and loudness inputs, the network generates audio in four different scales. While the different scales share the same architecture, they have different roles. The first (lower) scale introduce the articulation, while the top scales introduce much of the timbre and the final audio-spectrum quality, which we call timbre-painting. See Fig. 2.

The model is trained on a relatively short sample from the target instrument, typically consisting of few minutes. The network is trained to minimize multiple losses: an adversarial loss encourages the output to be indistinguishable from audio in the output domain, multi-scale reconstruction losses in the frequency domain are used to ensure that the network can recreate the training sample, and the f0 of the output is compared to the specifications.


One possible application of the network is for the task of music domain transfer, similar to the application of other timbre-transfer methods. In this case, the f0 and loudness inputs are extracted from an existing audio clip and the network generates the analog music in the target domain. Our experiments show that our method generates audio that sounds more realistic and is perceived to be of a better fit to the original melody than the recent state-of-the-art method DDSP [1].

2. RELATED WORK

The task of timbre-transfer was tackled by [2]. An image-to-image pipeline that uses cycle consistency losses [3] is applied to the audio domain by representing audio signals as 2D images with the Constant-Q-Transform (CQT). To move back from the CQT representation, a WaveNet [4] synthesizer that is conditioned on CQT representation was used. Another prominent work [5] suggested to learn the audio melody by using a WaveNet Autoencoder architecture [6]. One "universal" encoder is used to represent melody from raw data, and multiple domain-specific decoders are used for audio generation. By presenting domain-adversarial loss on the encoding, this method represents only the domain-invariant data needed for generation, which is predominantly the melody. Even though this method presents impressive results on timbre transfer and audio translation, it has few major disadvantages: the reliance on large amounts of data, and the heavy computation resources required (tens of GPUs).

Figure 1. An illustration of our method's articulation capabilities. (a) The spectrogram of a violin audio. (b) The extracted fundamental frequency (f0) of the violin. (c) The results of our method. Both the timbre and the articulations were manipulated. See arrows for a few specific locations where the violin's articulation is demonstrated.

The differentiable digital signal processing (DDSP) method [1], which was proposed recently, is much more efficient with regards to both data and computational needs. The method presents a DSP hybrid model in which a synthesizer with learned parameters is used. Like our method, DDSP conditions the signal generation on f0 and the loudness signal. Therefore, it can apply timbre-transfer to any audio for which a pitch tracker, e.g., CREPE [7], can successfully extract the f0 signal.

DDSP and other methods [8] follow the high fidelity speech synthesizer of [9] in employing convolutional neural networks as shape-shifting filters to a sine-wave input. While many speech generation techniques condition the network on the f0 signal, this line of methods employ the corresponding sine-wave.

Hierarchical generation was shown to be effective for image generation tasks. The progressive GAN method [10] breaks down the generation scheme into cascading generators and discriminators, improving the image generation quality and stabilizing the training process. The SinGAN method [11] performs convincing image-retargeting and image generation, using multi-scales learning from a single input image.

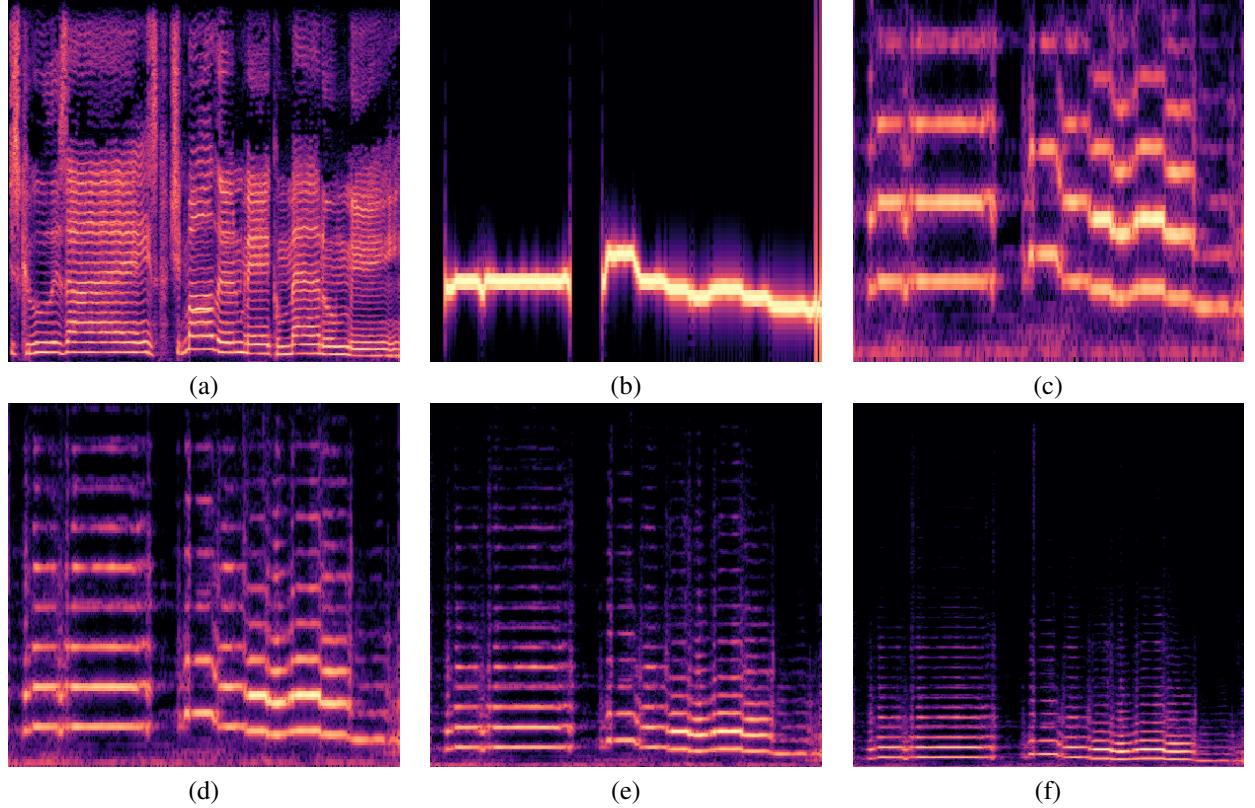
3. METHOD

Our method is hierarchical and consists of generators in four different scales. All generators have the same architecture of a non-autoregressive WaveNet applied on (scale-dependent) input and conditioned on extracted audio features on each scale. The learning process is optimized to: (i) decrease the distance between the spectral representations of the generated and the target audio, (ii) minimize pitch perceptual loss in order to improve pitch coherence, and (iii) create realistically sounding examples by the usage of an adversarial loss.

3.1 Input Features

An audio sample is denoted by $\boldsymbol{x^n} = (x_1^n, \ldots, x_T^n)$, where T is the length of the signal and n is the finest scale we consider. The scaled version of it are denoted by $\boldsymbol{x^{n-1}}$,

$\boldsymbol{x^{n-2}}$, up to $\boldsymbol{x^0}$, which is the coarsest scale. The scaling is carried out by down-sampling,

$$x^{n-1}[t] = \sum_{k=0}^{K-1} x^n[tM - k]h[k] \qquad (1)$$


Where M is the reduction factor, h a FIR anti-aliasing filter and K the length of the filter.

In our experiments, we use four scales $j = 0..3$. The finest generates audio in 16 kHz, while the coarsest generates audio in 2 kHz. We chose the coarsest scale to be as small as possible on the articulation generation phase, yet to include the f0 signal of our target instruments (max of 1kHz as given by Nyquist rule)

In our method, audio is generated based on the specifications of the loudness of the output audio and its pitch. The other characteristics (timbre, articulation, and spectral quality) are being added by the model, based on the training sample. The loudness is given, following [12], by the A-Weighting scheme, which is a weighted sum of the log of the power spectrum. We denote the loudness extraction computation by $\text{loud}(\boldsymbol{x^j})$, which is a 1D signal of a length that is 32 times shorter than the length of the input $\boldsymbol{x^j}$, $j = 0..3$, due to the power spectrum extraction.

The fundamental frequency f0, which is also a 1D signal, is extracted using the CREPE pitch tracking network [7], as is done in [1, 13]. We denote the extracted signal by $f0(\boldsymbol{x^n})$ and compute it only at the finest-resolution scale. The CREPE network has a resolution of 250Hz, which differs from the sampling rate of our network. However, this conditioning is provided as a sine-wave at the resolution of the coarsest layer (2kHz).

Specifically, following previous work in speech [9] and music synthesis [1, 8], we apply what is known as "neural source-filtering". In this technique, instead of conditioning the generated sample directly on the extracted f0 signal, the generator is conditioned on a raw waveform that is synthesized via a single sinusoid sine-excitation, calculated from upsampled $f0(\boldsymbol{x^n})$. The $f0$ is downsampled by 32 from the input signal $\boldsymbol{x^n}$ and the coarsest scales $j = 0$, which is generated first, has a frequency that is one eighth of the

Figure 2. An illustration of the hierarchical generation process. (a) A spectrogram depicting the original melody as sang by a male singer. (b) The extracted fundamental frequency (f0) of the melody. (c-f) The generated audio for a saxophone from the coarsest scale x^0 to the finest x^3, respectively. While articulation-based manipulations are already seen in x^0, the full effect of the timbre and spectral-quality is only observed at the final output x^3.

original audio. Scaling is, therefore, by a factor of 4. We denote the generated waveform by $\eta(f0(x^n))$.

$$\eta(f0(x^n)) = sin(\sum_{k=0}^{T} 2\pi\uparrow f0(x^n)_k/f_s), \qquad (2)$$

where f_s is the sample rate of the audio and $\uparrow$ denotes an upsampling operator.

3.2 Hierarchical Generation

The generated waveform $\eta(f0(x^n))$ serves as the input to the lowest scale generator in the hierarchy, which is denoted by G^0. Similarly to our other generators and unlike conventional GAN generators, the generator does not receive random noise as input.

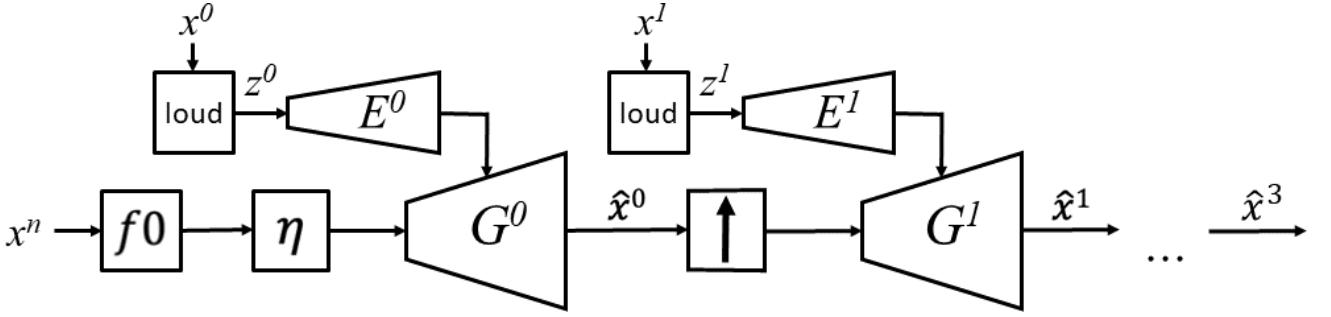
In our method, we propose a conceptual relaxation to the audio generation task, and divide the generation into two distinct phases: timbre painting and articulation on the lowest scale, followed by upsampling networks which learn to generate higher resolution audio based on the previous scale. By doing so, we separate what we consider the most difficult part in the generation, namely converting a sine wave into well-articulated music, from the aspects of timbre painting and spectral quality adjustment. Therefore, fewer errors are introduced during the generation process and the method produces more coherent audio samples.

Denote by $z^j = loud(x^j)$. A set of input encoding networks E^j transforms the raw input signal z^j into a sequence of vectors, which G is conditioned upon.

The lowest scale generator operates as follows:

$$\hat{x}_0 = G^0(\eta(f0(x^n)), E^0(z^0)), \qquad (3)$$

where the second input is the conditioning signal.

The following generation steps receive as input the output of the previous scale generator:


$$\hat{x}^j = G^n(\uparrow(\hat{x}^{j-1}), z^j), \qquad (4)$$

where $\uparrow(\hat{x}_{n-1})$ is an upsampled signal that matches the next scale. An illustration of the generation process is given in Fig. 3.

3.2.1 Architecture

The architecture of the generators and discriminators is similar to that of [14]. Each generator is composed of 30 layers stacked into three stacks. The kernel size is 3, using 64 residual channels and 64 skip channels. The dilation is exponentially growing in each stack, providing a receptive field of 3072 samples, which translates to a window size of 1.5sec on the lowest scale and 192ms on the finest.

The input encoder E^j is composed of instance normalization, followed by 1D-convolution with kernel size of 1 that is applied on the condition input z. The number of output channels is 80. The output of E^j is provided after upsampling via convolutional layers and nearest neighbor interpolation to the temporal dimension of the input signal.

Figure 3. An illustration of the generation process. The generator of the coarsest scale receives as input a sine-wave that is based on the fundamental frequency of the input sample. All generators are conditioned on the loudness signal of the appropriate scale. The output of the first generator G^0 serves as the input for the subsequent generator G^1 and so on.

Training involves a set of discriminators D^j, one per scale. Each discriminator is composed of 10 layers of 1D-convolution, followed by leakyReLU with negative slope of 0.2. The kernel size is 3, and 64 channels are used per layer. The dilation is growing linearly. Weight normalization is applied both on the generator and the discriminator.

3.3 Training

The learning setup and objective functions are the same for all the scales, with respect to the target audio signal. Conveniently, each generator G^j is trained separately, after the previous generator G^{j-1} is completely trained. We found that using the weights of the previous scale generator G^{j-1} to initialize the weights of G^j leads to faster convergence than random initialization on every scale. Similarly, the discriminator D^j that provides the adversarial training signal to the generator G^j is initialized based on D^{j-1}.

At each scale j, we obtain a training set S^j by dividing the training sample, after it has been downsampled to scale j to audio clips x^j of length 2sec.

3.3.1 Objective function

A time-frequency reconstruction loss is used to align to the generated audio sample with the target audio. Specifically, the spectral amplitude distance loss [15, 16], in multiple FFT resolutions [1, 9, 14] is used. For a given FFT size m, the spectral amplitude distance loss is defined as follows:

$$\mathcal{L}_{\text{recon}}^{(m,j)} = \sum_{\boldsymbol{x}^j \in S^j} \left(\frac{\||\text{STFT}(\boldsymbol{x}^j)| - |\text{STFT}(\hat{\boldsymbol{x}}^j)|\|_F}{\|\text{STFT}(\boldsymbol{x}^j)\|_F} + \frac{\|\log|\text{STFT}(\boldsymbol{x}^j)| - \log|\text{STFT}(\hat{\boldsymbol{x}}^j)|\|_1}{N} \right)$$
(5)

where $\hat{\boldsymbol{x}}^j$ is given by Eq. 3 and Eq 4, $\|\cdot\|_F$ and $\|\cdot\|_1$ denotes the Frobenius and the L_1 norms, respectively. The first element in the sum penalizes dominant bins in the magnitude while the second penalizes the silent parts. STFT denotes the magnitude of a Short-time Fourier transform with N elements in the spectrogram.

The multi-resolution loss is defined as the mean of the above loss for multiple scales:

$$\mathcal{L}_{recon}^j = \frac{1}{N_M} \sum_{m \in M} \mathcal{L}_{recon}^{(m,j)}$$
(6)

where $M = [2048, 1024, 512, 256, 128, 64]$ and $N_M = 6$ is the number of FFT scales. Using the multi-resolution loss, we implicitly constrain the phase of the output signal to be correct and prevent artifact noises.

To make the generated quality of the audio signals sound realistic, we introduce an adversarial loss. On each scale, we apply a different discriminator D^j to account for different statistics between scales. We follow the least-squares GAN [17], where the discriminator minimizes the loss

$$\mathcal{L}_D^j = \sum_{\boldsymbol{x} \in S^j} [||1 - D^j(\boldsymbol{x}^j)||_2^2 + ||D^j(\hat{\boldsymbol{x}}^j)||_2^2]$$
(7)

Each trained generator G^j minimizes the adversarial loss (recall that $\hat{\boldsymbol{x}}^j$ is computed with G^j):

$$\mathcal{L}_{adv}^j = \sum_{\boldsymbol{x}^j \in S^j} ||1 - D^j(\hat{\boldsymbol{x}}^j)||_2^2$$
(8)

To further improve the generation quality, we add a perceptual loss [18] on the generator output, using the CREPE network [7]. Denoting the mapping between the input signal x and the intermediate activations the CREPE network as $h(\uparrow x)$, which requires an upsampling to 16kHz, this loss takes the form:

$$\mathcal{L}_{percep}^j = \sum_{\boldsymbol{x}^j \in S^j} \|h(\uparrow \boldsymbol{x}^j) - h(\uparrow \hat{\boldsymbol{x}}^j)\|_1 .$$
(9)

The optimization with this loss requires the upsampling operator to be differentiable.

In order to support a more direct comparison of the methods, following DDSP [1], the fifth max-pool layer of the small CREPE model is employed.

Overall, the optimization loss for a generator G^j, is defined as:

$$\mathcal{L}_G^j = \mathcal{L}_{recon}^j + \alpha \mathcal{L}_{adv}^j + \beta \mathcal{L}_{percep}^j$$
(10)

where α, β are weight factors that balance the contribution of each loss term.

4. EXPERIMENTS

We conduct timbre-transfer experiments for multiple instruments, and compare the results to the state-of-the-art timbre transfer method DDSP [1].

Instrument/Method	Target Similarity		Melody Similarity	
	DDSP	Our	DDSP	Our
Cello	4.11 ± 0.16	4.24 ± 0.16	4.00 ± 0.32	4.01 ± 0.49
Saxophone	3.09 ± 0.53	3.47 ± 0.54	3.87 ± 0.41	3.91 ± 0.53
Trumpet	3.29 ± 0.45	4.01 ± 0.33	3.99 ± 0.29	4.11 ± 0.51
Violin	4.02 ± 0.35	4.13 ± 0.27	4.13 ± 0.39	4.22 ± 0.39
All samples	3.63 ± 0.60	3.96 ± 0.46	4.00 ± 0.36	4.06 ± 0.50

Table 1. MOS evaluation for the timbre transfer task for multiple target instruments.

4.1 Datasets

We used the University of Rochester Music Performance (URMP) dataset [19], a multi-modal audio-visual dataset containing classical music pieces. The music is assembled from separately recorded audio stems of various monophonic instruments. For our experiments, we used only the separated audio stems for each instrument. f0 extraction was carried out by CREPE [7], although the URMP dataset provides ground truth melody signals, since we wanted to apply similar methods during train and test.

We trained both the baseline DDSP [1] method and our model on generating four different instruments from the URMP dataset: cello, saxophone, trumpet and violin. As a prerocessing step the audio files were resampled to 16kHz. To improve the ability of learning meaningful f0 representation we removed in each dataset samples which achieved less than 0.85 mean confidence on CREPE extractor. Each dataset was separated into a training and evaluation set by 0.85/0.15 split. After the preprocessing, we ended up with small dataset sizes: 6.5 minutes of cello, 6 minutes of saxophone, 17 minutes of trumpet and 39 minutes of violin.

4.2 Experiment Setup

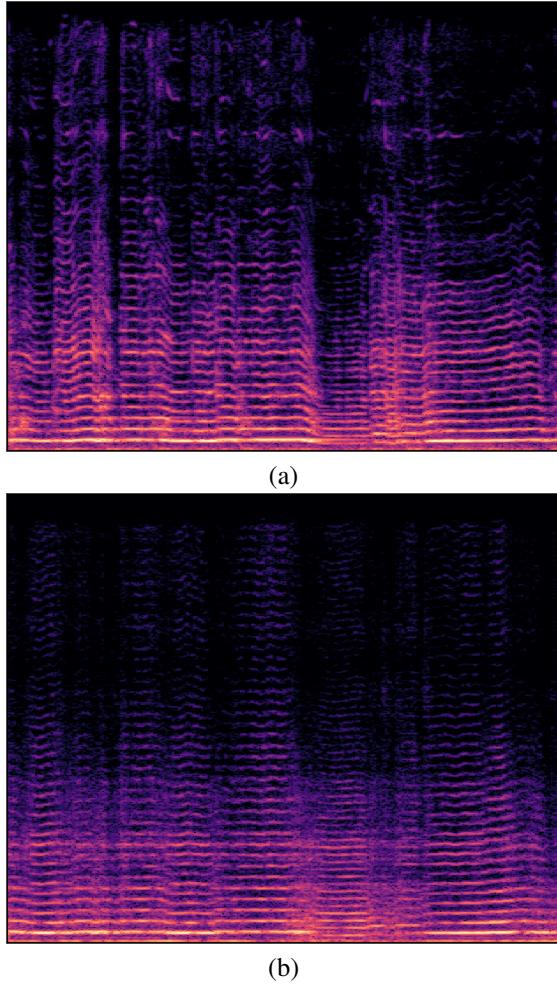
Our models were trained with α=1 and β=1. We used the Adam optimizer [20] with a learning rate of 0.0005 for the generators and 0.0001 for the discriminators. Each scale was trained for 120K iterations, with batch sizes of 32, 16, 8 and 4, from coarsest to finest. The learning rates were halved after 60K iterations. The discriminators were introduced to the training process on iteration 30K. To improve the robustness of our method we added a random Gaussian noise with a standard deviation of 0.003 to the $\eta(f0(\boldsymbol{x^n}))$ signal, inspired by [9].

For the baseline evaluation of the DDSP method, the open source GitHub implementation [1] provided by the authors of [1] was used. The experiments were carried out for 100K iterations with a batch size of 16. The hyperparameters used are the ones provided by the recipe available in that repository.

4.3 User Study

To inspect the results of the timbre transfer experiments we carried out a mean opinion scores (MOS) evaluation. We sampled six audio clips varying from 5-10s, long enough

for good evaluation. The origin instruments are: clarinet, saxophone, female singer, male singer, trumpet and violin. For each audio sample, we conducted timbre transfer using the four models of the target instruments, resulting in a matrix of 24 inspection files for our method and 24 for the baseline. The timbre-transfer was done by extracting the loudness and pitch features from the source audio, aligning pitch key to the target (if needed) and generation procedure. The evaluations samples are available in the supplementary material. Twenty raters were asked to rate the generated outputs by two criteria: (i) target similarity to the transferred instrument, and (ii) the melody similarity to the original tune. Scores vary on a scale of one to five.

4.4 Results


As can be seen in Tab. 1, our method outperforms DDSP both by the melody similarity and target similarity. While the baseline method gets a relatively close score on melody similarity, it is inferior in sound quality and its ability to mimic the target instrument. For example, in some cases DDSP fails to imitate the target domain timbre, and produces a sine-sounding signal in the correct pitch. An example of a challenging conversion is depicted in Fig. 4.

The high melody preserving results of both methods reflect the fact that both utilize a meaningful f0 sine-wave signal, which aligns the output melody well with the input melody. However, the target similarity results can be explained through the crux of the DDSP mechanism: the learnable function on this network optimizes control parameters of a deterministic noise-additive synthesizer, thus it is upper bounded by the quality of the best-setup synthesizer. Our method, on the other hand, enjoys the expressiveness of a fully capable neural generator, thus can deviate considerably from the source, if needed, in order to generate realistic sounds.

4.5 Data efficiency

Another advantage of our method is the need for a minimal amount of training data to generate high quality samples. Successful timbre-transfer results are produced from datasets of few minutes long. For comparison we have trained a state-of-the-art WaveNet based model for music translation [5] on two different datasets: URMP, as presented above, and a 30min subset of MusicNet [21], as discussed in Sec. 5. In both cases, the music translation method [5] failed due to the limited amount of data.

(a)

(b)

Figure 4. A challenging conversion from a female voice to a cello. (a) The results of DDSP. (b) Our results. While DDSP introduces synthetic noise in order to bridge the different characteristics of the two domains, our method successfully manages to overcome and adapt the input signal to cello's articulation and timbre .

5. DISCUSSION

Recent music AI models vary in the number of parameters and in the required size of the training data. The very recently introduced jukebox model [22] was trained on over a million songs using hundreds of GPUs, and include 7 billions parameters. The autoencoder-based music-domain translator [5] was trained on hours of audio, using tens of GPUs and includes 42M parameters. In comparison, models such as ours are trained on a single GPU, require minutes of audio, and have orders of magnitude less parameters, 1.4M on each scale in our case. The total number of parameters is even smaller than the lean DDSP model, which is of 6M parameters. Taking into account the fact that each scale is trained separately, our model is much more accessible to universities and other small-scale research labs than the other models in the literature.

The method generates sound by shape-shifting a sinewave, which serves as the skeleton of the rich-timbre painted output. Using scales reflects the inherent structure of the musical audio signal, which is composed of

harmonies on different pitch resolutions. The utilization of this strong prior allows us to achieve state-of-the-art results much more efficiently.

The hierarchical structure, which is natural for music generation, also exists in other methods, but in a different way. In the jukebox model, the hierarchy is used separately in the encoders and in the decoders, i.e., all encoder scales are applied, followed by the decoder scales. In our model, there is an interleaving structure in which generation is completed at the lowest scale (including both input encoding and the WaveNet decoder), moving to the processes of the next scale and so on.

Limitations   The economic nature of the model is not without limitations. Unlike the jukebox model, our model does not produce a discrete encoding that can be used (together with an sizable transformer model) for composing new music. In order to add a similar capability, we would need to quantize the input encoding modules (E^j) using techniques such as VQ-VAE [23] and to train an autoregressive model for each level of the hierarchy. Alternatively, any composition method can be used to generate the bare-bones input signal of the network, which would then add the articulation and the timbre to create a richer musical experience.

In the current form, unlike both jukebox and the autoencoder music translator, our model does not share information between different domains, and needs to be retrained on each domain. It is not difficult, however, to modify it to be conditioned on multiple target domains, a path that has been followed many times in the past for other WaveNet-based generators.

The current method relies on the f0 signal as extracted by a pretrained network that has been trained on monophonic instruments. Since the pitch tracker we employ was trained on monophonic instruments [7], the results on polyphonic instrument are mostly reasonable but not always. When successful, our method is successful in transforming the melody to the learned monophonic target domains. However, training polyphonic target instruments remains a challenge since it relies on such a success across the training samples. In the supplementary we present results obtained for polyphonic instruments (keyboard and piano samples from MusicNet), for both our method and DDSP. Both methods succeed to some degree with our method presenting what we consider to be a slight advantage (see supplementary samples). As future work, we note that our method can be readily extended to employ encoders, such as the ones of [5, 22], which were trained on large collections of polyphonic music.

6. CONCLUSIONS

We present a novel method of music generation which relies on neural source filtering and hierarchical generation. The method achieves high quality audio generation despite training on small training datasets. The generated input is conditioned on loudness and pitch signals, which are almost source-agnostic, and the characteristic articulation and timbre of the target instrument are introduced through a series of generators.

ABSTRACT

This paper presents exploratory work investigating the suitability of the Music Ontology [33] - the most widely used formal specification of the music domain - for modelling non-Western musical traditions. Four contrasting case studies from a variety of musical cultures are analysed: Dutch folk song research, reconstructive performance of rural Russian traditions, contemporary performance and composition of Persian classical music, and recreational use of a personal world music collection. We propose semantic models describing the respective domains and examine the applications of the Music Ontology for these case studies: which concepts can be successfully reused, where they need adjustments, and which parts of the reality in these case studies are not covered by the Music Ontology. The variety of traditions, contexts and modelling goals covered by our case studies sheds light on the generality of the Music Ontology and on the limits of generalisation "for all musics" that could be aspired for on the Semantic Web.

1. INTRODUCTION

Non-Western musical traditions are of interest to MIR research for several reasons: firstly, alongside Western classical and popular music, which have been studied extensively in MIR, the musics of other cultures are analysed in their own right [6, 13, 16, 25]; secondly, other musical cultures often present difficult, non-standard datasets and examples, showing the limits of existing MIR approaches [22, 30, 39]; finally, including non-Western musical traditions allows for a broader view of music and leads to new, more generally applicable technical solutions [24, 28, 40]. In this paper, we explore the latter avenue with the view of generalising existing standards of semantic modelling in music to include non-Western musical traditions.

Ontology in computer science is commonly defined as an "explicit formal specification of a shared conceptualisation of a domain " [15]. An ontology represents consen-

sual knowledge about the entities and their relationships in an area, preferably expressed using a machine-processable formal language that supports some form of inference [12]. This could be logic based, while more recently, ontologies found their use in machine learning as a mechanism to help structuring training data, formalise constraints, or become an integral part of the inference process [42].

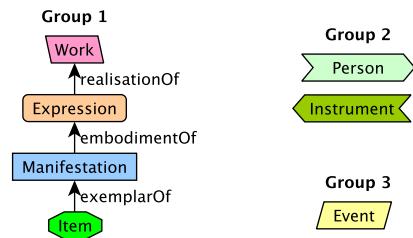
The Music Ontology (MO) [32, 33] is among the most comprehensive ontologies for the music domain, with broad ranging applications [9, 38] from recommendation systems [49] to live performance [51], and numerous extensions covering music production [10, 11] and audio effects [53, 54], audio features [1], music theoretical concepts [34, 43, 46], smart instruments and more generic or other "Musical Things" [48]. The ontology is based upon several broadly accepted domain models (see Section 2) adopted to the music domain. Moreover, it has been applied successfully to model jazz [31], a tradition distinct from Western classical and pop music; and it was found to be beneficial for modelling Chinese musical tradition due to its flexibility and layered structure [45]. This makes it a primary candidate for our analyses.

The Music Ontology makes general claims about representing discographic information, music creation, performance, production and consumption. Yet it has so far mainly been applied to Western music. MIR researchers with expertise in ethnomusicology [29, 50] suggest that computational approaches to non-Western music should all be culture and use case specific. We therefore aim to answer the following questions: Is the Music Ontology capable of representing the domains of non-Western musical traditions? What are the gaps that the Music Ontology fails to model? Can or should the Music Ontology be generalised to encompass many (or all) musical traditions? What are the limits of such generalisation?

While political and geographic borders, language and religion play an important role in forming musical traditions, modelling the domain of such a tradition goes far beyond adding a geo location. For instance, Kurdish music in northern Iraq is different from Kurdish music in Iran and Turkey; Persian musics in Iran, Afghanistan and Tajikistan are also different, even though people speak in the same language (Persian); likewise Azerbaijan and Armenia have different religions and languages, but their musics are very close. Also, music of a diaspora sometimes adheres closely to the original traditions and sometimes fuses with the mu-

sic of the host community, importing new elements and establishing new trends.

In addition to differences in musical systems and repertoires, how people create, perform and listen to music varies between cultures. To account for this diversity, we chose four case studies from a variety of musical traditions. The use cases are representative of the chosen traditions, based on authors' expertise as practitioners, researchers and consumers of those musical cultures. While by no means exhaustive, this investigation employs a qualitative approach to test the usefulness and representativeness of the Music Ontology in a large variety of contexts outside of Western classical and popular music.

First, we look at a Dutch state institution collecting folk songs of a tradition now largely extinct and how research on this collection is conducted (Sec. 3). Secondly, contemporary performance and composition in Iranian music are explored, encompassing Persian classical art music, folk music of many Iranian population groups and Western influences (Sec. 4). Thirdly, we take the genre of world music into consideration, where recording and consumption are broadly in line with Western popular music (Sec. 5). Additionally, we turn to Russian village music and how it is being actively revived through field research and performance (see Supplement [1]).


Dutch folk songs are a representative of folk music traditions of Western Europe and North America in our study; Russian village music is a polyphonic vocal tradition, which are common throughout Eastern Europe, and are found in other parts of the world. Iranian music is a maqamic tradition, strongly connected to the modal traditions encompassing the Near East, North Africa, and South Asia. The world music genre does not represent any particular culture and can include all kinds of musical content from around the world.

To illustrate how the Music Ontology (MO) classes and properties can or cannot be used to model our case studies, we introduced a consistent form- and colour coding throughout this paper: MO classes and their subclasses have solid line borders while other classes have dashed line borders; MO properties are thick blue arrows with straight heads; properties not present in the Music Ontology are thin red.

2. PREVIOUS WORK

The main standard for semantic modelling in cultural heritage is FRBR (Functional Requirements for Bibliographic Records). It is a conceptual model for describing entities and relationships in libraries, museums, and archives [47]. FRBR was developed by the International Federation of Library Associations and Institutions (IFLA) and is widely used by cultural institutions around the world, in particular for electronic cataloguing of physical and digital objects. It provides the basis for interoperability between holdings, collections, and datasets [3].

FRBR Group 1 defines four main entities to represent the products of intellectual or artistic endeavour: "Work

Figure 1. FRBR conceptual model. The shape and colour coding exemplified here is used throughout this paper to indicate classes implementing FRBR concepts

(a distinct intellectual or artistic creation) and expression (the intellectual or artistic realisation of a work) reflect intellectual or artistic content. Manifestation (the physical embodiment of an expression) and item (a single exemplar of a manifestation) reflect physical form." Group 2 includes persons and corporate bodies responsible for the custodianship of Group 1 intellectual or artistic endeavours (e. g., creators, consumers). Group 3 includes events and places [17] (Fig. 1).

The Music Ontology [32] provides a vocabulary for publishing and linking a wide range of music-related data on the Web [2]. It builds on four main ontologies: FRBR Ontology [3] (Fig. 1), the Timeline Ontology [4], the Event Ontology [5] and FOAF [6]. Fig. 2 illustrates how the Music Ontology classes implement FRBR. It has been extended to describe a variety of musical domains, such as audio content (Audio Features Ontology [7] [1]), recording sessions (Studio Ontology [8] [10]) and exploration, transformation and redistribution of audio content (AudioCommons Ontology [9] [4]). The Jazz Ontology [31] is a semantic model successfully developed on the basis of MO. It illustrates how the Music Ontology requires "tweaking" with shortcuts, new or qualified properties and some additional concepts to describe a musical tradition other than Western popular or classical music.

MusicBrainz [10] is the largest crowd-sourced collection of music metadata online. It has its own semantic model [18], focused on discographic information about published CDs, therefore less suitable to musical traditions which are not centred around published products.

Tian et al. [45] presented a detailed analysis of metadata standards in existence in 2013, including the Music Ontology, and their ability to model the domain of Chinese traditional music. They identified several aspects which were not covered by existing standards: function (purpose of creation, occasion of performance), performance practice (vocal style, stage performance, cosmetics and props, per-

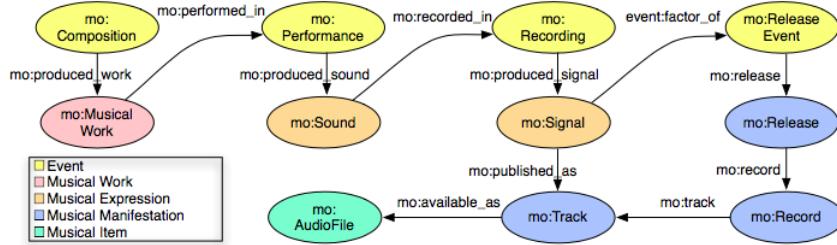

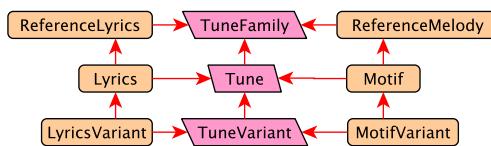

Figure 2. A fragment of the Music Ontology: key concepts and selected properties describing the music production workflow, showing the FRBR layers [12]

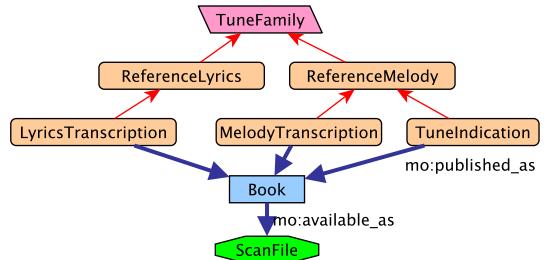
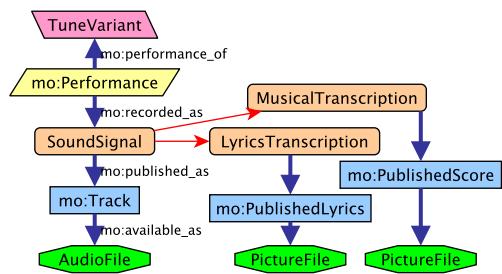
forming skills), musical characteristics (intonation, temperament), historical context, ethnic group, etc.

Further to cultural heritage sector, Coladangelo [5] provides a comprehensive description of contemporary (2020) semantic frameworks representing cultural heritage, including those related to music. Goienetxea et al. [14] describe an ontology representing Basque folk songs based on CIDOC Conceptual Reference Model (CIDOC CRM) - a complimentary standard for cultural heritage used primarily in the context of architecture and museum collections. FRBRoo is an object oriented model harmonising FRBR and CIDOC CRM [36]. Strle and Marolt [41] modelled Slovenian folk songs and chimes music based on FRBRoo. DOing REusable MUSical (DoReMus) Project [23] developed a model, also based on FRBRoo, describing varied collections from three French cultural institutions.

In this paper we conduct four diverse case studies originating from different musical traditions, analysing the ability of the Music Ontology to model their domains. The following sections describe the case studies: the cultural context, the musical content to be modelled, specific domain characteristics, providing diagrams of semantics models. We wrap up with a discussion of commonalities and differences displayed by the case studies and their application of the Music Ontology, the advantages and the limits of a generalised Ethno-Music-Ontology.


3. CASE STUDY: FOLK SONG RESEARCH ON THE DUTCH FOLK SONG ARCHIVE

Figure 3. The oral transmission (songs learnt and passed on through listening and participation) introduced continuous changes, giving rise to the coexistence of *TuneVariants*


The history of Western European folk song collection and research stretches back centuries: before the emergence of audio recording, folklorists wrote down folk songs performed by their informants or encountered in the field, which were then released in printed collections.

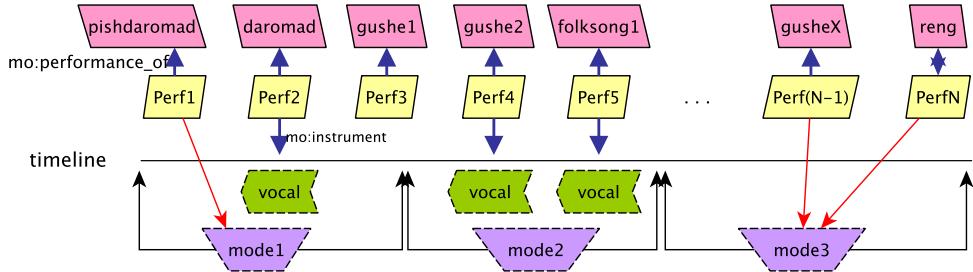
Songbooks would often only contain the lyrics; later, more research oriented editions would include a notated melody transcription. The idea of *TuneFamilies* (Fig. 3) – clusters of tunes descending from a common "ancestor" - was in line with other disciplines such as linguistics [2,7]. This line of inquiry was strengthened by the requirements of the medium – the book – used to publish the songs: usually only one representative of a tune family would be included in a print collection to avoid repetition (Fig. 4).


Figure 4. A *TuneFamily* was represented in a print book collection by only one of its member tunes.

The assignment of a tune to a family is performed manually by experts. An annotation experiment [52] has shown that the most salient feature for experts to assign songs to the same tune family was the presence of common melodic *Motifs*. It also confirmed the emergence of a prototypic *ReferenceMelody* representing a tune family (Fig. 3).

Figure 5. Audio field recordings capture real-life performances of folk songs and are stored in digital files.

When audio recordings of Dutch folk songs and digital processing were introduced, there was no need to limit the publication to just one representative of a family. A

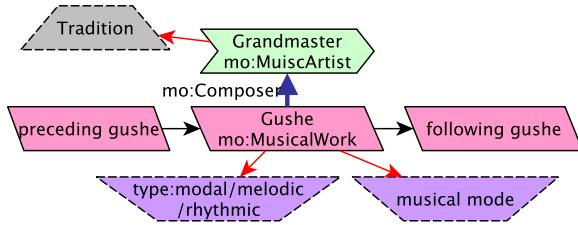
Figure 6. Traditional Iranian performance: The daràmad (opening section) comes at or near the beginning of the performance, and the following gushés are organised according to a gradually ascending pitch scheme, until a forud (cadence) leads a return to the original mode. During the modulations, the modal tonic gradually moves upwards. Usually, metered gushés are played between non-metered gushés. [55]

contemporary database of the Dutch folk songs (the Dutch Song Database [21]) contains metadata on 173K song occurrences from song books, manuscripts and field recordings from the 12th century to the present day. Songs from the earlier printed collections are linked to audio *Recordings* of their *Performances*, the *Lyrics*, the *Scans* of the book pages and *Transcriptions* in digital notation (Fig. 5). The songs are linked to other songs with the same lyrics, or the same *ReferenceMelody*, or the same *MelodicIncipit*. A general melodic similarity search on the whole database is a new tool that facilitates song relationship discovery.

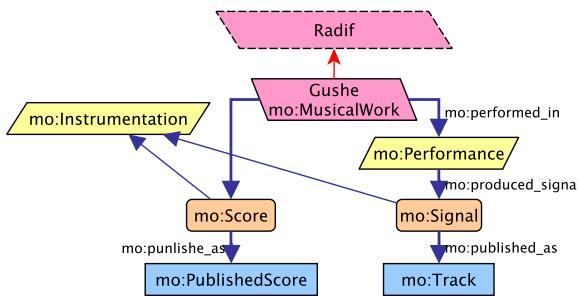
The diagrams in Figs. 3, 4 and 5 show that all the instances can be represented by MO classes or their subclasses (solid borders). Often MO properties (thick blue arrows) can be used. Yet connections between *Tunes* and *TuneVariants* from a *TuneFamily* (Fig. 3), which are paramount in folk song research, are not represented in the Music Ontology (red arrows). The relationships between primary and derivative kinds of *MusicalExpressions*, e.g. a melody and its transcription (Figs. 4 and 5), could be modeled via an event of transcription, analogously to *Sound -> RecordingEvent -> Signal* connections in the Music Ontology (Fig. 2). In contrast, the relationship between a *MusicalWork* and its *Expression*, which is similarly represented via a composition event in the Music Ontology (Fig. 2), cannot be used in the context of folk songs or traditional music more generally: there is usually no composer and no single event in which a song is created.

4. CASE STUDY: PERSIAN MUSIC - CONTEMPORARY COMPOSITION AND PERFORMANCE

Music in Iran is categorised, according to a scheme devised by Farhat, into urban, ethnic and pop [8]. Urban music, prevalently heard in the larger cities, includes both classical art music and pop music. Classical Persian music consists of free-rhythmic pieces (àvàz) and rhythmic pieces, typically in 2/4, 4/4, or 6/8. Ethnic music, which is in an Iranian form of maqàm, is that of the various ethnic groups living in towns, villages, deserts, and in the mountains. In addition to pieces in free and simple rhythms, irregular rhythms such as 5/8 and 7/8 are more often encountered in ethnic music. Classical Persian music uses

more ornaments, complex melodies and free rhythms than ethnic music. Iranian pop music, which has dominated the music scene in Iran since the mid-twentieth century [8], draws on either or both of the classical and ethnic traditions; it tends to simplify them and to reflect influences from other cultures, notably Western pop music.


The process of creative performance, called bedàhe navàzi (improvisation), which is at the heart of Persian music, is different from improvisation in Western music, as it involves both composition and new ways of rendering classical pieces (gushés); thus, there is no distinction between the role of the performer and the composer [27]. A performance is usually centred on a set of important gushés, whose order is conventionally accepted (Fig. 6). The texture of Persian ensemble music is heterophonic, meaning that the members of the ensemble play the melodic scheme simultaneously in different ways, characterised by a high degree of improvisation and ornamentation.

4.1 Persian modes and repertoire


Persian music is based on a modal system of seven main modes and their five derivatives that are collectively called the twelve dastgàhs [8, 16]. In a maqàm performance, different pieces are played in a single mode, while the performance in a dastgàh comprises a certain sequence of modulations from an opening section in the main mode of a dastgàh (daràmad), to derivative modes (àvàz) and finally a return to the starting mode. (Fig. 6).

A student of Persian music studies a Radif - a body of classical repertoire created by a Grandmaster (Fig. 7) - to form the basis of their performance and composition. In the past the transmission took place orally in a teacher-student relationship that would last for many years; nowadays musicians refer to scores and recordings of classical pieces performed by outstanding masters (Fig. 8).

In Fig. 6 a traditional Iranian performance is represented on a timeline (black line) using the Timeline Ontology (black arrows). The modes are specific to Iranian music and are not part of the Music Ontology, which only provides a concept of a Western-centric major/minor *Key*, though these could potentially be added and the concept generalised to represent modes. Alongside mode the gushe type also has to be documented (Fig. 7, for which there is

Figure 7. Radif - the core repertoire of Iranian classical music, a body of compositions by a *Grandmaster* from a particular regional tradition.

Figure 8. Documenting Radif

no correspondence in the Music Ontology. A Grandmaster is part of a Tradition, which provides the musical and cultural context (grey trapezoid) to the performance - see discussion to Fig. 1 of the Russian case study in the Supplementary Material. In Fig. 8 all relationships can be represented including the creation of a Score, with one exception: the belonging of a gushe to a particular radif. This is similar to the within-repertoire relationships discussed in Section 3 in relation to Dutch folk songs.

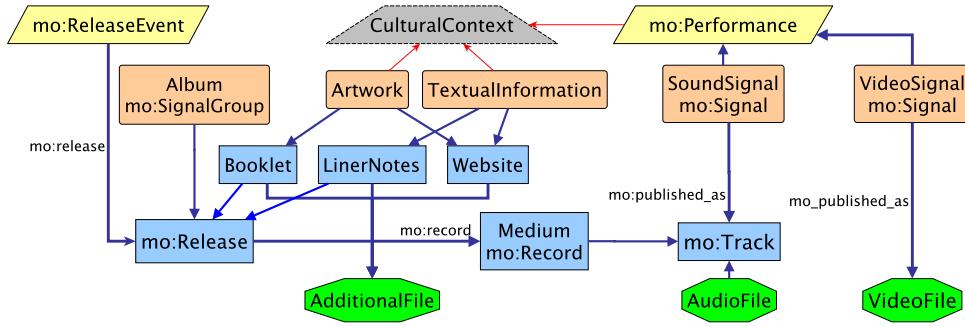
5. CASE STUDY: PERSONAL WORLD MUSIC COLLECTION

Personal world music [44] collections are ubiquitous and the exact specifics of their usage will differ between users. They are put together for enjoyment, to create playlists, share music with others, to have an overview of a variety of genres and traditions. The difference to other case studies is that the owner of the collection is not an expert in the majority of the styles represented in the collection. Moreover, a world music collection would be heterogeneous and include a large variety of cultures, genres, languages, instruments, contexts, etc. The authority of the sources and the authenticity/expertise of the performers are not always clearly documented or known; all kinds of cultural and stylistic mixtures can occur: for instance, a piece can originate from one culture but be performed in a different style; the musicians might have their roots in more than one culture, including diasporas; music can be performed using instruments not present in the culture of its origin; a mixture of styles can be deliberate or accidental.

Because the consumer is not an expert, the artwork, liner notes and other textual information play an impor-

tant role (Fig. 9). Tracks are commonly compiled into playlists which can be devoted to a particular theme (love songs), reflect or create a certain mood (chill out) or serve a function (music for exercise) (Fig. 10).

Fig. 9 shows that, apart from the cultural context, the Music Ontology is perfectly suitable to represent discographic information about world music collections. Yet we observe in Fig. 10 that factors determining the content of a playlist - aspects of cultural context or musical characteristics - are beyond the domain of the Music Ontology.

6. DISCUSSION


The Music Ontology captures FRBR group 1 concepts in all case studies, modelling the process of performance documentation from *Expressions* over *Manifestations* to *Items* (Figs. 4, 5, 8, 9). It is also well suited, in combination with the Timeline and the Event Ontologies, to document musical events (Figs. 6, 10). We identified three areas where the Music Ontology lacks descriptions: cultural contexts, musical characteristics and relationships within or between repertoires.

Our case studies demonstrate how varied cultural contexts (grey downward trapezoid in the diagrams) can be: function, social group and performance practice (Fig. 1 in Supplement [11]) in Russian traditional music; regional tradition in Persian Music (Fig. 7); culture, function, mood and theme in world music (Fig. 10). This is a very complex area, which is often described and discussed differently depending on the language, organisation or school of thought. It is not practical to construct a single taxonomy to describe pagan rituals and music for exercise; wedding songs alongside remembering sunrise; an Easter Vesper as well as indecent humorous couplets. Therefore, Broad categories could be offered like *SocialFunction*, *PerformancePractice*, *Mood*, whereas more detailed modelling should be culture- and use case specific.

Musical characteristics (magenta upwards trapezoid in the diagrams) are specific for each culture: traditions and repertoires can differ greatly in the complexity and variation in modality, rhythm, harmony, ornamentation. Case studies vary in which musical characteristics are important: mode and rhythm type are crucial in Persian music (Figs.6, 7) but are less important in other case studies. Therefore, it seems most viable to model musical characteristics separately for each musical tradition, choosing a subset of the model relevant for the use case. MusicOWL [19] and the Music Theory Ontology [34] offer a model for Western music. Modelling for other traditions should be conducted in collaboration with ethnomusicologists and tradition experts. It is important to keep in mind the gap between theory and practice [16]. Related musical cultures, such as maqamic traditions or Eastern European polyphonic vocal styles, could possibly benefit from a systemic view and a more generic modelling, which would facilitate crosscultural interoperability of the models.

Relationships within repertoires are crucial in some cultures and contexts: the order and modulations of gushes in

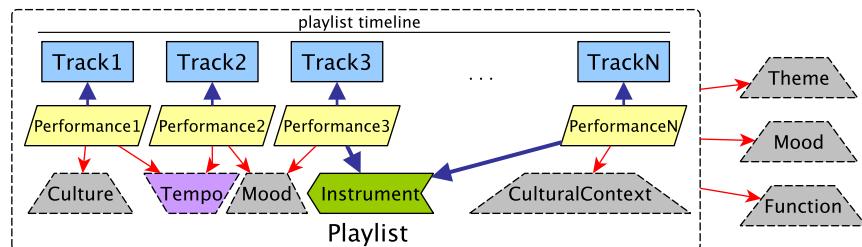
Figure 9. A world music collection: *TextualInformation* captures the cultural affiliations and the social context of the song/work performed as well as of the performance itself

Persian music (Figs. 6, 7) or the relationship between tunes in a folk music tune family (Fig. 3); they are less important in other cultures, like Russian village music. Cross-repertoire relationships, such as between tune families or Radifs, are of interest for comparative research. Such relationships will differ between cultures, yet there might be scope for generalisation within larger musical regions.

We also noticed that modelling musical instruments (Fig. 1 of supplement, Fig. 10) will represent a challenge, due to their variety and linguistic barriers. While a general instrument classification has long been established [37] and the Music Ontology refers to an instrument taxonomy [20], constructing a cross-cultural taxonomy of musical instruments is a long-term task. Alongside instruments, an addition of approximate dates (e.g. Figs. 1, 2 of supplement) as it was done in the Jazz Ontology [31] would be beneficial, since references to periods of the past and absence of exact dates are a common phenomenon in many traditional musics.


Caution must be exercised when using the FRBR/MO concept of *MusicalWork*. As Riley [35] noted, it is less well suited to describe traditional and folk music. It is often difficult to delineate works: are highly similar tunes one work or two? If a song has changed through oral transmission, or has been transformed through improvisation, is it still the same work? It is related to the problem of labelling works, when titles, lyrics and incipits vary between localities or through improvisation, such as instrumental tunes in our Russian example [26].

We conclude that the Music Ontology is a very useful

standard to implement for the domains of musical cultures other than Western classical and popular music. However, its further generalisation seems to offer few advantages, since cultural contexts, musical characteristics, intra- and inter-repertoire relationships are mostly culture specific: small domain specific extensions would be more useful than trying to build one big generic ontology.

In future work we suggest to investigate CIDOC Concept Reference Model as a way to provide generalised categories for cultural context, to interface with the Music Ontology. One option would be to adjust the Music Ontology to implement FRBRoo, the object-oriented model harmonising FRBR and CIDOC-CRM. This might allow to blend the advantages of FRBR for modelling music creation and consumption with the modelling of cultural contexts to some extent, though the simplicity and transparency of the Music Ontology's current version would suffer. Similarly, the usefulness of Hornbostel-Sachs categories to generalise musical instruments should be explored critically through case studies.

This generalisation approach could be taken further in relation to cross-cultural comparative research. We suggest to concentrate on two or three loosely related repertoires from a broad cultural area, for instance a Persian Radif, a Turkish Makam and an Indian Raga. Modelling similar use cases for such repertoires would allow to evaluate generalisation opportunities and advantages (or the lack thereof) in cultural context, musical characteristics, relationships within and between repertoires and musical instruments.

Figure 10. World music playlists are often compiled for variety, each track from a new culture, with different instrumentation and texture. Tempo and mood may be kept constant or raised gradually, depending on the aim of the playlist.
